Abstract

Objective

The first aim of this review was to investigate the association between age, sex, height, weight, physical activity level, posture, lumbar level and body side, and structural characteristics (cross-sectional area (CSA), thickness, linear dimensions and echo intensity) of the lumbar multifidus (LM) measured by ultrasound (US). Secondly, differences between healthy subjects and patients with chronic low back pain (CLBP) were investigated.

Type

Systematic review.

Literature Survey

Pubmed, Embase and Web of Science were searched until September 2018.

Methodology

Studies were included if (a) full text was available in English, Dutch or French, (b) subjects were aged over 18 years and were asymptomatic or had nonspecific CLBP and (c) the relation between structural characteristics of the LM, measured by US, and at least one of the above-mentioned factors was described, and/or a comparison between a CLBP and control group was made. Data was extracted independently by two reviewers. Quality of studies was assessed using an adapted version of the Downs and Black checklist.

Synthesis

Twenty-seven studies were included. Thickness and CSA of the LM do not correlate with age. Males have a larger LM size than females. Thickness and CSA of left and right LM are highly correlated in healthy subjects. More significant side-to-side differences are present in subjects with CLBP than in those without. Muscle size increases from proximal to caudal lumbar levels. The presence of CLBP is associated with muscle size and function.
Conclusions

The association between the factors age, sex, height, weight, physical activity level, posture, lumbar level, body side, and presence of CLBP, and the US characteristics of the LM is discussed. These factors should be taken into account in future research on structural muscle characteristics, or for example when correlating with functional behavior or investigating the effect of a targeted intervention.

Level of evidence

I

Key words: Low back pain, multifidus, paraspinal muscles, ultrasound
Introduction

Low back pain (LBP) is the main contributor to disability worldwide, with important personal, professional and socioeconomic implications.\(^1\)–\(^3\) In up to 85\% of patients with LBP, pain cannot be attributed to a specific cause and is considered to be nonspecific.\(^4\),\(^5\) Macintosh et al. previously suggested a role for the lumbar multifidus (LM) in the etiology of LBP.\(^6\),\(^7\) The LM is the largest and most medial of the lumbar back muscles, consisting of a repeating series of fascicles originating from the laminae and spinous processes of the lumbar vertebrae with a consistent pattern of caudal insertions.\(^7\) Functional impairments, such as decreased proprioception,\(^8\)–\(^10\) and decreased strength and endurance of the lumbar musculature,\(^11\)–\(^13\) have been identified in people with LBP. Moreover, the relation between these functional impairments and the development of LBP was demonstrated in several studies.\(^10\),\(^14\),\(^15\) However, the role of structural alterations of the LM in LBP, such as changes in thickness and cross-sectional area (CSA), is less understood. A recent review indicated a negative relationship between CSA of the LM and LBP,\(^16\) while other reviews showed only a weak or even no association between lumbar muscle characteristics (morphometry, fat infiltration) and clinical outcomes in LBP.\(^17\)–\(^19\) By extending our knowledge regarding structural characteristics of the lumbar muscles, we might gain more insight into the underlying mechanisms of LBP.

Previous studies indicated that ultrasonography (US) is a reliable and valid technique for the evaluation of CSA, thickness and linear dimensions (depth and length) of the LM.\(^20\),\(^21\) Echo intensity (EI) refers to the ability to reflect or transmit ultrasound waves in the context of surrounding tissue, whereby the structure can be characterized as hyper-echoic or hypo-echoic, representing lighter or darker pixels on the screen, respectively.\(^22\) Echo intensity is
considered to be an indicator of the ratio of adipose and connective tissue to muscle,\textsuperscript{23–25} as a higher EI is highly correlated with a higher level of adipose tissue using a muscle biopsy\textsuperscript{24} as well as with a higher intramuscular fat content using MRI.\textsuperscript{25} Ultrasonography is noninvasive, radiation free, widely available and inexpensive. Moreover, real time imaging allows a dynamic evaluation which is a unique advantage compared to other imaging techniques. Because of these features, the use of US in musculoskeletal conditions has significantly increased over the last years.\textsuperscript{26,27} To optimize the applicability of US for the evaluation of LM structural characteristics, it is essential to understand the factors associated with these measurements. Sex differences may play a role, as global skeletal muscle mass is greater in men than women.\textsuperscript{28} Independent of sex, global skeletal muscle mass decreases with age, especially above the age of 50 years and with an increasing rate above 65 years.\textsuperscript{29,30} Weight\textsuperscript{31,32} and physical activity\textsuperscript{33,34} have an influence on abdominal muscle size; hence, an impact on lumbar muscle size might be presumed. The influence of posture should also be taken into account. Only investigating lumbar muscle characteristics in a recumbent position might not be sufficient to distinguish between subjects with and without LBP.\textsuperscript{35,36} Additionally, cadaver studies by Macintosh et al.\textsuperscript{7} and Amonoo-Kuofi et al.\textsuperscript{37} suggest a lumbar muscle size difference related to spinal level. Lastly, symmetry of lumbar muscle structure might be of relevance. For example, localized muscle atrophy has been demonstrated in the presence of disc or nerve root injury,\textsuperscript{38,39} as well as in acute/subacute unilateral LBP.\textsuperscript{40}

Therefore, the first objective of this study was to provide a literature overview of the association between age, sex, height, weight, physical activity level, posture, lumbar level,
and body side, and the intrinsic structural characteristics (CSA, thickness, linear dimensions and EI) of the LM measured by US. Secondly, differences between healthy subjects and patients with chronic low back pain (CLBP) were summarized.
Methods

The review was performed following the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines. The protocol was registered in the PROSPERO database (CRD42018083743, http://www.crd.york.ac.uk/PROSPERO/display_record.php?ID=CRD42018083743). Studies were identified by searching the electronic databases Pubmed, Embase and Web of Science and scanning reference lists of the relevant articles. No restrictions were imposed regarding publication dates. The last search was applied on September, 18 2018. The following search terms were used for all databases: (“spine muscle” or “multifidus” or “lumbar muscle” or “paraspinal muscle” or “paravertebral muscle”) AND (ultrasound or ultrasonography or echography). When full text was not available, attempts to acquire it were made by contacting the authors. Table 1 shows the applied in- and exclusion criteria.

After removal of duplicates, assessment for eligibility was performed independently by two reviewers (S.R. and E.R). Disagreements were resolved by consensus or by consulting a third reviewer (A.D.G.). Using a basic spreadsheet, data was extracted by one reviewer (S.R.) and checked by a second reviewer (E.R.): author, publication year, population characteristics (number of subjects, age, sex, anthropometric parameters and LBP-related characteristics), measurement position, frequency and shape of the US probe, assessed lumbar level, structural characteristics of the LM assessed by US (thickness (mm), CSA (cm²), EI (grey level intensity on an arbitrary units scale)), and outcome measures (measure of association or comparison between control and CLBP group). Risk of bias was assessed by two reviewers (S.R. and E.R.) by using an adapted version of the Downs and Black checklist (Appendix).
This tool was identified as one of the two most useful instruments for the assessment of non-randomized studies\(^4^3\) and is recommended by the Cochrane collaboration for this purpose.\(^4^4\) The original tool was adapted for non-interventional studies, and has been used before.\(^4^5,4^6\) Related questions (items 4, 8, 9, 13, 14, 17, 19, 23, 24 and 26) were omitted. Case-series studies and case studies were not assessed on items related to a control group (items 21 and 22). We maintained item 15 related to blinding of the observer measuring the outcomes, as this was possible when different subject groups were investigated. Item 27 concerning the power of the study was adapted to: “Was a sample size calculation done? (yes = 1, no = 0)”. Consequently, the number of questions varied between study designs and the results on risk of bias were presented as a percentage score (Table 2). Inter-rater agreement for risk of bias assessment was measured by calculating the Kappa statistic using IBM SPSS Statistics Version 25. The following classification was used to interpret this agreement: poor (0.00), slight (0.01–0.20), fair (0.21–0.40), moderate (0.41–0.60), substantial (0.61–0.80) and almost perfect (0.81–1.00).\(^4^7\) No articles were excluded based on bias assessment. Interpretation of the strength of reported correlations was done following the rule of thumb of Hinkle et al.: little if any (0.00-0.30), low (0.30-0.50), moderate (0.5-0.70), high (0.70-0.90) and very high (0.90-1.00).\(^4^8\)
Results

See Figure 1 for a flowchart of study selection. 1666 articles were identified through database searching, and no additional articles were found from the reference list search. A total of 27 articles were included. Results of assessment of risk of bias are shown in Table 2. Total risk of bias scores ranged from 53 to 80% between studies. Scores from both reviewers were equal in 94% of the cases (431/459). The agreement between both reviewers was almost perfect (Kappa = 0.89; 95% confidence interval = 0.85 to 0.93, p < 0.0005). In Table 3 the extracted data and results of individual studies are provided.

Age

Five studies included age in their analysis. No significant association was found between age and CSA of the LM at L4, L5 nor at L2 to L5 in healthy subjects nor patients with CLBP. Stokes et al. reported a smaller shape ratio, which is a ratio of linear measurements (anteroposterior divided by lateral dimensions), at L5 in younger compared to older healthy persons. No difference in symmetry was seen between age groups. For thickness at rest, no association with age was reported for the LM at L4 in women without LBP. Two studies analyzed the relation between EI of the LM and age in healthy subjects, one showing a moderate positive correlation, the other showing no significant association.

Sex

Associations with sex were investigated in eight studies. Four studies found a significantly larger CSA of the LM in males compared to females at L2, L3, L4 and L5 in subjects with and without CLBP, although two of these studies could not confirm these findings for certain lumbar levels. No significant difference in symmetry of CSA was
observed between sexes in an asymptomatic population\textsuperscript{50} nor in patients with CLBP.\textsuperscript{49} In healthy subjects, Stokes et al. reported a smaller shape ratio in females compared to males.\textsuperscript{50} A larger muscle thickness in males compared to females was demonstrated in healthy subjects at L4-5 at rest\textsuperscript{53,56} and during contraction\textsuperscript{56}, as well as in patients with CLBP at L5 at rest.\textsuperscript{54} Two studies did not show a sex effect on thickness change during contraction of the LM at L2 to L5 in subjects with and without CLBP\textsuperscript{57} or at L4-5 in healthy subjects.\textsuperscript{56} Cai et al. found a smaller thickness change in male runners with CLBP compared to healthy subjects, but not in females.\textsuperscript{55} Importantly, when taking into account anthropometric parameters, the sex difference in CSA was no longer significant in the study of Stokes et al.\textsuperscript{50} but remained significant in two other studies on CSA\textsuperscript{58} and thickness.\textsuperscript{56} Yoshiko et al. reported a lower EI of the LM in healthy males compared to females.\textsuperscript{53}

\textit{Anthropometric parameters}

In four studies, anthropometric parameters were analyzed in healthy subjects.\textsuperscript{50,58–60} Hides et al. found positive correlations between CSA at L4 and weight, height and weight x height.\textsuperscript{59} In males, these correlations were stronger than in females.\textsuperscript{59} A strong positive correlation between CSA and weight was seen at L4 by Stokes et al., in females only.\textsuperscript{50} A moderate positive correlation was confirmed at L4 and L5 by Nuzzo et al. in an all-male population.\textsuperscript{60} In contrast, Watson et al. found a moderate negative relationship between percent body fat and CSA at L5.\textsuperscript{58} Two studies did not find a relation between body mass index (BMI) and CSA at L4\textsuperscript{50,59} and L5,\textsuperscript{50} nor between height and CSA.\textsuperscript{50} Nuzzo et al. demonstrated a moderate positive correlation between weight and thickness at rest of the LM at L4 and L5.\textsuperscript{60}
Only two studies analyzed physical activity level.\textsuperscript{51,57} Wallwork et al. reported a positive association between weekly physical activity level and CSA of the LM at L3, L4 and L5 (not at L2), without any difference between subjects with or without CLBP.\textsuperscript{57} No significant association was found with muscle thickness at rest and during contraction.\textsuperscript{57} In the elderly (age 86.9 ± 6.2 years), a smaller thickness at rest of the LM at L4 was observed by Ikezoe et al. in women who were dependent (chronically bedridden) compared to those able to perform activities of daily living independently.\textsuperscript{51} The LM was also thinner in the dependent elderly group compared with young women, but no differences in muscle thickness were seen between the young and independent elderly group.\textsuperscript{51}

Three studies investigated the influence of posture.\textsuperscript{61–63} Coldron et al. did not report a significant difference in the CSA of the LM at L5 between prone and side lying in healthy subjects.\textsuperscript{62} In healthy subjects, two studies observed an increase in CSA of the LM at L4 from prone lying to upright standing and a gradual decrease in CSA from 25° to 45° forward stooping.\textsuperscript{61,63} These differences in CSA were not significant at L5.\textsuperscript{63}

Four studies included lumbar level in their analysis.\textsuperscript{20,49,50,64} Three studies on healthy subjects observed a significant difference in CSA of the LM between lumbar levels ranging from L2 to S1, with greater CSA at caudal levels.\textsuperscript{20,49,50} Correlations between CSA at L4 and L5 were high and significant in healthy subjects in the study of Stokes et al.\textsuperscript{50} In females, a smaller shape ratio was reported at L5 compared to L4, because of a larger lateral dimension of the LM at
L5. Dar et al. found no significant difference in thickness at rest or thickness change during contraction between L4-5 and L5-S1 in healthy subjects.64

Symmetry

Fifteen studies investigated the difference between left and right side of the body.20,48,49,53,55–58,63–69 Several studies found a high correlation between left and right CSA of the LM in healthy subjects at L5,58,65 L2 to L5,49 S168 and L2 to S1,20 and in patients with CLBP at L5,65 with side-to-side differences smaller than 5%. However, in two studies a larger asymmetry in CSA was observed in healthy subjects at L4 and L5.50,67 No influence of sex, age or vertebral level on symmetry of the CSA was reported by Stokes et al.50 Side-to-side differences larger than 10% were also seen by Hides et al. in subjects with unilateral CLBP at L4 and L5 but not at L2 and L3.49 Side-to-side differences in patients with central or bilateral pain were lower.49 Smaller asymmetry was found in CSA than in shape.50,59 For thickness at rest, side-to-side differences were reported to be around 5% in healthy subjects56 and around 10% in patients with CLBP.54 There was no significant asymmetry in resting thickness in subjects with unilateral CLBP in prone or standing at L4-5 and L5-S1,70 nor in subjects with and without CLBP at L4-5.69 Dar et al. described a significant side-to-side difference in thickness change during contraction at L5-S1, but not at L4-5, in a subgroup of healthy subjects.64 A small but significant asymmetry in thickness change was observed by Wallwork et al. from L2 to L5 in subjects with and without CLBP.57 This asymmetry was not confirmed by Sweeney et al. in subjects with CLBP at L4-5 or L5-S1.70

Chronic low back pain
In fourteen studies, the influence of CLBP was analyzed.\textsuperscript{49,55,71–74,57,61,63,65–67,69,70} Asymptomatic subjects had a larger CSA of the LM compared with subjects with CLBP at L4 and L5,\textsuperscript{49,57,61,63,72,73} although findings were not significant for all levels\textsuperscript{57} or in all positions.\textsuperscript{63} In unilateral CLBP, a significant asymmetry in CSA was noted at L4 and L5,\textsuperscript{49} as well as a strong relation between pain scores and the ratio of the CSA of the unaffected and affected side at L5.\textsuperscript{66} However, Zhang et al. did not report a difference in CSA of the LM between unaffected and affected sides,\textsuperscript{73} nor was a difference in CSA confirmed between subjects with and without CLBP at L2,\textsuperscript{49} L3\textsuperscript{49} or L5.\textsuperscript{65} At L2, Wallwork et al. even observed a slightly larger CSA in subjects with CLBP compared to healthy controls.\textsuperscript{57} Lee et al. reported a different change in CSA of the LM at L4 and L5 in different postures in patients with CLBP compared to healthy controls.\textsuperscript{63} The largest CSA was observed in upright standing in healthy subjects, while in patients with CLBP the maximal CSA occurred at 25° forward stooping.\textsuperscript{63} Yet, this group difference was not confirmed by Chan et al.\textsuperscript{61} In the study of Rostami et al., the difference between contracted and resting CSA of the right LM at L4 was significantly smaller in patients with CLBP compared to controls.\textsuperscript{72} Wallwork et al. confirmed this finding at L5, but not at L2, L3 and L4.\textsuperscript{57} Regarding thickness of the LM, four studies showed no significant differences between subjects with and without CLBP at rest at L4,\textsuperscript{67,74} L4-5,\textsuperscript{68,69} L5\textsuperscript{67} or L5-S1\textsuperscript{70}, nor at L4-5 during maximal contraction lifting the head, upper trunk and contralateral arm against static resistance.\textsuperscript{69} Zhang et al. reported a smaller thickness at rest and during contraction in subjects with CLBP compared with healthy controls.\textsuperscript{73} A smaller thickness change during contraction of the LM was found in subjects with CLBP compared with healthy controls at L4\textsuperscript{73} and L4-5.\textsuperscript{55,69,71} On the other hand, Sweeney et al. found a larger thickness change at L5-S1 (not at L4-5) in subjects with CLBP during a contralateral
arm lift in standing, but not in prone position.\textsuperscript{70} The \textbf{fat area} at L4 was higher in subjects with CLBP in the study of Chan et al.\textsuperscript{61}
The main objective of this systematic review was to provide an overview of the association of predefined factors with the intrinsic structural characteristics of the LM defined by US, in subjects with and without CLBP.

Ultrasound-assessed thickness and CSA of the LM did not correlate with age in subjects with nor without CLBP. In terms of shape at L5, a more ovoid muscle in the anteroposterior direction was associated with older age. Prior studies using magnetic resonance imaging (MRI) have reported inconsistent associations between LM size and age, probably due to methodological differences in outcomes (CSA versus volume), regions of interests, and study samples. Age-related muscle atrophy has been frequently demonstrated for upper and lower limbs, as well as for superficial abdominal muscles. In deep trunk muscles such as the LM or deep abdominal muscles, age-related atrophy is less obvious. This might be explained by the fact that deep trunk muscles predominantly contain type I fibers, in which less age-related atrophy occurs in comparison with type II muscle fibers. Qualitative age-related differences such as increased fatty infiltration were previously reported in several studies using MRI or computed tomography (CT). By contrast, opposite findings regarding the association between age and EI were reported in the current review.

Ultrasound-assessed thickness and CSA of the LM were found to be larger in males than females. There may be a more ovoid LM muscle shape in females than males. However, few studies took into account weight, percent body fat or BMI as covariates for sex-related differences. Although none of the included studies could confirm a
relationship between CSA of the LM and BMI,$^{50,59}$ there were moderate to strong positive
correlations with weight.$^{50,59,60}$ By contrast, Watson et al. found a moderate negative
correlation between percent body fat and CSA of the LM at L5.$^{58}$ They hypothesized that a
sedentary lifestyle might lead to an increase in body fat deposition and muscle fat
infiltration, as well as disuse atrophy of the LM.$^{58}$ On MRI, Crawford et al. reported a higher
fat infiltration in paravertebral muscles including the LM in women compared to men, after
controlling for BMI.$^{86}$ Correspondingly, in the current review, a higher EI was reported in
women than in men.$^{53}$

Furthermore, the influence of physical activity level on weight and body fat should not be
overlooked. A direct relationship between physical activity level and CSA and thickness of
the LM was reported in two studies, although both had a high risk of bias (Table 2).$^{51,57}$
Ikezoe et al. suggested that the muscle mass of the LM might be maintained by small muscle
contraction during daily physical activities, given the fact that independent elderly women
had a larger LM thickness compared to chronically bedridden women.$^{51}$ This statement is
supported by Cholewicki et al. who previously documented electromyographically that only
1-3% of the maximum voluntary contraction of the LM is needed to maintain segmental
stability around a neutral spine position.$^{88}$ On MRI, Hides et al. noted a decrease in CSA of
the LM after eight weeks of bed rest, most likely because of removal of normal axial
gravitational loading as a stimulus for muscle activity.$^{89}$ Moreover, it is possible that specific
sport-related physical demands lead to hypertrophy of the LM as seen in elite athletes
(weightlifters$^{90}$ and rowers$^{91}$) compared to normal healthy controls, even in the presence of
LBP. Important to note is that analyses were mostly based on self-reported physical activity,
which tends to overestimate the activity level. In addition, patients with LBP are even more likely to underestimate sedentary time.\textsuperscript{92}

Ultrasound measurement of the CSA of the LM can be performed in prone or side lying position, as no significant difference between either position was demonstrated.\textsuperscript{62} Two studies investigated the CSA of the LM in four positions.\textsuperscript{61,63} Even though the risk of bias was high in both studies (Table 2), they both reported an increase in CSA of the LM in standing compared to a prone lying position.\textsuperscript{61,63} This increase in CSA might reflect the exerted force of the LM to stabilize the lumbar region in standing position.\textsuperscript{63} The CSA of the LM decreased in a stooped position compared to standing,\textsuperscript{61,63} which might be explained by an eccentric type of contraction in stooping.

For lumbar level, several studies reported an increasing CSA of the LM caudally from L2 to S1.\textsuperscript{49,50,59} These findings are in line with the cadaver study of Amonoo-Kuofi in 1983, documenting a larger LM at caudal levels.\textsuperscript{37} No difference in thickness change of the LM was observed between L4-5 and L5-S1,\textsuperscript{64} but the risk of bias in this one study examining the association between lumbar level and thickness change was high (Table 2).

Correlation between left and right side CSA and thickness of the LM is high in healthy subjects at L2 to S1.\textsuperscript{20,49,58,65,68} Side-to-side differences in shape of the LM were larger compared to side-to-side differences in CSA in healthy subjects,\textsuperscript{50,59} suggesting that shape might be a less sensitive parameter to investigate asymmetry. Most studies on healthy subjects reported approximately 5% asymmetry in CSA and thickness of the LM.\textsuperscript{49,58,59,68} Based on previous studies, an asymmetry in CSA of > 10% was suggested as potentially
abnormal. But this criterion of 10% asymmetry in CSA might not be applicable for all populations, as asymmetry up to 40% has been reported in healthy subjects, based on US\textsuperscript{59,67} and MRI images.\textsuperscript{93} Moreover, asymmetry may be normal in some groups, for example because of predominant unilateral use of muscles in sports.\textsuperscript{59} Other factors (e.g. handedness, physical activity) influencing asymmetry were investigated, but results were inconsistent.\textsuperscript{94} On the contrary, some studies indicate that LM asymmetry may be related to occurrence of injuries in cricket\textsuperscript{95} and football.\textsuperscript{96}

Subjects with CLBP have a smaller CSA of the LM on US, as demonstrated in several studies included in this review,\textsuperscript{49,57,61,63,72} and confirmed in studies using CT and MRI.\textsuperscript{97,98} However, this difference between subjects with and without CLBP might not be present at the upper lumbar levels\textsuperscript{49,57} or in specific populations such as elite athletes.\textsuperscript{65} In subjects with CLBP, asymmetry in CSA of the LM seems to be more pronounced compared to healthy subjects.\textsuperscript{49,63} Asymmetry of the LM was also seen on MRI in patients with chronic unilateral LBP.\textsuperscript{99} On the other hand, Fortin et al. found no association between LBP history and LM asymmetry on MRI.\textsuperscript{94} Muscle atrophy in subjects with CLBP might be the result of inhibition of muscle activity because of perceived pain or because of the incapacity of a muscle or ligament to recover to its initial resting length due to long-lasting strain.\textsuperscript{61} But curiously, no significant differences in LM thickness in rest were found between subjects with and without CLBP.\textsuperscript{67,69,70,74} Thus, thickness measures of the LM might be insufficient to detect size differences as they do not account for medial to lateral expansion. A larger fat area of the LM was reported in subjects with CLBP compared to asymptomatic controls, however, only the L4 level was investigated.\textsuperscript{61} This implicates a larger proportion of noncontractile tissue in
the LM and possibly a reduction in muscle quality which could contribute to differences in
muscle function.

It is suggested that subjects with LBP have altered neuromuscular control resulting in
different muscle activation.\textsuperscript{9,100,101} Several studies in this review confirmed lower activation
ratios in subjects with CLBP.\textsuperscript{55,57,69,71,72} On the contrary, Sweeney et al. reported a larger
thickness change in subjects with CLBP, however, only during a contralateral arm lift in
standing.\textsuperscript{70} Moreover, Lee et al. hypothesized that the LM is not able to respond to the
postural demand in subjects with CLBP, particularly in upright positions, as they found an
altered LM CSA in standing and stooping positions in subjects with CLBP compared to those
without.\textsuperscript{63} However, this group difference in change in CSA of the LM in different positions
was not confirmed in the study of Chan et al.\textsuperscript{61}

\textit{Methodological considerations and implications for future research}
This systematic review has several limitations. No inter-rater agreement was calculated for
data extraction. Because of the heterogeneity of the included studies, the results were
summarized qualitatively. Across the included studies, several factors increasing the risk of
bias were present (Table 2). First, study populations were sometimes small, and clear
definitions of the patient and control groups were frequently not available. Definition and
aspects (duration, intensity, location) of LBP differed between studies or were not
mentioned. Information about participant recruitment was mostly insufficient, making it
more difficult to compare results. In most studies the investigator was not blinded for LBP
status of the study participant, possibly increasing the risk of bias. Moreover, potential
confounding factors such as age, BMI or activity level were often not taken into account. Sex
differences should be related to weight and other anthropometric parameters for a correct interpretation of findings. More research is needed to determine the association between anthropometric parameters and the structural characteristics of the LM, especially in populations with a higher BMI. The role of physical activity level in the structure and function of the LM is still unclear and should be further investigated using objective measurements of physical activity. Furthermore, US protocols varied between studies, with some investigating left and right sides separately, and some pooling the results for both sides. However, side-to-side differences of the LM may be present in case of unilateral LBP, which implies both sides should be examined separately. Several studies investigated only one lumbar level, which limits interpretation of the findings. As characteristics of the LM differ between lumbar levels, investigating more than one level is recommended to be able to understand the differences related to LBP. Most studies analyze CSA or thickness to assess muscle size or symmetry, but do not determine EI as a reflection of fatty infiltration. However, greater infiltration with fatty or fibrous tissue can influence muscle quality without altering muscle size. Further investigating the change of EI in subjects with CLBP versus healthy subjects can provide more insight in the structural muscle alterations in CLBP.

The clinical relevance of LM shape has yet to be explored. Hypertrophy is only possible in the lateral or posterior direction because medial and anterior borders are defined by bony structures. Larger muscles thus tend to be more triangular, which cannot be deduced from the shape ratio. In patients with acute LBP, a rounder shape of the LM was seen at the affected level. This might be caused by a change in muscle tone or presence of a muscle spasm.
Conclusion

In this systematic review, several factors associated with the US characteristics of the LM are identified. A relation between age and LM size is not confirmed. Males have a larger thickness and CSA of the LM than females. The correlation between the left and right LM size is high in healthy subjects. More significant side-to-side differences are present in subjects with CLBP than in those without. An increase in LM size is seen from proximal to caudal lumbar levels. The presence of CLBP is associated with muscle size and function. The role of physical activity and body weight in characteristics of the LM is unclear. Muscle EI was not sufficiently investigated to reach any conclusions. The above-mentioned factors should be taken into account in future research on structural characteristics of the lumbar muscles, the relation with functional behavior or the effect of a targeted intervention.

Disclosure

This research did not receive any specific grant. All authors declare no conflict of interest.
