22 male sport students participated in the present study. They performed 6 maximal isometric plantarflexions in an ankle ergometer equipped with moment transducers. For each contraction participants were instructed to contract as fast and powerful as possible. Maximal rate of force development (RFDmax) and maximum force (MVC) were calculated from the torque curves. Additionally, surface elektromyogramms (EMG) of M. soleus (SOL) M. gastrocnemius medialis (GM) and M. tibialis anterior (TA) were recorded. EMG was rectified and integrated in four time intervals of 50ms for the first 200ms of each contraction and for a time interval of 200ms around MVC. Prior to three contractions the triceps surae (SOL and GM) was vibrated for 40s with a muscle vibration device (Neurostim®) at 32 Hz. To control effects of muscle vibration on Ia afferent pathways, H-reflexes with peak to peak amplitudes of approx. 20% of the maximal M-wave were evoked throughout the experiment. Muscle vibration resulted in a massive reduction of the H-reflex (23 ± 3 % versus 2 ± 2 % Mmax; $p < 0.001$, Students paired t-test). This indicated suppression of the Ia afferent pathways projecting to SOL and GM. With muscle vibration, MVC was significantly reduced by 3 ± 6 % ($p < 0.05$, Students paired t-test) but no significant changes were observed for RFDmax or for any of the EMG parameters. We could not observe any effect of vibration induced suppression of Ia afferent pathways on the rate of force development during maximal isometric plantarflexions. Therefore, we assume a minor role of the Ia afferent pathways during the early phase of maximal voluntary muscle contractions. Interestingly, MVC was reduced indicating that the Ia afferent input to the cord might be important during later parts of maximal contractions.

EFFECT OF CREATINE SUPPLEMENTATION ON INTRAMYOCELLULAR LIPID CONTENT DURING LEG IMMOBILISATION AND REHABILITATION TRAINING

VAISY, M.

RESEARCH CENTRE FOR EXERCISE AND HEALTH

Introduction: Elevated intramyocellular lipid (IMCL) content has been associated with the incidence of insulin resistance in obesity and type 2 diabetes (1, 2). Creatine intake has been found to lower the insulinogenic index in rat (3) as well as to negate abnormal glucose tolerance in a transgenic mouse model of Huntington disease (4).In the current study we investigated the effect of oral creatine on IMCL content during an episode of leg immobilisation and subsequent rehabilitation training.

Methods

A double-blind placebo-controlled trail was performed in young healthy volunteers. The right leg of each subject was first immobilised for 2 weeks using a cast, where after they participated in knee-extension resistance training program for 6 weeks. Half of the subjects (CR; n=11) received creatine monohydrate supplements throughout the study, whereas the others ingested placebo (PL). Needle biopsy samples were obtained from m. vastus lateralis of the right leg before and after training and rehabilitation, as well as from the contralateral leg, for determination of fibre-specific IMCL content using ORO-staining. Succinate dehydrogenase activity (SDH) and FAT/CD36 content were assayed on muscle samples.

Results: In PL but not in CR, IMCL content in type I fibres increased by ~20% during immobilisation ($P<0.05$). At the end of the rehabilitation period IMCL content had returned to baseline in PL, yet was ~35% lower in CR ($p<0.05$). In type IIa fibres the immobilisation increased IMCL content, whilst retraining decreased IMCL content ($p<0.05$), but values were similar between groups at any time. IMCL content significantly changed in the contralateral leg during the study in neither CR nor in PL. Muscle SDH activity and FAT/CD36 protein content significantly changed ($p<0.05$) due to immobilisation and rehabilitation, but values were similar between groups at any time.

Discussion: Our current study shows that a short period of muscle inactivity due to immobilisation is accompanied by an increase in IMCL content in type I fibres, and that this increase is negated by 6 weeks of rehabilitation training. Interestingly, however, we found oral creatine supplementation to prevent the increase in type I fiber IMCL content due to immobilisation, and even to reduce IMCL content to markedly below baseline levels during rehabilitation training. These effect were explained neither by altered oxidative capacity as estimated from SDH activity, nor by altered FAT/CD36 protein content. The physiological mechanims by which oral creatine supplementation impact on IMCL content in type I fibres during an episode of muscle inactivity and subsequent reconditioning, remain to be elucidated.

EFFECT OF HEAVY STRENGTH TRAINING ON CLASSICAL INDICATORS OF ENDURANCE CYCLING PERFORMANCE

RØNNESTAD, B., HANSEN, E.A., RAASTAD, T.

LILLEHAMMER UNIVERSITY COLLEGE

Training is the first and most obvious way to improve cycling performance (2). Incorporation of strength training in cyclists' preparation has previously received some attention (1), and it has been shown that strength training may improve lactate threshold and cycling performance in untrained subjects (3). However, the effect of adding heavy strength training to usual endurance training in well-trained cyclists on endurance cycling performance indicators has not been thoroughly studied. Thus, the aim was to test the hypothesis that heavy strength training improves classical indicators of endurance cycling performance.

Twenty well-trained cyclists were assigned to either usual endurance training combined with heavy strength training (E+S; n=11 (♂=11), 27±2 years, 75±3 kg, VO2max 66.8±1.6 ml∙kg-1∙min-1) or to usual endurance training only (E; n=9 (♂=7, ♀=2), 30±2 years, 74±3 kg, VO2max 65.9± 2.0 ml∙kg-1∙min-1). The strength training consisted of four lower body exercises (half squat, leg press with one foot at a time, one-legged hip flexion, and toe raise, 3x4-10RM), which were performed twice a week for 12 weeks. Pre- and post-tests determined the cyclists' thigh muscle cross-sectional area (CSA), maximal voluntary contraction force (MVC) in isometric half squat, peak power output during a 30 s Wingate test, power output at 2 mmol blood lactate concentration during an incremental cycling test, VO2max, and mean power output during a 40-min all out cycling trial. Data are presented as mean±SE.

At baseline, the groups were similar. After the intervention period, E+S increased CSA of thigh muscles (4.5±0.6%), MVC (21.2±4.9%), peak power output in the 30 s Wingate test (9.5±2.9%), and power output at 2 mmol blood lactate concentration (4.1±1.5%). These variables were not changed in E. There was a significant difference between groups in relative improvement in MVC half squat, CSA of the thigh muscles, and peak power output. Both E+S and E increased their VO2max (3±1% and 6±2%, respectively) with no statistical difference between groups. E+S increased their mean power output during 40-min all out cycling while there was a tendency for a similar finding in E ($p=0.054$).

The overall finding was that adding heavy strength training to usual endurance cycling training results in favourable adaptations in classical performance indicators without compromising the development of VO2max. In contrast, adding explosive strength training to trained cyclists has been reported not to affect cycling performance and cycling economy (1). It is possible that the discrepancy is due to the difference between strength training regimens. In conclusion, adding heavy strength training to usual endurance training improves classical indicators that routinely are used to evaluate and predict endurance cycling performance.

RESPONSES TO FOUR ECCENTRIC EXERCISE BOUTS OF THE ELBOW FLEXORS PERFORMED EVERY FOUR WEEKS

NOSAKA, K., CHEN, T.C., CHEN, H.L., LIN, M.R., WU, C.J.

EDITH COWAN UNIVERSITY

INTRODUCTION: An initial eccentric exercise confers protective adaptation to a subsequent bout of the same or more demanding eccentric exercise, which is known as the repeated bout effect. Although many studies exist concerning the repeated bout effect, most of them investigated the effect based on two bouts of eccentric exercise. Only two previous studies (1,2) examined the repeated bout effect of more than three eccentric exercise bouts, but the repeated bouts were performed before full recovery from the initial bout. It is not clear what happens if the same exercise is repeated more than three times after a full recovery. This study compared responses to four bouts of maximal eccentric exercise performed every 4 weeks to examine if additional protective adaptation is induced by the additional bouts.

METHODS: Fifteen untrained men (21.8 ± 1.9 yrs) performed four bouts of 30 maximal isokinetic (90°/s) eccentric contractions of the elbow flexors for the range of 90° by the non-dominant arm every 4 weeks. Measurements of maximal isometric and concentric isokinetic strength, optimum angle (OA), range of motion (ROM), upper arm circumference, plasma creatine kinase and lactate dehydrogenase activities, myoglobin concentration, muscle soreness, and B-mode ultrasound images were taken before, immediately after and for 5 days following each bout. Changes in the variables over time were compared amongst the four exercise bouts by a two-way (bouts x time) repeated measures ANOVA with a Scheffé's post-hoc test. A significant level was set at $P<0.05$.

RESULTS: No significant differences existed among the bouts for the pre-exercise values of any variables. Changes in all variables except for OA following the second to fourth bouts were significantly smaller than those after the first bout. No significant differences across the exercise bouts for changes in OA, although increases in OA were evident after each bout. The magnitude of decrease in muscle strength and ROM immediately after the fourth bout was significantly smaller than that of the other bouts.

DISCUSSION: The protective effect was conferred by the initial bout, and the additional bouts did not produce as significant protective effect as the initial bout. However, the magnitude of decrease in muscle strength and ROM immediately after the fourth bout was significantly smaller than that after the other bouts. This type of adaptation has been shown for resistance-trained subjects when they performed a similar eccentric exercise to that performed in the present study (3). A shift of OA does not appear to involve in the repeated bout effect. It is concluded that the first bout confers the greatest adaptation, but further adaptation is induced when the exercise is repeated more than 3 times.

EVALUATION OF A NOVEL MUSCLE STRENGTH TEST FOR ATHLETES WITH ACL INJURY

MIRKOV, D., KNEZEVIC, O., KADIJA, M., MILOVANOVIC, D., PAZIN, N.

FACULTY OF SPORT AND PHYSICAL EDUCATION, UNIVERSITY OF BELGRADE; THE INSTITUTE OF ORTHOPAEDIC SURGERY AND TRAUMATOLOGY, CLINICAL CENTER OF SERBIA

Introduction: The anterior cruciate ligament (ACL) injuries represent one of the most serious disabling injuries in associated with athletic activity. Despite the applied treatment methods (i.e., either conservative or operative), a lengthy rehabilitation procedure has to be not only performed, but also closely monitored. Various methods for the assessment of neuromuscular function have been applied and their potential advantages and disadvantages still remain to be explored. The aim of this study was to preliminary evaluate application of the consecutive maximum contraction test (CMC; Suzovic et al, 2008) for the assessment of muscle function in patients that have been undergoing rehabilitation following the ACL injury.

Methods: Ten competitive athletes with recent (3 to 12 months following the surgery) ACL reconstruction participated in the study. The concentric knee flexor and knee extensor strength of both legs was assessed by means of both an isokinetic dynamometer and CMC test (i.e., consecutive isometric force exertion and relaxation by self-selected frequency. Following a familiarization, the tests were performed within two consecutive sessions. The variables derived from two isokinetic tests were isokinetic knee flexor and extensor peak torques exerted at 60°/s and 120°/s of the injured and non-injured leg. These variables were compared with the peak torques and the rate of torque developments of the knee flexor and extensor muscle derived from the force-time curves recorded in CMC.

Results: The isokinetic tests revealed no differences in torque between the knee flexors, while the knee extension torque of the injured leg was significantly lower than in the non-injured one only under the 60 °/s condition. CMC test, however, not only revealed a lower peak torque of knee extensors, but also lower rate of torque development of both muscle groups of the injured leg, as compared with the non-injured one. Finally, note that the peak force of CMC significantly correlated with peak torques of the isokinetic tests (correlation coefficients being r=0.81-0.91).

Discussion and Conclusions

The variables derived from CMC could be more sensitive in capturing the differences in the neuromuscular output between the injured and non-injured leg than the variables obtained from the standard isokinetic test. The peak force obtained from CMC could also assess muscles' ability to exert maximum sustained contraction despite being both transient and relatively low. Therefore, the results obtained suggest that CMC could be developed into standard assessment tool for neuromuscular function in athletes rehabilitating after ACL reconstruction.

EFFECT OF DIFFERENT LOCAL COOLING APPLICATIONS ON THE ENDURANCE CAPACITY DURING CYCLING

HOHENAUER, E., CLIJSEN, R., CABRI, J., CLARYS, P.

UNIVERSITY COLLEGE PHYSIOTHERAPY

Hohenauer, E.1, Clijsen, R.1, Cabri, J.2, Clarys, P.3

1: University College TVDL (Landquart, Switzerland), 2: FMH-UTL (Lisbon, Portugal), 3: VUB (Brussel, Belgium)

INTRODUCTION: The production of heat during intense exercise causes an increase of muscle temperature and core temperature, which can amount up to 40°C. In order to avoid losing endurance capacity, the body adjusts by rapidly reducing temperature. Evaporation is the primary mechanism by which muscle heat is released during exercise (Nybo et al., 2007).

AIM: The aim of this study was to investigate the effects of local upper arms cooling, upper body cooling and combined cooling of the upper arms and upper body on the endurance capacity during cycling.

METHODS: Seven male young healthy subjects (n=7) volunteered in this study. A random, cross-over design was used. The subjects were tested under four different conditions: A= without cooling; B= Energicer cooling bands; C= Energicer cooling vest; D= Energicer cooling bands and vest. The cooling bands (7.5 x 5 x 0.5 cm) were placed on the left and right upper arm. Both vest and bands were saturated (bands 25ml each, vest 225ml) with a menthol-alcohol liquid (Liquid Ice Cosmedicals GmbH, Unterägeri, Switzerland). We conducted a standardized incremental bike ergometer test following the Swiss Olympic Guidelines. Time to exhaustion was determined and used as the independent variable for endurance capacity. At the end of each incremental step following variables were measured: blood lactate, heart rate, body temperature and perceived exhaustion (BORG scale).The 4 experiments were accomplished within one week to decrease the chance of adaptation. Environmental temperature (35°C) and relative humidity (44%) of the lab were kept constant.

RESULTS: Mean age and BMI of the subjects were 39,11 y and

28,2 kg.m-2 respectively. Mean time to exhaustion didn't differ between the four conditions (p>0,05). We observed no significant differences at blood lactate, heart rate and body temperature during examination between the four conditions.

DISCUSSION: Our results are in line with Duffield et al. (2003). However all participants mentioned to feel more comfortable when wearing the cooling vest under the used environmental conditions. This effect might aggravate with the airflow when cycling under outdoor conditions which may lead to psychological advantages for the athlete. We didn't observe any significant changes in body temperature, and endurance capacity if cooling bands and/or cooling vests were used.

CONCLUSION: Under hot and humid environmental conditions local cooling of the upper arms and/or upper body by Energicer bands and/or vests don't enhance endurance capacity during cycling. Further studies are needed to analyse the effects of Energicer bands and vests when simulating the airflow in hot and humid environmental conditions and the effects on the skin temperature.

THE EFFECT OF REPETITIVE COOLING ON PRECOOLING EFFICIENCY AND EXERCISE PERFORMANCE: A PILOT STUDY

KOCJAN, N., SCHATTI, O., BOGERD, C.P., ROSSI, R.M.

EMPA, SWISS FEDERAL LABORATORIES FOR MATERIALS TESTING AND RESEARCH

Introduction: It is known that repetitive cold exposure improves thermal sensation and, decreases skin and body core temperatures (1, 2). Such responses could potentially improve precooling efficiency, defined as the ease with which body heat storage is reduced. Up to now, no studies have been published on the effect of repetitive cooling on precooling efficiency and, subsequent exercise performance. Therefore, we aimed at investigating: i) if repetitive cooling increases the efficiency of precooling and, ii) how such response affects various thermophysiological parameters during exercise in hot and humid ambient.

Methods: Four physically fit men with an average (SD) VO2peak of 65.4 (4.1) ml/min/kg participated in this study. They reported to the laboratory for 10 consecutive days. Each time, the subjects were submitted to 1 hour of cooling with an ice vest (Arctic Heat, Burleigh Heads, QLD, Australia) while sitting at an ambient temperature (Ta) of 20.2 (0.2) °C. On the 1st and the 10th day, this was followed by 25 min of cycling exercise at 60% subject's VO2peak in Ta of 30.2 (0.1) °C and relative humidity of 71.4 (0.8)%. On the 1st and the 10th day, during cooling and exercise, body core temperature (Tc) and skin temperatures on eight body locations (Tsk), were registered every 10 s. In addition, during the first and the last 5 min of cooling, skin blood flow (SkBF) was measured on forearm. While, rating of thermal perception (TP) was noted each 15 min.

Results: On the 10th, compared with the 1st cooling day, SkBF increased for 80 (49) %. Where, such response indicates a decrease in vasoconstrictor response. Cooling decreased Tsk on both occasions to a similar extend (1st day: 27.62 (1.30) °C; 10th day: 27.72 (1.11) °C). However, on the 10th day the time to reach this value halved. Despite, Tc was before the start of cooling slightly higher on the 10th day, at end of cooling, a similar Tc was reached. This was observed due to enhanced decrease of Tc on the 10th day. On average, TP improved from -2.3 (1.3) on the 1st day, to -1.3 (1.0) on the 10th day. Finally, during subsequent exercise there were no apparent differences between the 1st and the 10th cooling day in any of the variables investigated.

Conclusion

It is suggested that 10 days of consecutive cooling, when using an ice vest, can improve the efficiency of precooling. In particular, this is ascribed to reduced vasoconstrictor response. Repetitive cooling does not affect any of the investigated thermophysiological parameters during subsequent exercise performance in warm and humid ambient.

THE EFFECTS OF PRE-COOLING ON PERFORMANCE, PACING STRATEGY AND CONTRACTILE FUNCTION DURING ENDURANCE CYCLING IN THE HEAT.

DUFFIELD, R., GREEN, R., CASTLE, P., MAXWELL, N.

CHARELS STURT UNIVERSITY

Introduction: The reduction in exercise performance noted when performing prolonged exercise in the heat is well documented (Gonzalez-Alonso et al., 1999). Further, the ergogenic benefits of pre-cooling prior to exercising in hot conditions are also well established (Marino 2002). However, to date the mechanisms underlying the improved performances following pre-cooling in the heat remain equivocal. Accordingly, this study investigated the effects of pre-cooling on performance and pacing during free-paced endurance cycling in the heat, and further, the effects of pre-cooling on contractile function as a mechanism for performance improvement.

Methods: Following familiarisation, eight male cyclists performed two randomised 40-min time trials on a cycle ergometer (SRM power cranks) in 33oC. Prior to the time trials, participants underwent either a 20-min lower-body cold-water immersion procedure (14oC) or no cooling intervention. Prior to and following the respective intervention and time trial, 10 x 5 s isometric voluntary force (MVC) and evoked twitch force (Pf), muscle temperature and anaerobic blood metabolites were measured. Further, before, during and following the intervention and time trial, measures of core (rectal) and skin temperature and heart rate were recorded.

Results: Results indicated that performance was improved with pre-cooling, with a greater distance covered (19.3±1.3 v 18.0±1.4 km) and a higher mean power output maintained (198±25 v 178±26 W) for pre-cooling and control, respectively (P=0.05). While core, muscle, skin and mean body temperatures were lower in the cooling condition until the 20th min (P<0.05), performance did not differ until the latter parts of the time trial (29th min), by which time no differences in physiological measures were present. Further, while MVC was reduced post-exercise in both conditions, neither MVC nor Pf were different between conditions pre- or post-exercise.

Discussion: A 20-min lower-body pre-cooling intervention improved free-paced endurance exercise; however, the improvements in performance became evident after physiological differences induced by pre-cooling had dissipated. Further, rather than pre-cooling increasing power output per se, it seems pre-cooling prevented the reduction in self-selected exercise intensity noted in the final 10-min during exercise without cooling. Moreover, the lack of difference between conditions in MVC or the change in Pf indicates improvements in performance did not result from the prevention of interference of voluntary or evoked contractile function, suggesting cooling induced improvements may result from mechanisms related to muscle recruitment and/or activation.

THE EFFECTS OF PRE-EXERCISE SODIUM LOADING AND DRINK TEMPERATURE ON EXERCISE CAPACITY IN A WARM ENVIRONMENT

TRUELOVE, J.

UNIVERSITY OF EXETER

Performance benefits from acute plasma volume (PVol) expansion and reduced core body temperature are well documented, but the majority of strategies are impractical in a sporting environment. The effects of pre-exercise sodium (Na+) loading and pre-cooling by cold fluid ingestion on cardiovascular and thermoregulatory responses and endurance capacity were measured in 18 moderately-trained male cyclists (VO2peak: 55 ± 5 ml.kg-1.min-1; age: 26 ± 9 yr) during rest and exercise in a warm environment (32oC, 50 % RH). Participants completed two of four tests in a randomly-controlled incomplete block design consisting of ingesting 10 ml.kg-1 of either: warm-low Na+ (26oC, 10 mmol Na+.L-1); cold-low Na+ (4oC, 10 mmol Na+.L-1); warm-high Na+ (26oC, 164 mmol Na+.L-1); or cold-high Na+ (4oC, 164 mmol Na+.L-1) fluid over 45 min of pre-exercise conditioning. Participants then exercised for 45 min at 10 % ∆ (difference between Gas Exchange Threshold and VO2peak), followed by exercising to exhaustion at 60 % ∆. Heart rate (HR) and rectal temperature (Trec) were measured throughout conditioning and exercise. Blood was sampled before and after conditioning, and at exhaustion. A two-way ANOVA was used to analyse main effects for sodium concentration and drink temperature. Na+ loading elevated plasma volume (PVol) by 4.7 ± 0.3 % (P < 0.001), reduced mean HR by 12 ± 9 b.min-1 (P < 0.001) and increased time to exhaustion (TTE) by 51 ± 5 % (P < 0.001). Pre-cooling lowered Trec by 0.4 ± 0.04oC (P < 0.001), reduced mean HR by 12 ± 7 b.min-1 (P < 0.001), and increased TTE by 49 ± 4 % (P < 0.001). TTE demonstrated a strong positive association with elevated PVol (R2 = .41, P < 0.001) and reduced Trec (R2 = .38, P < 0.001), at the start of exercise. There were no interactive effects of pre-cooling and Na+ loading. Pre-cooling and Na+ loading are highly practical methods of improving exercise performance in the heat. Pre-cooling lowered Trec, Na+ loading elevated PVol, and both interventions maintained a reduced heart rate response and a resultant increase in exercise capacity.

TRANSIENT SWEAT RESPONSE OF THE HUMAN HEAD DURING CYCLING.

DE BRUYNE, G., AERTS, J.M., VANDER SLOTEN, J., GOFFIN, J., VERPOEST, I., BERCKMANS, D.

KATHOLIEKE UNIVERSITEIT LEUVEN

Introduction: This research aims at quantifying transient spatial gradients in sweat production on a human head while cycling, whereas previous studies only reported constant steady state sweat production (Machado-Moreira et al. 2008 and De Bruyne et al. 2008). This could be used to enhance physiological insight of the sweating process. Furthermore, it can also help in designing sweating thermal manikins that show more realistic sweating behaviour. Knowledge of the dynamics of sweat production might also be valuable for designing active controlled headgear since the controller should take the transient behaviour of sweat rate into account.

Methods: Six test persons were studied. Each test lasted 30 minutes while a change in work rate was applied after the first 5 minutes (80 to 150 Watt for males and 50 to 125 Watt for females). Two conditions were analyzed in this research: warm (28.3+/-0.1°C, 38+/-0.6% RH and 0.1+/-0.1 m/s air velocity) and standard (16.1°+/-0.2°C, 45%+/-0.6 RH and 2.4+/-0.2 m/s air velocity). Sweat production of the head was measured as a function of time on the right temple, left temple and forehead. This allowed modelling the dynamic characteristics of the sweat production response such as the time delay [s] between a change in work rate and the onset of sweating, the time constant [s]

describing how fast the sweat rate changes and the steady state gain [mg/(min.cm2.W)] describing how much sweat [mg/(min.cm2)] is produced per unit change of work rate [W].

Results: Time constants of sweat production were significantly smaller (P<0.05) in the warm condition compared to the standard condition. Mean and SEM time constant of sweat production varied from 561+/-144s (frontal region) to 1117+/-230s (left temple) and 1080+/-232s (right temple) in the warm condition. In the standard condition, the time constant of sweat production varied from 873+/-121s at the frontal region to 1431+/-195s at the left temple and 1727+/-196s at the right temple. Additionally, also constant steady state sweat production was 0.4 to 0.7 mg.min-1.cm-2 higher in the warm compared to the standard condition (P<0.05). However, no differences (P>0.05) were observed for steady state gain and time delay of sweat production between the standard and warm condition. The results showed that the sweat production response was predominantly affected by the applied work rate in the given thermal conditions, a non-thermal factor.

Conclusions: Local sweat production on the human head was mainly affected by the applied work rate, while the environmental condition affected the time constant of sweat production, but not its time delay or steady state gain.

SCALP HAIR ABSENCE DOES NOT ALTER SELF-PACED 10 KM RUNNING PERFORMANCE

PRADO, L., MARTINI, A.R., FERREIRA JR, J.B., BORBA, D.A., RODRIGUES, L.O.C.

FEDERAL UNIVERSITY OF MINAS GERAIS

Objective: Aim of the present investigation was to test the hypothesis that human scalp hair may act as a natural protection against sun radiation which would allow subjects to better perform during prolonged running bouts under the sun.

Methods: Participated in this investigation 12 male healthy subjects (29.5 ± 3.7 years old; 174.9 ± 4.3 cm; 72.7 ± 3.2 kg and 44.6 ± 3.4 ml.kg-1.min-1 VO2max). They presented at least 6 cm of stretched scalp hair at the beginning of the study. There were 4 exercise situations. On the first day, after anthropometric characterization, a field test for estimating aerobic capacity was carried out. Two days later, one familiarization run was carried out, followed by two experimental situations: scalp hair presence (HAIR) and shaved scalp hair (NOHAIR), in this order. In each exercise situation subjects performed a 10km self-paced run at maximal subjective intensity in an external environment, under the sun. HAIR and NOHAIR were carried out at least one week apart. All experimental situations took place on a 200m flat grassy circuit. Environmental heat stress was measured by the Wet Bulb Globe Temperature index (WBGT). Running velocity, heart rate, rectal temperature, physiological stress index and rate of heat storage were measured.

Results: There was no difference on WBTG between experimental situations (24.0 ± 1.4 e 23.2 ± 1.5 °C, for HAIR and NOHAIR, respectively). Running velocity (ANOVA, F=0.0066, p=0.94), heart rate (ANOVA, F=2.45, p=0.145), rectal temperature (ANOVA, F=0.27, p=0.6), physiological stress index (ANOVA, F=0.0176, p=0.89) and rate of heat storage (ANOVA, F=2.4, p=0.15) were not significantly different between HAIR and NOHAIR.

Conclusion: For the present experimental situations, the absence of scalp hair did not alter 10 km self-paced, maximal running velocity under the sun.

ARCHITECTURAL FEATURES OF HUMAN TIBIALIS ANTERIOR DURING PASSIVE ANKLE ANGLE CHANGES MEASURED BY 3D-ULTRASONOGRAPHY

IKEGAWA, S., KURIHARA, T., IWANUMA, S., AKAGI, R., SAKAGUCHI, M., KANEHISA, H., FUKUNAGA, T., KAWAKAMI, Y.

JUMONJIGAKUEN WOMEN'S UNIVERSITY

In pennate muscles, fascicles are arranged obliquely with respect to the tendon or aponeurosis. The fascicle length and the pennation angle change by joint angle. Detailed information on these changes is important for modeling of muscle. In the Tibialis anterior (a bipennate muscle), the informations of changes in fascicle length and pennation angle with joint angle are limited. The aim of the present study is to clarify the characteristics of fascicle length and pennation angle of the tibialis anterior muscle during passive ankle angle changing.

METHODS: Eight healthy men participated as subjects in the experiment. The ankle joint was set at 20 deg plantar flexion(P20) and it is changed to 20deg dorsi flexion(D20) with the knee joint positioned at 0 deg (full extension). In the present study, we employed 3D-ultrasonogram. The fascicle length and pennation angle were measured in the longitudinal images which most clear view of fascicle oriented from central aponeurosis to superficial aponeurosis and to Tibia or interoseous membrane. These measurements were performed the proximal, central and distal sites. A three-way ANOVA with repeated measures was to analyze fascicle lengths and pennation angles (2 × 2 × 3, ankle angles (P20, D20), muscle depth (superficial or deep), measurement site (proximal, central or distal).

RESULTS AND DISCUSSION: The fascicle lengths of superficial proximal site at P20 indicated 60.0 (9.4) mm. It decreased to 47.5 (6.4) mm at D20 and it is 23.1% decrements. The fascicle lengths of superficial central and distal sites were 22.0% and 23.8% decrements, respectively. In the deep, the fascicle lengths of proximal, central and distal sites were 18.0%, 20.0% and 25.3% decrement, respectively. The pennation angles of superficial indicated 33.1% to 47.2% increments at three sites with ankle angle changing. In the deep, pennation

angle increased 37.1% to 41.4% at three sites with ankle angle changing . The fascicle lengths and pennation angles were affected by ankle angles and muscle depths. The fascicle length was affected by three measurement sites but pennation angle was not. Maganaris and Valzopoulas, (1999) reported no difference was found the fascicle length and the pennation angle between either the unipennate parts of tibialis anterior or the different scanned site along the muscle at a given ankle angle. However, Hiblar et al(2003) reported the pennation angle decreased along the length of the muscle(central to distal) using 3D ultrasongraphy. Our result is in line with Hiblar et al(2003) and have important implication for construction of 3D muscle model.

APONEUROSIS BEHAVIOR IN HUMAN TIBIALIS ANTERIOR DURING SUBMAXIMAL AND MAXIMAL ISOMETRIC CONTRACTIONS

TILP, M., STEIB, S., HERZOG, W.

UNIVERSITY OF CALGARY

Introduction: The aponeurosis within a muscle transfers force developed by the muscle fibres via the tendon to the bone. In classical muscle models the aponeurosis is modeled as a passive elastic element in series to the contractile elements. However, there have been different reports regarding the aponeurosis behavior during muscle contractions. While some authors (e.g. Arampatzis et al, 2005) reported lengthening of the aponeurosis with increasing activation (force) others found e.g. shorter aponeurosis lengths in activated compared to the passive state at the same muscle lengths (Zuurbier et al, 1994) which would contradict the purely passive behavior of an elastic element in series. Therefore, the aim of the study was to determine the length changes of the human tibialis anterior (TA) during submaximal and maximal isometric contractions so as to decide whether the aponeurosis can be considered a purely passive element in series.

Methods: To measure the length changes of the TA aponeurosis in vivo, nine healthy subjects (7 males, 2 females, 27 +/- 5 years, 179 +/- 9 cm, 73 +/- 9 kg) were asked to perform isometric dorsiflexions with 20, 40 and 100 % of maximal voluntary effort (MVE). An isokinetic dynamometer (Biodex®, System 3) was used to control ankle joint movement and to measure torque. Two ultrasound systems (Phillips Envisor, 49 Hz) were used to observe the movements of the proximal and distal ends of the TA aponeurosis simultaneously. Surface electromyograms (EMGs) were obtained from the TA and the medial gastrocnemius (MG) muscles (Biovision® system). Torque and EMG were collected using WinDaq Data Acquisition software (DataQ Instruments®) at 1000 Hz and were synchronized with the ultrasound images using a synchronization signal produced by a function generator.

Results: Mean aponeurosis lengths increased slightly by 0.02 cm (+/- 0.2), 0.07 cm (+/-0.2), and 0.20 cm (+/- 0.23) with increasing torques at 20, 40 and 100% of MVE, respectively. Not all subject demonstrated a lengthening of aponeurosis. Especially at low activation levels (20% of MVE) three out of the nine subjects showed a decrease in aponeurosis lengths due to activation.

Discussion: Aponeurosis lengths only increase slightly with increasing forces indicating that either the aponeuroses are very stiff and do not contribute much to the expected passive length changes in muscles with increasing force, or aponeuroses are inherently soft but they are not arranged in series with the muscle fibres. Therefore, we conclude that aponeuroses in human TA play no appreciable functional role in series elasticity storage or return.

LATERAL FORCE TRANSMISSION BETWEEN LOWER LEG MUSCLES

BOJSEN-MØLLER, J., SCHWARTZ, S., FINNI, T., KALLIOKOSKI, K., MAGNUSSON, S.P.

BISPEBJERG HOSPITAL, UNIVERSITY OF COPENHAGEN, NORWEGIAN SCHOOL OF SPORTS SCIENCES, UNIVERSITY OF JYVASKYLA, TURKU PET CENTRE

The mechanisms that underlie tendon injury are elusive, however, suboptimal muscle activation patterns and non-uniform force transmission from muscle to bone may be candidates for injury mechanisms. Musculotendinous force transmission may occur in a more complex manner than previously appreciated, and for example, it has been shown in animals that lateral force transmission occurs between synergist and even between agonist and antagonist muscles.

Purpose: To determine if lateral force transmission occurs within and between superficial and deep plantarflexor muscles in humans in vivo.

Methods: Seven subjects performed 5 types of either active contractile plantar flexions or passive joint manipulations: 1) voluntary plantarflexion, 2) voluntary hallux flexion, 3) passive hallux extension 4) passive knee extension, and 5) selective percutaneous stimulation of the medial gastrocnemius (MG). The corresponding muscle displacement during manipulations was determined by ultrasonography obtained at a proximal and at a distal site for 2 superficial plantarflexor muscles (MG (proximal site), soleus (SOL) (proximal and distal site), and 1 deep plantarflexor (flexor hallucis longus (FHL)) at the distal site. Neural activation of muscles was assessed by EMG.

Results: During passive hallux extension the FHL muscle tissue underwent 5±1 mm (mean±sem) displacement in the distal direction without any movement in the adjacent SOL muscle. The FHL moved 4±1 mm in the proximal direction during selective FHL contraction with no concurring SOL movement. During voluntary plantar flexion SOL and MG displacement in the proximal direction was similar (~7±1 mm), while FHL displaced proximally on average 2±1 mm. However, 4 subjects displayed proximal FHL displacement while 3 subjects had distal displacement of the FHL during plantarflexion. Percutaneous stimulation of MG generated 3±1 mm of displacement of GM and 2±1mm in SOL in the proximal direction while FHL remained fixed. Passive knee extension induced similar displacement of both the GM and SOL (~4±1 mm).

Discussion: The present data indicate that the FHL, which is a fairly strong plantarflexor muscle, seems to be an independent actuator with respect to intermuscular force transfer, and further support the notion that the FHL activation displays large inter-individual variation. Moreover, the data suggest that lateral force transmission occurs between the superficial plantarflexor muscles (GM and SOL). Recent work has challenged the classic understanding of muscles as single actuators, and suggested that muscle function and force transfer in a limb where muscles and tendons lie in close proximity should be considered as one interdependent system where force is transferred laterally between structures to minimize stress concentrations. This notion is partly supported by the present data.

IN VIVO MECHANICAL PROPERTIES OF THE PATELLAR TENDON IN ADULTS AND PRE-PUBERTAL CHILDREN

O'BRIEN, T.D., BALTZOPOULOS, V., REEVES, N.D., JONES, D.A., MAGANARIS, C.N.

UNIVERSITY OF HULL, MANCHESTER METROPOLITAN UNIVERSITY, UNIVERSITY OF BIRMINGHAM

An increase in tendon stiffness in vitro with maturation has been reported in many species, with an associated increase in tensile strength. The risk of strain-induced injury to tendon is related to its mechanical properties and associated tensile strength. Therefore, an understanding of how the in vivo mechanical properties of tendon change as a result of maturation may be valuable in gaining insight into the risk of strain-induced tendon injury at different ages. The mechanical properties of the patellar tendon were measured in men, women, boys and girls (each group, n=10). Patellar tendon force (Fpt) was calculated from the measured joint moment during ramped knee extension maximum voluntary contractions. Antagonist co-activation was quantified from its electromyographical activity, and the patellar tendon moment arm was measured from magnetic resonance images. Tendon elongation was imaged using sagittal plane ultrasound scans throughout the contraction. Tendon cross-sectional area was measured at rest from ultrasound scans in the transverse plane. Maximal Fpt and tendon elongation were [mean (SE)] 5453 (307)N and 5 (0.5)mm for the men, 3877 (307)N and 4.9 (0.6)mm for the women, 2017 (170)N and 6.2 (0.5)mm for the boys and 2169 (182)N and 5.9 (0.7)mm for the girls, respectively. In all groups tendon stiffness and Young's modulus were examined at the level that corresponded to the maximal 30% of the weakest participant's Fpt (925-1321N) and stress (11.5-16.5MPa), respectively. In this force region stiffness was significantly greater in both adult groups than either child group ($p<0.01$), with no differences between men and women, or boys and girls [men 915 (74)N/mm; women 876 (119)N/mm; boys 472 (60)N/mm; girls 478 (49)N/mm]. Young's modulus was also significantly greater in both adult groups than in boys ($p<0.01$) or girls ($p<0.05$), and there were no differences between men and women, or boys and girls [men 444 (39)MPa; women 443 (60)MPa; boys 224 (38)MPa; girls 266 (27)MPa). As a result of the reduced Young's modulus, the patellar tendon in children experienced greater strains at maximum voluntary contractions compared to adults, despite being under a lower stress. These findings indicate that children may be at a greater risk of strain-induced tendon injury than adults. Tendon stiffness also impacts the degree of fascicle shortening during contraction. To investigate whether the different tendon stiffness of each group results in differences in fascicle shortening between groups ultrasound recordings were made from the mid-belly of the vastus lateralis at rest and maximum voluntary contraction in a subsample of each group (n=3). It was found that fascicle shortening was ~20% of resting length in all groups. This indicates that tendon stiffness will not contribute to differences in the moment-angle relationship between adults and children.

DISTRIBUTION OF MEDIO-LATERAL BONE DENSITY AT THE ACHILLES TENDON INSERTION OF THE HUMAN CALCANEUS

LERSCH, C., FIRNER, S., POTTHAST, W., BRÜGGEMANN, G.P.

GERMAN SPORT UNIVERSITY COLOGNE

Introduction: Asymmetrical load distribution within the human Achilles tendon (AT) is considered to be an important etiological factor for AT injuries (Arndt et al.) A previous cadaver study revealed that particularly the variation of frontal plane Calcaneus (CA) position has an influence on medio-lateral load distribution within the AT (Lersch et al.) Due to the adaption of bone to mechanical load it was hypothesized that tendon induced loading, that acts asymmetrically in a long term, results in an asymmetrical distribution of bone density in the region of the tendon insertion. Therefore it was the purpose of this study to determine the medio-lateral distribution of bone density in the region of the AT insertion to get further insight into long-term force transmission between AT and CA.

Methods: Ten CA were assessed by Peripheral Quantitative Computed Tomography (pQCT) in intact condition after determining the position of the AT insertion by ultrasound in the sagittal plane. Subsequently to taking a low resulution pQCT scan of the entire bone in the sagittal plane, three transverse sections of the AT insertion, additionally one distal and one proximal to the insertion were recorded (slice thickness 0.5mm; voxel size 0.5mm). Slices were divided into medial and lateral parts and the following parameters were analyzed: Total cross sectional bone area (CSA, mm2), total bone mineral density (BMD, mg/cm3), total bone mineral content (BMC, mg), cortical area (CortA, mm2), Cortical Bone Mineral Density (CortBMD, mg/cm3).

Results: First data indicated that bone parameters differ between the different pQCT-slices. For both, medial and lateral parts CortBMD and CortA increased from proximal to distal (759.1–837.2mg/cm3; 1.5-9.8mm2). CortBMD was found to be higher on the medial side in all slices. The same was found for CortA, which differed most at the distal part of the AT insertion from medial to lateral (16.8 vs. 3.3 mm2).

Discussion: First data of this study showed that bone parameters of CA are not homogeneously distributed in the region of AT insertion. Particularly the medial aspect of the insertion exhibited higher values in analyzed parameters. This can be related to the findings of a previous study which revealed that AT loading in neutral and eversion CA positions led to inversion moments around the CA. The results of the present study support the hypothesis that higher tensile forces are applied to the medial aspect of the AT insertion than to the lateral aspect. The findings of this study could lead to a better understanding of the etiology of AT pathologies.

THE ANTERIOR AND POSTERIOR HUMAN PATELLAR TENDON - MARKED BIOMECHANICAL, STRUCTURAL AND BIOCHEMICAL DIFFERENCES

HANSEN, P., HARALDSSON, B.T., KROGSGAARD, M., QVORTRUP, K., LARSEN, J.O., KJAER, M., AAGAARD, P., MAGNUSSON, S.P.

BISPEBJERG HOSPITAL AND FACULTY OF HEALTH SCIENCES, UNIVERSITY OF COPENHAGEN, DENMARK

Introduction: Patellar tendinopathy is common in sports with prevalences up to 30-50% among elite jumping athletes. Different magnitudes of tensile strain during knee flexion have been demonstrated between the anterior and posterior aspects of human patellar tendon, which may lead to corresponding intratendinous alterations. We hypothesize that region-dependant differences in mechanical properties exist between the anterior and posterior patellar tendon fascicles and that such differences are paralleled by alterations in collagen fibril morphology and the biochemical cross-link composition of the tendon. Materials and methods: Patellar tendon samples were obtained from healthy young men (mean±SD, 32±9 yrs, n=8) during anterior cruciate ligament reconstruction. Collagen fascicles

were dissected from the anterior and posterior tendon. Fascicle mechanical properties were measured micromechanically. Collagen fibril morphology was examined by transmission electron microscopy (TEM). Hydroxlysylpyridinoline (HP), lysylpyridinoline (LP) and pentosidine (PE) cross-link content was determined by HPLC. A Student´s T-test was used to detect differences between the anterior (AF) and posterior fascicles (PF) for all mentioned analyses. Regression analyses were performed to reveal associations between the measured parameters. Results (mean ± SD): Mechanical properties: Peak stress was greater for AF (56.6±14.5.6 vs. 39.3±23.5 MPa, p<0.05). Strain was greater for PF (14±4 % vs. 19±3 %, p<0.01), while Young´s modulus was greater for AF (618±201 vs. 360±153 MPa, p<0.001). Biochemical analyses: HP and LP content were significantly greater for the PF (HP: 0.859±0.197 vs. 1.416±0.250 pmol/pmol, p=0.001; LP: 0.023±0.006 vs. 0.035±0.006 pmol/pmol, p<0.01). No differences were found for PE (0.024±0.015 vs. 0.024±0.013; p=0.92). TEM: (n=5 AF vs. 5 PF): Fibril diameters (FD) tended to be less for PF (7848±2391 vs. 4826±1603 nm², p=0.103) while fibril density showed a strong trend to be greater for PF (71±23 vs. 101±14 #/µm², p=0.0535). Regression analyses: For both AF and PF there were no significant correlations between cross-link concentrations (HP, LP and PE, respectively) and mechanical properties (peak stress, tangent modulus and strain, respectively). Pentosidine concentration and subject age were positively related for both AF (r^2=0.9, p=0.01) and PF (r^2=0.9, p=0.01). Conclusion: PF were markedly weaker than AF while HP and LP content was greater. Neither cross-link content nor fibril morphology could explain the decreased mechanical properties of PF. Interestingly, the cross-link composition of PF resembles the composition reported for human ligaments. We speculate that differences in loading patterns for AF and PF may explain the observed differences, which are presumed closely related to the frequent occurrence of tendinopathy in the posterior patellar tendon.

IS-BM01 Strength training A: Hypertrophy

MYOSTATIN IN ADULT SKELETAL MUSCLE

SCHJERLING, P.

BISPEBJERG HOSPITAL

Myostatin (growth differentiation factor 8) is a growth factor which belongs to the TGF-beta superfamily. Myostatin is an important negative factor for skeletal muscle size as hyper muscularity is seen in mice, domestic animal races and humans when the myostatin gene is defect. It is well established that myostatin is important in muscle development, whereas the exact importance of postnatal myostatin expression on the adult muscle is still under debate.

Myostatin is produced as a precursor peptide of 376 amino acids, which at some point is cleaved into a 110 amino acids mature myostatin peptide and the so-called latency-associated peptide (LAP). The LAP remains associated to the mature myostatin, inhibiting receptor binding, until the LAP is cleaved by extracellular peptidases. The mature myostatin is then able to signal via at least two different receptors, the activin type II receptor and a yet unknown receptor. When signaling through the activin type II receptor, the SMAD transcription factors are phosphorylated which allows them to enter the nuclei and activate transcription of different genes.

Although myostatin is mainly recognized for its effect on muscle cells, recent experiments suggest that myostatin may as well play a role for fibroblasts in the muscle (Li et al. 2008).

The role of myostatin in adult skeletal muscle will be discussed in this presentation.

Li ZB, Kollias HD, and Wagner KR. Myostatin directly regulates skeletal muscle fibrosis. J Biol Chem. (2008) 283:19371-8.

TESTOSTERONE AND MUSCLE HYPERTROPHY

KVORNING, T.

TEAM DANMARK

Muscle hypertrophy (MH) induced by strength training (ST) involves the orchestration of several anabolic mechanisms. One important factor in this process is testosterone (T) and thus the primary aim of this presentation is to highlight the importance of endogenous T in ST-induced MH.

T supplementation in humans induces MH (1). Conversely, suppression of T production by GnRH-analogues results in decreases in protein synthesis, strength, and fat oxidation (5). Inducing chronic changes in T concentrations by GnRH-analogues and T supplementation in five graded doses resulted in a positive relationship between T concentrations and lean mass, strength, and fat mass (2, 7). Also, MH was associated with an increase in satellite cells, which correlated with graded T concentrations (6).

To further elucidate the role of T in the adaptations to ST, 22 young men were treated with 3.6 mg goserelin (GnRH-analogue) every 4 wks or placebo, in a randomized design, for a period of 12 wks (3, 4). Attention was focused on the effect of T on lean mass, muscle strength, androgen receptors (AR), satellite cells and expression of signaling genes underlying MH (myoD, myogenin IGF-IEa, IGF-IEb, IGF-IEc and myostatin). The ST period of 8 wks started after 4 wks of treatment. Testing was performed before and after the ST period and acute measures were taken during the final ST session in the ST period.

Goserelin suppressed resting levels of T below 10% of normal, blocked the acute increase in T during ST, significantly attenuated the increase in lean mass, and abolished the increase in strength due to the ST period. Fat mass increased in the goserelin-treated group and decreased in placebo. The absence of the acute increase in T, however, had no influence on the acute mRNA expression of myoD, myogenin, myostatin, IGF-IEa, IGF-IEb, IGF-IEc, and AR during the final ST session. Similarly, the lower resting level of T had no effect on the resting mRNA expression before or after the ST period. Therefore, T does not seem to be involved in the transcriptional regulation of the genes expected to stimulate MH. Increases in the number of satellite cells after the ST period were observed around type II fibers, with no significant effect between the two groups.

It can be concluded that T is important for MH since suppression of T attenuates the increase in lean mass and strength induced by ST. However this happens in spite of similar mRNA response and satellite cell activity. This implies that T may regulate intracellular factors downstream from myoD, myogenin, myostatin, IGF-IEa, IGF-IEb, and IGF-IEc mRNA transcription, and indicate that satellite cells are only partially involved in MH.

ROLE OF IGF-I IN HYPERTROPHY

HARRIDGE, S.

KING'S COLLEGE LONDON

The growth hormone (GH) and insulin like growth factor -1 (IGF-I) axis is extremely important during growth and development. GH causes the synthesis of IGF-I in the liver and this is the major source of circulating IGF-I. In the circulation IGF-I binds to a number of different binding proteins which regulate its biological activity. However, in regard to the hypertrophy of adult muscle, circulating IGF-I seems to be of considerably less importance than IGF-I produced locally in muscle. This is evidenced by recombinant growth hormone administration induced increases in IGF-I not increasing muscle protein synthesis or causing hypertrophy. The IGF-I gene can be subject to a process of alternative splicing. The subsequent E-peptides that are cleaved during processing of the pro-hormone leaving the same "mature" IGF-I peptide, which is 70 amino acids long. Administration of this peptide into the muscles of mice in vivo, and to cells in culture, has been shown to cause hypertrophy. Furthermore, gene transfer (somatic and germ line) studies where IGF-I has been over expressed in muscle (and not the circulation) have confirmed the anabolic actions of this protein. How does IGF-I exert its actions? IGF-I stimulates muscle protein synthesis through activation of the P13/AKt signalling pathway. Activation of this pathway also causes AKT phosphorylation to inhibit the action of FOXO, a regulator of atrogene expression, which itself regulates muscle protein degradation. IGF-I is also unique in that is causes the proliferation and differentiation of satellite cells, whose activation is ultimately required for growth to occur. What of the E-peptides derived from alternative splicing? There are three of these, termed IGF-IEc, Eb and Ec. IGF-I Ec is also known as mechano growth factor (MGF). The expression of these splice variants has been limited to the measurement of mRNA as no good antibodies are commercially available. MGF is the only one of these peptides whose role has been investigated in any detail. Its mRNA expression levels are markedly lower levels than those of IGF-IEa, but MGF is more rapidly upregulated in response to exercise. It seems that this particular peptide may play a specific role in muscle adaptation by stimulating satellite cell proliferation.

STAGES OF CHANGE AND PHYSICAL ACTIVITY: HOW DO THE STAGES MATCH SELF REPORTED PHYSICAL ACTIVITY, SELF-EFFICACY AND PHYSIOLOGICAL MEASURES

SØRENSEN, M.

THE NORWEGIAN SCHOOL OF SPORT SCIENCES

STAGES OF CHANGE AND PHYSICAL ACTIVITY: HOW DO THE STAGES MATCH SELF REPORTED PHYSICAL ACTIVITY, SELF EFFICACY AND PHYSIOLOGICAL MEASURES?

Marit Sørensen1 and Sidsel Graff-Iversen2

1The Norwegian School of Sport Sciences, Norway

2National Institute of Public Health, Norway

Introduction: The stages of change model, or The Transtheoretical Model (TTM) has been heavily critisised. Among the issues are: not being applicable to complex behaviours like physical activity, lack of validated staging algorithms, and over-simplification. The purpose of this presentation is therefore to examine the relationship between self reported stages of change of physical activity behaviour, 3 different self-reported physical activity measures, self regulatory self-efficacy of exercise, and physiological measures related to physical activity, namely waist-hip ratio, triglycerides in the blood, and pulse counts, in a population study.

Methods: Data were obtained from a population-based cohort study by the National institute of public health in two counties during the years 2000-2001 (Norwegian Institute of Public Health, 2003). Questionnaires were collected by health personnel in conjunction with a physical examination. The sample for this study consisted of those individuals who answered the questions about stages of change of physical activity (N= 9374, 55.3% females and 44.7% men).

Results: The largest group for both genders and in all age groups were the preparers (37%), people who describe themselves as physically active but not regularly. Nearly as many defined themselves at the maintenance stage (35%). There were very few in the action stage (4.4%). The stages correlated reasonably with the self reported physical activity measures for leisure time activity. Cross-tabulations demonstrated that the main pattern of responses for all three activity measures supported the staging algorithms. However, a varying percentage gave inconsistent responses (variation raged from 1,5% up to 36,4% in some categories). The mean scores of exercise self efficacy, waist-hip ratio, triglycerides and pulse counts changed in a linear fashion with the 5 stages from precontemplation to maintenance.

Conclusion.

The staging algorithms were supported by the physiological markers and exercise self-efficacy, and to some extent by simple self-reports of physical activity in leisure time.

THE COMPARISON OF EXERCISE AND DIETING BEHAVIORS AMONG STUDENTS

HEIN, V.

UNIVERSITY OF TARTU

Previous research of the motivational model, based on self-determination theory and theory of planned behaviour, has shown that relative autonomous motivation predicted intentions to exercise or diet via the mediation of attitudes and perceived behavioral control, and the latter two predicted actual level of exercise and dieting behaviour via the mediation of intentions (Hagger et al., 2006). The aims of the present study were: 1) to retest motivational models of exercise and dieting behaviour with Estonian students; and 2) to compare the components of motivational models for exercise and dieting behaviour among overweight students.

Participants were 251 students aged 18 to 23 years. The motivational model components were measured according to the method reported by Hagger et al (2006) A structural equation modeling procedures were used. The comparison of the models components was made by the Paired - Sample T - Test. According to self-reported data about height and weight (Davis, 1990), 32 participants had BMI over 25 and were viewed as overweight.

The fit indexes of the models were acceptable (NNFI = 0.95, CFI = 0.96 and RMSEA = 0,07; NNFI = 0.94, CFI = 0.95 and RMSEA = 0,08, respectively for motivational models of exercise and dieting behavior). The models explained 56 and 35 % of the variance in the dieting and exercise behavior respectively. The direct effect from autonomous motivation to intention was followed in the both motivational models. The testing the mediation effect of intention between autonomous motivation and actual behaviors showed the existence of the complete mediation in the motivational model for exercise behavior and partial mediation in dieting behavior.

The comparison of the model components showed that all participants evaluated all motivational types, expect amotivation, higher for exercise behavior than for dieting behavior. The similar trend was followed in respect of the attitude and perceived behavioral control. The analysis of the group with overweight indicated that they were more intrinsically motivated in respect of physical activity than in the following the diet. Also the attitude toward the physical exercise was high than for diet.

The results of this study confirmed that the motivational models can be replicated not only in both behavioral contexts but is also applicable in other cultural context. Students were more motivated in physical activity than in following the diet.

IMPAIRMENTS IN COGNITIVE PERFORMANCE DURING LONG LASTING PHYSICAL ACTIVITY

DOPPELMAYR, M.

UNIVERSITY OF SALZBURG

It is generally accepted, that short bouts of aerobic exercises are capable to improve cognitive performance (Audiffren et al. 2008), while on the other hand, very long lasting strenuous physical activity, possibly accompanied by dehydration or sleep deprivation, leads to a severe reduction in intellectual capabilities (Tomporowski, 2003, Lieberman et al., 2005). Although there are several studies addressing these in- or decreases in cognitive performance for exercise intervals up to three hours, there are almost no reports exceeding this time interval.

Three studies will be presented focusing on cognitive performance changes during foot races lasting 24 hours or longer. The first study is a single case report of a 24 hours race where the subject underwent EEG recordings and reaction time tests approximately every two hours. In the second study the results of two subjects participating in the Badwater Ultramarathon (216 km in the Death Valley, with ambient temperatures well above 50°C) are reported. Concentration (as a part of the working memory system) and sustained attention have been investigated at 6 points along the route. The third study, carried out again during the Badwater Race included 5 subjects that have been tested until km 130. Reaction times, working memory span, long term memory (encoding and retrieval) have been investigated.

In general we can conclude that cognitive performance is at least in part somewhat impaired after more than 24 hours of exercise, although most of these effects are small and show considerable interindividual variations. While the performance in simple reaction time tasks, or working memory span is almost unimpaired, the encoding into long term memory shows a dramatic decrease. The fact that ultra-race participants are unable to encode and retrieve information into and from long-term memory, is of relevance for the organization of those events.

MODIFICATIONS OF BODY STATE IMAGE AFTER A PHYSICAL ACTIVITY SESSION

NART, A., SCARPA, S., CAENA, F., CAVALLO, A.

UNIVERSITY OF PADUA

Introduction: Body image (BI) can be considered as a multidimensional construction about perceptions and attitudes that individuals refer to their bodies and in particular to their appearance. Despite the fact that athletes are generally more satisfied with their bodies than others, physical activities seem to wield both negative and positive influences on BI. The aim of the study was to understand the role played by physical activity (PA) in BI modifications. In particular we wanted to observe if a single session of sport or PA in general could have some positive influences on BI state, meant as an episodical evaluative and affective perception of physical appearance.

Methods: 180 subjects (128 women, 71.1% and 52 men, 28,9%) aged from 15 to 78 (M= 37.42, SD=18.78) were involved in the study. The main research tools were the following: (a) the Body Image States Scale (BISS, Cronbach's alpha in neutral context .77); an Italian version was obtained by means of back-translation (Cronbach's alpha .74); (b) one hour session of PA or sport; (c) additional personal information (sex, age, body mass index, physical and sport activity type, reasons linked to their practice, intensity and enjoyment level of the practised activity). Written informed consent was obtained from all participants.

BISS is a six-item questionnaire with a 9-point response format for each item. The measure of BI is obtained by the composite mean of the six items. Higher scores reflect more positive BI states. Procedure foresaw three compilations of BISS: the first one hour before, the second at the beginning and the third at the end of a PA or sports session (duration of one hour).

Results: The composite mean of initial compilation of BISS was 5.49 (SD .91), the second one was 5.49 (SD .92) and the final one was 5.91 (SD 1.03, p = .000). Male BI state scores significantly higher than the female one (5.8 vs 5.3 at baseline, p = .002), but the trend was the same for both males and females with a positive fallout from PA sessions. Age, BMI, motivation and PA type did not seem to influence BI state modifications, while there was a positive effect on BI state of both PA enjoyment and intensity.

Discussion: Results showed that sport and PA had a positive influence on BI state and seemed to confirm the validity of the BI state construct, changing with time and in different contexts. Those findings could have significant implications in the field of BI disturbances and their prevention. At least two cornerstones should be considered in promoting programs of adapted physical activities: (a) activities should have an intensity range from moderate to high; (b) due consideration should be given to enjoyment as a factor that increases the positive effects of physical exercise over BI.

THE EFFECT OF THE ECOLOGY OF PRACTICE ON ACHIEVEMENT ORIENTATIONS AND SPORTPERSONSHIP AMONG SOCCER PLAYERS UNDER-16 YEARS

GONÇALVES, C., DOMINGUES, M., COELHO E SILVA, M.

UNIVERSITY OF COIMBRA

Coaches are believed to have an important role in shaping the quality of the youhg athletes experiences. Scholars suggest that the climate fostered by the ecology of practice can influence the athletes' achievement orientations and moral attitudes. The purpose of this study is to examine the effects of practice context's climate on (a) achievement goals (Task and Ego Orientations in Sport Questionnaire/TEOSQ) ; (b) the sportpersonship attitudes (Sports Attitudes Questionnaire/SAQ).

Methods: Soccer players aged 13-16 years (n=132, 85 from an academy of a professional club and 47 from a local club) fullfilled the portuguese versions of TEOSQ and SAQ. To analyze the effects of ecological climate on dependent variables t-test and ANOVA were performed.

Results and Discussion: In TEOSQ players from the academy scored significantly higher than their peers both on task and ego items. In SAQ significant effects were found on commitment, and gamesmanship,the athletes from the academy showing higher scores. No effects were found on convention and cheating.

Conclusions: The competitive level seems to have effect on achievement goals, and on sport attitudes. The players with professional orientation show an high ego- and high task-orientation, simultaneously with a greater commitment in sport and a greater orientation toward winning. The findings suggest that sport organizations with different philosophies exert different effects on adolescents' motivational orientation and sportpersonship.

A CROSS-CULTURAL STUDY OF SELF-PRESENTATIONAL CONCERN AMONG INTERCOLLEGIATE SOCCER PLAYERS

GEISLER, G., LEITH, L.M.

UNIVERSITY OF TSUKUBA

This study examined evaluative fear and sport-specific self-presentational concerns among 179 intercollegiate soccer players in Canada, Germany, and Japan. Participants completed the brief Fear of Negative Evaluation (FNE) scale (Leary, 1983) and listed their sport-specific self-presentational concerns as well as the target people of those concerns. Independent samples t tests and post hoc Tukey tests were used to analyze the FNE scores and showed that the Japanese players had significantly higher evaluative fear than the Canadian and German cohorts. Content analysis then revealed 23 conceptual clusters denoting both general and performance-specific self-presentational concerns, 19 of which were team-oriented while four pertained to individual concerns. However, the highest scoring category in Canada and Germany was that players had no specific concerns about impressions. In contrast, not one such response was found in the Japanese sample, and only five clusters were endorsed by the participants in all three nations. With respect to the target people of players' self-presentational thinking, the four universal categories from the 18 clusters that emerged included general spectators, teammates in general, friends, and opposing players/teams. Overall, the results suggest that Canadian and German university players wish to look competent and competitive and are cognizant of the impressions left on a variety of different people, while Japanese players' concerns are largely team-oriented and directed toward peers or those associated with their in-groups. They also suggest that the notion of maintaining "face" in Japanese life extends to sport, presumably through a cultural sense of obligation and group responsibility and the corresponding pressure to win. Follow-up research should examine elite players in different nations plus the effects of psychological skills training on self-presentational concern and performance among Japanese athletes, as it is possible that evaluative fear serves an adaptive function for sports competitors in Japan. Such research is necessary before instructing coaches to apply intervention strategies that reduce self-presentational thinking.

MOVING BEYOND A PRESIDENTIAL ELECTION: A NETWORK OF STAKEHOLDER INFLUENCES

SKIRSTAD, B.

NORWEGIAN SCHOOL OF SPORT SCIENCES

Introduction: The purpose of this paper is to explain the presidential election process of the Norwegian Olympic and Paralympic Committee and Confederation of Sports (NOC) in 2007. Stakeholder and network theory is used as the theoretical framework in order to understand the election process and explore the power play between the different stakeholders in sport in relation to have their candidate elected as president. The stakeholder picture is multifaceted and consists of several formal and informal stakeholders, of whom some are internal and some are external.The most influential stakeholders are the sport federations (55) and the regional sport associations (19), and each group has 75 votes. In addition comes the executive board of the NOC. Stakeholder theory is one important example of a theory that develops tools to assess the relative importance of different constituents and to find rational strategies for balancing the attention given to their demands (Mitchell, Agle, & Wood, 1997). Power as conceptualized by Mitchell et al. (1997) refers to abilities to influence the outcome according to the stakeholders' desires. Even within a stakeholder group not all members are homogeneous. Stakeholders lacking sufficient power to influence the organization demonstrated that it may still be able to influence through forming an alliance with another powerful stakeholder (Frooman, 1999).

Method: Qualitative case-study of observations at the GA for three days and field notes, analysis of news paper clippings, and seven semi-structured retrospective interviews with the key-actors (spokesperson for the districts, the sport federations, the leader of the nomination committee, two vice-presidents, the elected president, and the major opponent). The interviews were tape-recorded and written down and analysed according to power, urgency and salience.

Results: The Nomination Committee planted a seed for a female president. This started the chase by the big federations to find a "heavy" candidate to substitute her. They did not succeed because the downfall of the big federations' power was caused by not playing by the democratic rules, too many dirty stories about opponents, arrogance, and failure of organizing fraction meetings. A troika (president and two vice-presidents) united just before the finish line by negotiations on divisions of power and work areas as well as salary. The theoretical framework gave more in-depth knowledge of the election process and how the different stakeholders operated.

SCIENTIFIC SUPPORT FOR THE "COACH CAMPAIGN" IN GERMAN TOP LEVEL SPORTS

POHLMANN, A.

FEDERAL INSTITUTE OF SPORT SCIENCE

INTRODUCTION: Despite their exceptional importance for the athletic and personal development of their athletes, systematic research on analysing the professional profile and working conditions of coaches working in German top level sport has not been done yet. In order to address the important role of top level coaches and to improve their working conditions, in 2006 the German Olympic Sport Federation has started a so-called "Coach Campaign". The Federal Institute of Sport Science supports this campaign by the initiation and funding of two research projects: (a) "coach profession profile" and (b) "coach information supply".

The project "coach profession profile" deals with the structural conditions of the coaches' profession and explores the following issues: What are the structural and working conditions of coaches in top level sports? What are the conditions for being employed as a coach? Which measures have to be taken to establish the coach profession as a durable, well honoured and dominant profession, which is characterized by well defined and structured job qualification levels and job profiles?

In order to reach top level performances, coaches depend upon a permanent information supply about the latest training and coaching methods as well as for being up to date for the high demands put upon them in their job as coaches. In the research project "coach information supply", the common information supplies used and asked for by coaches are investigated. The main purpose of this study is to identify information deficits and information needs in order to optimize the information supply for top level coaches.

METHODOLOGY: Both studies were realized by the Institute of Sport Science and the Institute of Media Science at the University of Tübingen, Germany. For both research projects, more than 1.500 top level coaches were asked to fill out extensive questionnaires. Moreover, an analysis of literature and documents related to the topics of the surveys took place, including the use of coach related internet sites, as well as additional half-standardized interviews with experts were carried out.

RESULTS/DISCUSSION: Both research projects were finished in autumn 2008. The overall response rate was rather high (study a: 47,1 %; study b: 27 %), especially in consideration of questionnaire size in both studies.

Selected findings of both studies are

- a high need and interest of coaches for improving professional and structural working conditions;
- high academic and coaching qualification levels of top level coaches, including many years of coaching experiences in top level sports and a former successful individual sport career;
- a preference for non-formal methods of information supply (particularly the interchange of information with other coaches, own observation, analysis and evaluation) and the use of coach training programs.

Additional studies are intended to carry on the improvement of professional profile and working conditions of coaches working in German top level sport.

A COMPARISON OF THE PERCEPTION OF SPORT MANAGEMENT STUDENTS ABOUT GENDER STEREOTYPING IN MANAGERIAL SKILLS

ALAY, S., KARAKILIÇ, M., KOÇAK, S.

GAZI UNIVERSITY, ANKARA, TURKEY., KIRIKKALE UNIVERSITY, KIRIKKALE, TURKEY., MIDDLE EAST TECHNICAL UNIVERSITY, ANKARA, TURKEY.

Introduction and aim: In mid-level managerial jobs, some skills such as relationships and doing tasks are important. Knowing the degree of resemblance between women, men and managers in midlevel managerial skills can show the way to explain the gender stereotyping in sport management. Therefore, the purpose of this study was to examine and compare how perceptions of women, men, and successful mid-level sport managers fared with respect to relationship orientation, task orientation, and emotional stability dimensions that characterize a successful mid-level sport manager.

Methodology: 483 undergraduate sport management students were participated in this study (289 male and 194 female). Data were collected by using Turkish version of Schein Descriptive Index (Sümer, 2006) to define both the sex role stereotypes and the characteristics of successful mid-level sport managers. The instrument consists of 69 items with three subscales; relationship-orientation (23 items), task-orientation (31 items), and emotional-stability (15 items). Internal consistency reliabilities of the subscales were .81, .86, and .72 respectively. Participants filled out only one form of the index. A 2 x 3 (respondent's gender x target person's type) ANOVA was conducted to examine how perceptions of women, men, and successful midlevel sport managers positioned on relationship-orientation, task-orientation, and emotional stability.

Results: Results of the ANOVA on the relationship-orientation measure yielded a strong target person's type effect, $F(2,1187)=16.84$, $p<.001$, $n2=.03$, along with a significant respondent's gender X target person's type interaction effect, $F(2,1187)=4.80$, $p<.05$, $n2=.008$, and main effect of respondent's gender $F(1,1187)=7.95$, $p<.05$, $n2=.007$. The ANOVA results on the task-orientation variable resulted in a strong target person's type effect, $F(2,1187)=95.03$, $p<.001$, $n2=.14$, along with a significant respondent's gender X target person's type interaction effect, $F(2,1187)=27.16$, $p<.001$, $n2=.04$, and main effect of respondent's gender $F(1,1187)=20.71$, $p<.001$, $n2=.02$. Results of the ANOVA on the emotional stability measure yielded a strong target person's type effect, $F(2,1187)=17.25$, $p<.001$, $n2=.03$, along with a non significant respondent's gender X target person's type interaction effect, $F(2,1187)=.03$, $p>.05$, $n2=.00$, and main effect of respondent's gender $F(1,1187)=29.54$, $p<.001$, $n2=.02$.

Conclusion: The results revealed that successful mid-level sport managers were perceived by both female and male respondents to be relatively high on relationship-orientation and task-orientation, and low on emotional instability. It could be stated that generally relationship-orientation is a characteristics more commonly ascribed to successful mid-level sport mangers and women than men, and task-orientation and less neuroticism are characteristics more commonly ascribed to successful mid-level sport managers and men than women.

TEN YEARS AFTER THE ESTABLISHMENT OF WADA: TIME TO EVALUATE ROLES OF THE ACTORS?

HANSTAD, D.V.

NORWEGIAN SCHOOL OF SPORT SCIENCES

Introduction: Since the establishment of the World Anti-Doping Agency (WADA) in 1999 the number of actors involved in anti-doping activity has increased and the credibility of testing has improved. The aim of this paper is to (i) analyze how the different units have become increasingly interconnected, and (ii) present some suggestions to redistribute tasks between the actors. The role of international federations (IFs) will be emphasized.

Methods: The paper is a result of a four year study (PhD) and based on four case studies which approach the network of anti-doping activity from four perspectives; the global, international, national and athletes perspective. The qualitative case studies were based on interviews, document analysis and archival records.

Results: National and international sports organizations and anti-doping organizations are signatories of the World Anti-Doping Code and required to adopt and implement anti-doping policies and rules, while governments have ratified the International Convention against Doping in Sport. Many organizations are not compliant with the Code, which probably is due to variations in resources, including infrastructure, personnel and economy, as well as in political and socio-cultural differences. Further, the anti-doping activity is still characterized by a lack of trust. The fact that positive doping tests have consequences for an organization may result in a conscious strategy to avoid doping scandals by failing to provide high quality doping controls. To take IFs as one example, they do not have independent anti-doping organizations.

Discussion: It may be a matter of fact that leaders of IFs do not want their sport full of doping, but are they ready to pay the price to get rid of it? In many sports such a process will be a difficult one, which may involve doping scandals and negative publicity for the sport. As a consequence sponsors, TV right-holders and spectators may disappear. To avoid mistrust IFs should not be involved in doping controls of their own athletes. Instead they should be responsible for funding the controls carried out by effective and independent national anti-doping organizations and coordinated by WADA. The funding could, for Olympic sports, be organized by earmarking some part of the income at the Olympics which is distributed to the IFs (in the 2004 Olympics the 28 summer IFs received 253 million USD from television rights). This would give a more trustworthy anti-doping activity. The main task for IFs regarding anti-doping could be responsibility to administer (registered) testing pools in accordance to the WADA regulations and run education program for their own athletes.

HOW DO NORWEGIAN CROSS-COUNTRY SKIERS EVALUATE AND INTERPRET THE WHEREABOUTS INFORMATION SYSTEM?

HANSEN, P.

NORWEGIAN SCHOOL OF SPORT SCIENCES

Aim: The whereabouts information system is probably the most discussed topic in antidoping. All the athletes who are in the national or international registered testing pool (RTP) have to provide information about their whereabouts. The system enables no-advance notice testing. The two studies on the whereabouts information system which have been carried out (BACL, 2008; Hanstad & Loland, 2009) indicated that many athletes were dissatisfied with the system and especially the technical solutions. The paper will examine the athletes` attitudes towards the whereabouts information system in light of how they evaluate the legal and technical aspects. The harmonization of anti-doping, and their everyday routines connected with the reporting are also taken into account.

Method: The study was carried out as a case study with a qualitative approach. A total of 10 individual interviews were carried out (5 athletes and 5 employees (2 from Antidoping Norway (ADN), 3 from the Norwegian Ski Association). In addition a focus group was used (consisting of 3 athletes).

Results: The meanings of the athletes vary from those who think that the whereabouts information is stressful, to those who doesn't think it`s stressful. All agree that there must be an efficient out-of-competition testing program, but that the technical system creates difficulties for the athletes. The lack of harmonization is also something that worries the athletes.

Discussion: Many athletes are dissatisfied with the system because they find ADAMS too advanced. There are indications that the sensegiving process connected to ADAMS has been executed poorly. The lack of sensegiving affects the sensemaking process within the national team. Furthermore, there seem to be a gap between what the employees in ADN find plausible and what the athletes find plausible. How other athletes evaluate and interpret the system influences the athlete to some extent.

GAMBLING MOTIVATIONS AND FINANCIAL RISK TAKING ATTITUDES OF SPORT GAMBLING UNIVERSITY STUDENTS AND THEIR PERSONALITY DIFFERENCES FROM NON GAMBLERS

KARLI, Ü., AKPINAR, S., KOÇAK, M.S.

NIGDE UNIVERSITY, NIGDE, TURKEY, 1. MIDDLE EAST TECHNICAL UNIVERSITY, ANKARA, TURKEY.

Introduction and aim: Sport gambling is a developing market in sport industry and sport gamblers are the stakeholders of the market. Analyzing sport gamblers in the scope of consumer behavior would be beneficial for creating successful marketing decisions. Therefore, the purpose of this study was three-fold; to determine the personality and financial risk-taking attitude differences between sports gambling students and non-gambling students, to specify gambling motivations of the sport gambling students and to identify the relationship among personality traits, financial risk-taking attitude and gambling motivations of the students who gamble on sport events.

Method: The subject group was composed of 1109 (male 700, female 409) Middle East Technical University students who were participating in sport gambling activities (n=435) and who had never participated in sport gambling activities (n=674). Big Five Personality Inventory (John, Donahue, & Kentle, 1991), Investment Risk Attitude Scale (Nyhus, 1995) and Gambling Motivation Scales (Chantal, Vallerand and Vallieres, 1994) were used in the data collection. ANOVA, MANOVA and Hierarchical Multiple Regression were conducted in statistical analysis.

Results: Results indicated that sport gambling students and non-gambling students showed significant differences in personality, Pillai's Trace = .24, $F(5,1101) = 70.51$, $p<.01$. Also, results demonstrated that sport gambling students and non-gambling students showed significant differences in their financial risk-taking attitudes, $F(1, 1105) = 29.39$, $p<.01$. Personality ($R2=.03$, $F(5, 429)= 2.613$, $p<.05$), gambling motivations ($R2change =.10$, $F(3, 426)=15.95$, $p<.05$) and gender ($R2change =.04$, $F(1, 425)=21.18$, $p<.05$) accounted for a significant amount on the financial risk-taking attitude of sport gambling subjects. Sport gambling students showed no significant difference in their gambling motivations according to their gender, Pillai's = .013, $F(7,427) = 800$, $p>.01$. Sport gambling students were primarily motivated with intrinsic motivating factors of gambling.

Conclusion: Finally, this study pointed that university students who were more extraverted and more open were more prone to gambling on sport events and were more permissive towards financial risk-taking. Additionally, results revealed that enjoyment, amusement and learning were the primary motivating factors that lead university students towards sport gambling.

OP-RE03 Rehabilitation 3

THE RELATIONSHIP BETWEEN ACL INJURIES AND PHYSICAL FITNESS IN JUNIOR AUSTRIAN ALPINE SKI RACERS - A 10 YEAR LONGITUDINAL STUDY

RASCHNER, C., PLATZER, H.P., PATTERSON, C., HILDEBRANDT, C., LEMBERT, S., MILDNER, E., HUBER, R.

UNIVERSITY INNSBRUCK

INTRODUCTION: The development of ski equipment as well as changing environmental factors such as aggressive artificial snow result in higher loads on knees of junior ski racing athletes. Knee injuries are the most common injuries in skiing and ski racing with a higher incidence of ACL ruptures in female athletes (Pujol et al. 2007).

Based on retrospectively registered data, the aim of this study was to identify the link between physical fitness and ACL injuries of junior alpine ski racers.

METHODS: 485 female and 549 male adolescent (14-19 years of age) ski racers of the Skigymnasium Stams underwent the same test battery three times annually from 1996 to 2006. The following tests were conducted: maximum isometric unilateral leg extension strength, maximum isometric core strength flexion/extension, counter movement jump (CMJ), ski specific CMJ, drop jump, jump coordi-

nation, strength endurance, anaerobic shuttle run and Cooper test. Based on these tests, norm profiles were established in all age groups. In case of an ACL injury the last test result before the injury was compared with the norm values. Over the 10 year period 39 female and 18 male athletes sustained an ALC injury. Z score transformations for all variables normalized the different age groups. T-tests were used to calculate performance differences between injured and non-injured athletes.

RESULTS: Injured female athletes had lower performance in strength endurance (p=0.031), maximum relative isometric core extension strength (p=0.030) and core/leg strength ratio (p=0.039). In injured male ski racers maximum absolute & relative core flexion strength (p=0.032/p=0.030), jump coordination (p=0.017) and drop jump height (p=0.042) were lower than in non-injured athletes. Injured males had longer drop jump contact time (p=0.005). The calculated parameter of core flexion to extension ratio was also lower (p=0.009) in injured males.

DISCUSSION: Core strength is fundamental in ski racing for body stabilisation and force generation. Leetun et al. (2004) have noted that decreased core stability contributes to lower extremity injuries. In this study core strength, core/leg strength ratio and core flexion/extension strength ratio seems to be a critical factor for ACL injuries. Knee injury prevention must improve strength capacity and neuromuscular patterns in leg and core muscles (Hewett et al. 1999). Enhanced incorporation of fatigue resistance training in female and specific plyometric training programs coupled with unanticipated event management in male athletes are recommended. The longitudinal examination of physical fitness provides ski coaches with helpful information to develop more effective injury prevention programs.

RELIABILITY OF SINGLE-LEG AND DOUBLE-LEG BALANCE TESTS IN SUBJECTS WITH ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION AND CONTROLS

KOUVELIOTI, V., KELLIS, E.

ARISTOTLE UNIVERSITY OF THESSALONIKI

Balance assessment and training are important elements of rehabilitation following anterior cruciate ligament (ACL) reconstruction. Assessment of balance in double and single-limb stance involves recording of the movement of the centre of pressure (COP) using various platforms. It is important to ensure that the assessment tools we use in the clinical setting and in research have minimal measurement error (Ageberg 2007). Translating reliability coefficients into clinically meaningful representations of measurement error is a necessary and important step when the goal is to link clinical research to clinical practice. Therefore, the aim of this study was to assess the test-retest reliability of balance variables measured in both and single-limb stance in patients and controls. Fifteen healthy subjects and ten subjects with ACL reconstruction performed stability tests at two occasions, a week apart. The subjects were instructed to stand erect, barefoot with feet shoulder width apart with opened eyes for 30 sec. They then performed a single-limb balance test by standing on one foot with the other leg flexed at 90° at the hip and the knee joints with both arms hanging relaxed at the sides (Ageberg, 2005). The assessment for both tests, included 3 measurements, and 5-min rest was provided between successive trials. The best trial was further analyzed. All tests were performed on an EPS pressure platform (Loran Engineering S.r.l., Bologna – Italy). The COP was recorded at 30 Hz and it was used to estimate the total path of the COP, the COP standard deviation in the anteroposterior and mediolateral axis, the velocity of the COP in both axis, the sway area and the ellipse formulated by the COP trajectory paths over time. For the total COP path, the intraclass correlation coefficient (ICC) ranged from 0.71 to 0.83. For the COP standard deviation the ICCs ranged from 0.74 to 0.94. For the COP speed, the ICCs ranged from 0.65 to 0.79. The sway area and ellipse scores displayed ICCs values of 0.91 to 0.95 and 0.86 to 0.92, respectively. In general, the ICCs were higher for double leg tests compared with single-stance ones. The above results indicate that 30-s balance tests in double and single-leg stance are reliable tools to assess static balance. Consequently, the use of such tests to monitor rehabilitation programs following ACL reconstruction is recommended.

CROSS ECCENTRIC EXERCISE IMPROVES ACCELERATION REACTION TIME AND SUBJECTIVE SCORES ON QUADRICEPS FOLLOWING ACL RECONSTRUCTION

PAPANDREOU, M., PAPATHANASIOU, G., GEORGOUDIS, G., SPYROPOULOS, P., BILLIS, E., PAPAIOANNOU, N.

TECHNOLOGICAL EDUCATION INSTITUTE (TEI)

Purpose

Anterior cruciate ligament (ACL) reconstruction can cause knee impairments and disability. Knee impairments are related to quadriceps performance - accelerated reaction time (ART) - and disability to performance of daily living activities which is assessed by questionnaires (Lysholm knee score). The purposes of this study were to investigate the effect of cross exercise to the early rehabilitation phase of ACL reconstruction: a) on quadriceps ART at 450, 600 and 900 of knee flexion and, b) on the subjective scores of disability in ACL reconstructed patients.

Methods

42 patients who underwent ACL reconstruction were randomly divided into 3 groups, two experimental and one control. All groups followed the same rehabilitation program. The experimental groups followed 8 weeks of cross eccentric exercise (CEE) on the uninjured knee; 3d/w, and 5d/w respectively.

Quadriceps ART was measured at 450, 600 and 900 of knee flexion pre and nine weeks post-operatively using an isokinetic dynamometer. Patients completed pre and post operatively the Lysholm questionnaire whereby subjective scores were recorded.

Results: Two factor ANOVA showed significant differences in ART at 900 among the groups ($F=4.29$, $p=0.02$, $p<0.05$). Post hoc Tukey HSD analysis determined that the significant results arose from the first experimental group in comparison to the control ($D=-0.83$, $p=0.01$). No significant differences were revealed at 450 and 600.

Significant differences were found in the Lysholm score among the groups (F=4.75, p=0.01, p<0.05). These significant results arose from the first experimental group in comparison with the control (D=7.5, p<0.01) and from the second experimental in comparison with the control (D=3.78, p=0.03).

Conclusions: These findings provide some evidence that adding CEE as supplementary program at the early phase of ACL reconstruction improves quadriceps ART at 900 at a sequence of 3d/w and, the subjective scores of disability at a sequence of 3d/w and 5d/w respectively on ACL reconstructed patients.

A SCREENING TEST FOR KNEE PAIN

LARSSON, H., TEGERN, M., HARMS-RINGDAHL, K.

DIVISION OF PHYSIOTHERAPY

Background

Research on military populations indicates that failing to complete the training is a significant problem for armed forces around the world 1). The loss of new recruits is costly, both in terms of military preparedness and economically. Musculoskeletal disorders, especially knee pain2) during the service have been reported as one important risk factor. Preventive interventions are important however the problems have to be identified. A screening test for identifying low-level disorders that an individual may not be aware of but potentially increases the risk of injury during military training was designed. The study evaluated the capacity of the test to detect current knee pain before military training. The study also aimed to examine the reproducibility of the tests.

Method: When starting their basic training, 859 conscripts from two different army units were tested in four simple physical test of the lower limb. They also rated pain intensity during the test. Conscripts from one unit were followed and retested at the end of their basic training. Those who were premature discharged were registered.

Results: One of the four tests identified 82% of the conscripts who had knee pain, including subjects who in a questionnaire did not report any complaints.

Those who tested positive were to a higher level discharged, 34% compared to those who tested negative 7% (p<0.001). The reproducibility of pain ratings in relation to the tests was 'good' to 'excellent'.

Conclusions

The set of four lower-limb loading tests is a reliable and valid tool in detecting knee pain in conscripts. The construction of the test implies that many subjects could effectively perform the test at the same time. The screening tests can also be used in evaluating knee pain in other physically demanding occupations, as well as for athletes.

EFFECT OF HEAVY LOAD STRENGTH TRAINING ON RAPID FORCE CAPACITY OF CHRONICALLY PAINFUL MUSCLES

ANDERSEN, L.L., ANDERSEN, J.L., SUETTA, C., KJÆR, M., SØGAARD, K., SJØGAARD, G.

NATIONAL RESEARCH CENTRE FOR THE WORKING ENVIRONMENT

Background: Rapid force capacity of chronically painful muscles is inhibited markedly more than maximal force capacity, and is therefore relevant to assess in rehabilitation settings.

Aim: To investigate the effect of three contrasting interventions on rapid force capacity, as well as neural and muscular adaptations in women with chronic neck muscle pain.

Methods: A group of employed women (n=48) with a clinical diagnosis of trapezius myalgia participated in a 10-wk randomized controlled trial; specific strength training of the neck/shoulder muscles, general fitness training performed as leg-bicycling, or a reference intervention without physical activity. Maximal voluntary shoulder abductions were performed at static angles of 35° and 115° with simultaneous recording of electromyography (EMG) in the trapezius and deltoid. Maximal muscle strength and activation (peak torque and peak EMG) as well as rapid muscle strength and activation (rate of torque development and rate of EMG rise) were subsequently determined. Trapezius muscle fiber characteristics were determined with ATPase histochemistry.

Results: Significant changes were observed only in the specific strength training group. Whereas peak torque increased 18-29% (P<0.01-0.001), rate of torque development increased 61-115% (P<0.001). Peak EMG and rate of EMG rise increased correspondingly (P<0.05-0.001), and trapezius type II muscle fibers hypertrophied 20% (P<0.001).

Conclusion: Rapid force capacity of chronically painful muscles is highly responsive to rehabilitation with specific strength training. The underlying mechanisms were related to both pain reduction and general neuromuscular adaptations to strength training. Potentially, the present method can be a useful clinical screening tool of muscle function in rehabilitation settings.

CHANGES IN LOCOMOTION PERFORMANCE AFTER TOTAL KNEE ARTHROPLASTY

BRANDES, M., RINGLING, M., HILLMANN, A., ROSENBAUM, D.

UNIVERSITY BREMEN

In patients suffering from knee osteoarthritis (OA), functional outcome after total knee arthroplasty (TKA) is usually assessed with questionnaires which may cause subjective and cognitive limitations. Thus, little is known about how the patients' activity level develops after

total knee arthroplasty. Therefore, this study assesses the physical activity level of subjects undergoing TKA using two accelerometry-based devices.

51 subjects (33 females, 67 ± 7.5 years, BMI 30.5 ± 4.5), designated for primary knee replacement were recruited. All subjects received a mobile bearing knee implant (Innex CR, Zimmer Inc.).

Time spent in different activity categories (locomotion, standing, sitting and lying) of 1 day was measured with the DynaPort ADL-monitor (McRoberts B.V., The Netherlands). The Step-Activity-Monitor (OrthoCare Innovations, USA) collected the number of gait cycles for 7 consecutive days. American Knee Society Score (KSS) and Short Form 36 (SF-36) were applied to assess the functional outcome and quality of life. All procedures were applied before surgery and at 3 (n=49), 6 (n=39) and 12 (n=29) months follow up.

Percentage of locomotion increased from 9.3% before surgery to 11.4% at 12 months FU ($p<0.05$). Categories reflecting resting (sitting, lying) decreased without reaching statistical significance. The number of daily gait cycles increased from 4790 gait cycles at 3M FU to 5864 gait cycles at 12M FU ($p<0.05$) which extrapolates to more than 2.1 million gait cycles per year. KSS showed significant improvements at each follow-up period up to 92.7% at 12 months FU. The mean outcome of the SF-36 as well as the subcategories physical functioning and pain reached significant improvements.

KSS and SF-36 show that ~90% of the subjects improved to a similar degree as subjects in other clinical studies. The number of gait cycles compares to hip or knee OA patients of a different region in Germany [2]. The baseline until 3 months FU points out that the recovery process from TKA takes longer after surgery. Furthermore, the gait cycles measured at six and twelve months after surgery indicate that the process of recovering or making use of the enhanced possibilities takes at least six months. Afterwards, European values reported for healthy subjects (~6600 gait cycles/day) [2, 3] are reached only by few subjects.

The percentage of locomotion indicates that TKA enables the subjects to load the affected knee more than before surgery. Resting periods are apparently less frequent than before surgery.

For pre-clinical testing of prostheses, load cycles should exceed 2 million cycles in order to reflect the loading of one year.

In conclusion, most patients benefit from TKA with respect to an improvement in quality of life as well as locomotion performance but do not achieve an activity level comparable to healthy subjects.

IS-SS04 Preventing harassment and abuse in sport

ASSESSING THE NEED FOR HARASSMENT PREVENTION IN NORWEGIAN SPORT.

FASTING, K., SAND, T.S., SISJORD, M.K., THORESEN, T., BROCH, T.

NORWEGIAN UNIVERSITY OF SPORT

Introduction: This paper presents some results from a study documenting the current state of equality within Norwegian sports and fitness activities, especially with regard to gender. The project was initiated in 2007 by The Norwegian Equality and Anti-Discrimination Ombud, and carried through by a research group at the Norwegian School of Sport Sciences. The results discussed in this paper answered this question: To what degree is work being done at the various organisational levels for the prevention of harassment-- particularly sexual harassment, racism, homophobia and negative attitudes towards gays and lesbians.

Methods: Representatives from 24 individual sport associations, 6 regional confederations and 43 clubs were interviewed. In addition, the researchers reviewed their annual reports, strategy documents and action plans.

Results: Most national sport associations did not have specific guidelines and/ or procedures for handling complaints concerning gender and/or sexual harassment. Furthermore, the topic did not appear to be included in the education of coaches and managers. None of the clubs had clear guidelines or procedures for handling sexual harassment.

The question of preventing and counteracting homophobia seems in many ways to be regarded as a non-issue in the sporting community. The general picture that emerged was that there is little openness about homosexuality at any level of the organisation, although there are some exceptions. The attitude of waiting until a case arises before "taking action" seems to be prevalent both with regard to sexual harassment and homophobia.

As regards activity to counteract racism, there is a great deal of variation between the individual sporting associations. When racism is addressed, it is done within the context of discussion concerning attitudes and values in general, often in connection with expectations related to fair play. It is rarely dealt with as a separate topic in the education of coaches and managers. Among the clubs that were interviewed almost none reported any experience of racism, and almost none had any guidelines or routines in place for dealing with the problem should it arise.

All the national sport associations have ethical guidelines, written or unwritten, although these focus primarily on alcohol and doping. There have been some campaigns designed to promote tolerance and diversity, however, particularly at the team and club level. Examples of such campaigns organised by national associations are Shut up and Play (The Norwegian Basketball Association) and Colourful Football (The Norwegian Football Association).

Discussion: The initiation of this project can be looked upon as a follow up of IOC's recommendations concern the need for more research in this area. The results are discussed in relation to the consequences it may have and have had for the prevention of harassment to occur in Norwegian sport.

PREVENTING EMOTIONAL ABUSE IN CANADIAN SPORT

KERR, G.

UNIVERSITY OF TORONTO

Recent research has indicated that emotional abuse is a common, yet unrecognized problem in competitive sport (Gervis & Dunn, 2004; Kirby, Greaves, & Hankivsky, 2000; Stirling, 2007). Emotional abuse has been defined as a pattern of deliberate non-contact behaviours by a person within a critical relationship role that has the potential to be harmful (Glaser, 2002; Stirling & Kerr, 2008). Given the serious, negative developmental consequences for young athletes who have experienced emotional abuse (Stirling & Kerr, 2007), significant efforts are needed to protect children and prevent abuse in this environment. Effective preventative measures call for a multifaceted approach that involves research, education, policy development, and advocacy. This presentation will address and critique various initiatives that have been incorporated in Canadian sport in attempts to prevent the abuse of athletes. Although some progress has been made, effective prevention will not be achieved until policies and educational programmes are informed by empirical research, are uniformly implemented, and include accountability measures. Recommendations for achieving these outcomes and preventing emotional abuse of athletes are suggested.

SYMPOSIUM CONTRIBUTION: MEASURING THE EFFECTIVENESS OF A HARASSMENT PREVENTION PROJECT IN ENGLISH FOOTBALL

BRACKENRIDGE, C.

BRUNEL UNIVERSITY

Introduction: The English Football Association undertook a major national consultation three years ago that revealed significant concerns about poor behaviour by players and spectators and about the associated loss of referees from the game. This paper reports the findings of a two year study of the remedial action taken by the FA in the form of a set of interventions called 'Respect'. These are aimed at enhance the quality of relationships between referees, players and spectators and also reducing referee attrition.

Methods: A multi-method research study was conducted during a ten week pilot of Respect from January to March 2008. This was followed by qualitative and quantitative data collection between October 2008 and March 2009. Methods included on-line surveys, stakeholder interviews and analysis of disciplinary performance indicators (such as red and yellow cards issued).

Results and Discussion: The Pilot yielded very positive results which were repeated in the main study. The research design and headline findings from the main study will be presented.

IS-SM07 How much physical activity for health benefits in women?

PHYSICAL ACTIVITY AND HEALTH IN WOMEN: UPDATING THE EVIDENCE

BROWN, W.

UNIVERSITY OF QUEENSLAND

Introduction: During the last ten years a wealth of new evidence on the health benefits of physical activity (PA) for women has come to light. This symposium will provide a critical review of research findings about (1) the benefits of PA for physical health, (2) the benefits of PA for mental health and (3) the health hazards for women who do too much exercise. Suggestions for using the research findings in prevention and health promotion practice will be made.

Methods and Results: The first paper will review the benefits of PA for women's physical health. This will include new information on the role of PA in the primary prevention of several chronic health problems including stroke, cancer, diabetes and osteoarthritis, as well as in the prevention of weight gain, which is a determinant of many chronic heath problems in mid- and older-age women. There is now strong evidence to demonstrate dose-response relationships between PA and health in women, with benefits from relatively low levels of PA for some health outcomes, and from higher levels of activity for others, including the prevention of weight gain. The evidence will be drawn from several large cohort studies, including the Australian Longitudinal Study of Women's Health, which has been tracking the health of young (18-23 years at baseline), mid-age (45-50) and older (70-75) women for the last 12 years.

Discussion: The evidence suggest that, for many health problems, unstructured activity like walking can be as effective as more vigorous activity in reducing risk, and that as little as one hour of brisk walking each week is associated with reduced risk of several major health problems. This is important for the many women around the world who juggle roles in caring, homemaking and the paid workforce, making it hard to find time for PA. There is also evidence to show that mid-age and older women who increase levels of PA in mid-age can improve their health outcomes – it is never too late to stat being more active.

BENEFITS OF PHYSICAL ACTIVITY FOR MENTAL HEALTH

DUNN, A.L.

KLEIN BUENDEL

Introduction: Mental disorders are major causes of morbidity and mortality in developed and developing countries. A World Health Organization (WHO) survey in 14 countries found prevalence estimates ranging from 4.3% in Shanghai to 26.4% in the U.S. For many of these disorders, especially the most common ones, two to three times more women are affected than men but reasons are unknown. There is a large unmet need for treatment of mental disorders and it is possible that physical activity could play a role in the prevention and treatment of several mental health diseases.

Methods and Results: This presentation will examine the benefits of physical activity for selected mental disorders. Physical activity and structured exercise have both been examined in epidemiological studies and randomized controlled trials (RCTs) to examine effects on depressive and anxiety symptoms. Although gender differences have been examined, they are inconclusive. For example, 28 prospective cohort studies from 11 nations found that individuals classified as being physically active have a 25 to 40% lower risk of developing depression disorders or depressive symptoms, compared to inactive peers. This appears to be equally true for men and women. Results are more equivocal for anxiety disorders because there are fewer studies. Collectively, RCTs demonstrate a 1.1 SD reduction in depression symptoms when exercise treatments are compared with no treatment controls, but many of the studies have scientific weaknesses that weaken enthusiasm for use of exercise by clinical counselors. The studies done exclusively in women have been confounded by other treatments, a lack of clarity of phase of treatment, and small sample sizes. One dose-response study comparing different amounts and frequencies of exercise controlled for many of the scientific weaknesses of previous studies. This study reported remission and response rates that were comparable to rates achieved in studies of standard treatments, such as antidepressant medications and cognitive behavioral therapy; gender differences were not significantly different. There are fewer studies in anxiety but the results are similar to those in studies of depression. Most studies of exercise would be termed acute phase studies (8 to 12 weeks in duration). There are few continuation or maintenance phase studies in individuals diagnosed with depression or anxiety.

Discussion: Recommendations will be made concerning how to overcome scientific weaknesses that use exercise as a monotherapy, and as augmentation or adjunct treatment with standard treatments for depression, anxiety, and schizophrenia. In addition, exercise can improve many chronic diseases such as diabetes and cardiovascular disease that are often co-morbid with diagnosed depression and severe mental illness. Finally recommendations will be made for how physical activity or exercise might be integrated into clinical treatment using tailored web-based approaches.

EXERCISE- IS IT POSSIBLE TO HAVE TOO MUCH OF A GOOD THING?

SUNDGOT-BORGEN, J.

NORWAY

Introduction: The health benefits of physical activity and exercise for women are well known. The aim of this presentation is to consider whether too much exercise may be detrimental to women's health.

Methods: This question will be examined by considering the prevalence of overuse injuries, overtraining, and components of the female athlete triad, across the lifespan. Possible prevention strategies will also be considered.

Results: Overuse is one of the most common etiologic factors leading to injuries in the pediatric and adolescent athlete. The combination of heavy training, inadequate recovery and limited social support networks for young athletes can result in overtraining in young and aspiring elite athletes. Higher incidence rates for overtraining in adolescents have been reported in individual sports (48%) than in team sports (30%) and less physically demanding sports (18%). Overtraining can lead to burnout, which may have a detrimental effect on children's lifelong participation in sport.

Negative energy balance and energy drain occur in women of all ages when energy intake is insufficient to cover the energy costs of daily living, exercise training and competition, building and repair of muscle tissue, menstrual function, and any additional energy costs related to life stressors, such as illness or psychological stress. Training associated with inadequate caloric intake, exposes the young female athlete to several health risks and hazards, including menstrual irregularities. As a consequence, bone demineralization may develop, with increased risk of skeletal fragility, fractures, and vertebral instability and curvature. The prevalence of these different triad components varies from 5-75%, depending on the definition used and population investigated.

No studies have examined the issue of too much exercise for older women. However, vigorous activity after age 70 has higher risk of injury and lower adherence.

Discussion: To prevent overuse injuries and overtraining in young women, we need more research to allow us to recognize the key signs and symptoms, and to identify the central determining factors. Furthermore, effort should be made to optimize nutrition for female athletes, and if not successful, to reduce the training load in order to prevent menstrual abnormalities and deleterious bone effects, particularly during the critical period of rapid bone growth.

OP-ST08 Sports 8

UPHILL RUNNING ECONOMY AND MOUNTAIN RUNNING PERFORMANCE.

ROUSOPOULOS, E., ZACHAROGIANNIS, E., PARADISIS, G., SMIRNIOTI, A., SOULAS, D.

ATHENS UNIVERSITY

Introduction: The majority of previous research efforts aimed at determining the physiological characteristics that contribute to level distance running success with little attention on uphill mountain racing.

Purpose: The purpose of this study was to examine the power of uphill running economy parameters in predicting mountain running performance.

Methods: Nineteen trained endurance runners (mean±SD) (age, 38.8±6.1 years, VO2max, 50.16±6.9, ml.kgr-1.min-1) were tested using open circuit spirometry 7-14 days before participating a mountain race (12km 5% mean inclination). Uphill running economy (URE, ml.kgr-1.min-1) was determined during 6min run at 8 km.h-1 speed and 10% inclination. The speed decrements due to inclination (SDI, km.h-1.1%-1 inclination) was also estimated (SDI=[(level speed which corresponds at 10%, 8km.h-1 VO2)-8]/10).

Results: The subjects averaged 71.1±10minutes on the 12km mountain race, 0.62±0.1 km.h-1.1%-1 SDI, 46.2±3.2 ml.kgr-1.min-1 URE and 92.9±7.1 %VO2max at 10%, 8km.h-1. The relationship between URE and performance was r=-0.41 ($p>0.05$) and the relationship between SDI and %VO2max at 10%, 8km.h-1 with performance was r=0.644 and r=-0.647 ($p<0.01$) respectively. Applying stepwise multiple linear regression the multiple R increased significantly with the addition of %VO2max at 10%, 8km.h-1 together with SDI, the combination of those two parameters account for the greatest amount of total variance (87.3%).

Conclusions: These data suggest that among trained and experience runners the speed decrements due to inclination together with the percentage of VO2max which is been used by the runner on a standard speed and inclination, submaximal test, can account for a large portion of the variance in performance during continuous uphill mountain race.

MUSCLE METABOLISM AND PERFORMANCE IMPROVEMENT AFTER TWO TRAINING PROGRAMS OF SPRINT RUNNING DIFFERING IN REST INTERVAL DURATION

BOGDANIS, G.C., SARASLANIDIS, P., PETRIDOU, A., GALANIS, N., TSALIS, G., KELLIS, S., KAPETANOS, A.G., MOUGIOS, V.

UNIVERSITY OF ATHENS AND ARISTOTLE UNIVERSITY OF THESSALONIKI

Introduction: Recent studies have shown that high-intensity training with repeated bouts of sprint exercise has a significant effect on the metabolic response to exercise and results in enhanced fatigue resistance (Mohr et al., 2007; Iaia et al., 2009). However, the effect of the length of the recovery interval on metabolic and performance parameters has not been investigated. The present study examined the effects of two sprint training programs differing in rest interval duration on muscle metabolism and performance.

Methods: Fourteen young, moderately trained, males were randomly assigned to 2 groups (n = 7 in each group) and trained three times per week for eight weeks. Each training session included 2 sets (during the first 4 weeks) or 3 sets (during the remaining 4 weeks) of two 80 m sprints for both groups. Sets were separated by 20 min of passive recovery, while the rest interval between the two sprints was either 10 s (group A) or 1 min (group B). Pre- and post-training field tests included maximal sprints of 100, 200, and 300 m to assess changes in performance. Muscle biopsies were obtained from the vastus lateralis muscle after warm-up and after the first set of two 80 m sprints during the first and last training session. Muscle biopsies were snap frozen and later freeze-dried, homogenized and analysed by enzymic spectrophotometric assays for ATP, ADP, creatine phosphate (CP), creatine, glucose, glucose 1-phosphate, glucose 6-phosphate (G6P), fructose 6-phosphate (F6P), glycerol 3-phosphate, pyruvate and lactate.

Results: Both training programs improved sprint performance ($p < 0.05$), but the improvement was greater in group A compared to group B at the final 100 m of the 200 m run (0.98 ± 0.15 vs. 0.61 ± 0.09 s, $p = 0.049$) and at the final 100 m of the 300 m run (1.11 ± 0.16 vs. 0.36 ± 0.15 s, $p = 0.005$). Changes in muscle metabolites after the two 80 m sprints were not affected by training, except for a mitigation in the drop of ATP ($p = 0.002$). The drop in CP, the increase in G6P and F6P, as well as the calculated anaerobic carbohydrate breakdown were greater in group A to group B ($p = 0.096$, 0.027, 0.017 and 0.084, respectively).

Discussion: We conclude that, in moderately trained athletes, training with repeated sprints is more effective when performed with a very short (10 s) compared to a longer (1 min) rest interval. This may be due to the greater activation of glycolysis caused by the limited resynthesis of CP during the very short rest interval. It is suggested that this type of short interval training may be used by coaches for improving speed endurance in single 200 m or 300 m sprints.

MUSCLE ACTIVATION LEVEL IN GENERIC AND SPECIFIC STRENGTH TRAINING EXERCISES FOR ORIENTEERS

JOHANSEN, E., GJERSET, A., NILSSON, J.

THE NORWEGIAN SCHOOL OF SPORT SCIENCES, OSLO, NORWAY AND THE SWEDISH SCHOOL OF SPORT AND HEALTH SCIENCES, STOCKHOLM SWEDEN

Introduction: To improve muscular strength a relative tension in the musculature of approximately 60-70 percent of one repetition maximum (1RM) is needed (McDonagh & Davies 1984). By means of electromyography (EMG) it is possible to determine the EMG activation level at different levels of 1RM in generic exercises such as squats and ankle extensions. It is also possible to determine the highest EMG activation level in different maximal voluntary dynamic actions (MVDA) such as vertical jump, squat and ankle extension. The relationship between activation level and relative muscle tension (% 1RM) allow specific strength training exercises among orienteers to be evaluated. The purpose of the present study was to compare the EMG activation level in specific strength training exercises commonly used by orienteers with the activation level in generic exercises in order to evaluate possible strength training potential in the specific exercises.

Methods: In total six male elite orienteers, mean (range) age, height and weight; 25 (19-32) years, 1.80 (1.74-1.88) m and 71(67-75) kg, participated in the study. EMG was recorded with surface electrodes on four muscles: m. gluteus maximus (GM), m. rectus femoris (RF), m. vastus lateralis (VL) and m. soleus (SOL) on the right leg. The participants performed the following generic strength exercises: 5RM squats and 5RM ankle extensions on the right leg. In addition MVDA in form of 5 maximal vertical jumps were performed on the right leg and with both legs. The participants performed the following specific exercises: leaping i.e. running with very long strides and maximal effort on a horizontal gravel stone road and uphill in forest terrain. The maximal level of EMG activity during the generic exercises and MVDA was set to 100%.

Results: The results show that both generic (squats and ankle extensions) and specific strength training exercises (leaping on the horizontal and uphill) reach higher mean levels of EMG activation than was suggested by McDonagh & Davies (1984) for adaptive responses in mammalian skeletal muscles to exercise. The results also show that the activation levels during the specific strength exercises are compatible with the 5RM generic exercises commonly used to increase muscular strength.

Discussion: From the results in the present investigation it can be concluded that the EMG activation level in specific strength exercises such as leaping on the horizontal and uphill are compatible with generic exercises and show high relative EMG activation levels, which

indicate a possible strength training potential. Information obtained in this study can be used to enable a development of specificity in strength training and also a larger degree of integration between trained capacities among orienteers.

THE HIT & TURN TENNIS TEST - AN ACOUSTICALLY CONTROLLED ENDURANCE TEST FOR TENNIS PLAYERS

FERRAUTI, A., KINNER, V.

RUHR UNIVERSITY OF BOCHUM

Worldwide no unique tennis specific endurance test exists. The Test profile is mostly characterised by multistage linear running on a treadmill (TT) which seems to be insignificantly valid in respect to the tennis specific profile of demands. Tests using a tennis ball machine (BMT) had been shown to be more valid, but they are difficult to standardise. Based on these problems the "Multistage 20 m Shuttle Run for Aerobic Fitness" (MFT) was internationally established for game players and could be useful in tennis as well. On the other hand, tennis players have to run shorter distances by using a specific foot work. Thus we found, that an adapted MFT for tennis players should be developed and transferred on the dimensions of a tennis court. Our study consisted of three steps, including test construction (step 1), test validation (step 2), and the development of norm values (step 3).

Step 1: We developed the Hit & Turn Tennis Test (HTT) as an acoustically controlled and progressive fitness test for tennis players. The test can be easily carried out with a racket on a tennis court. The object of the test is to follow as long as possible the audible signals and to hold up the required footwork. The player has to run along the base line and to simulate a forehand or backhand shot in the respective corners just in time with the signals. The test consists of 20 levels (each 45 seconds) including an increasing number of forehand and backhand strokes. All levels are interrupted by a rest period of ten seconds. After level 4, 8, 12 and 16 a longer break of 20 seconds that can be used to take blood lactate samples.

Step 2: On five experimental days twelve regionally ranked male tennis players completed five endurance tests in a randomised counter-balanced order: 1. HTT carpet I, 2. HTT carpet II, 3. HTT clay, 4. TT, 5. BMT. We determined VO2max (Cortex Metamax II, Leipzig, Germany) and submaximum performance at 4 mmol/l blood lactate concentration (P4). VO2max and P4 correlated significantly between HTT carpet I and II (0.942** and 0.848**) and between HTT carpet and HTT clay (0.713** and 0.880**) pointing to a sufficient reliability. VO2max and P4 showed a closer correlation between HTT and BMT (0.961** and 0.756**) than between TT and BMT (0.619* and 0.617*) which underlines the HTT validity.

Step 3: We determined maximum test level (Lmax) and VO2max during the HTT in 70 nationally ranked female (under 14, under 16) and male junior tennis players (under 14, under 16, under 18) in different age groups. Lmax increased slightly in female (11.3 under 14, 11.6 under 16) and clearly in male players (13.2 under 14, 14.2 under 16, 15.3 under 18) with increasing age. VO2max showed no age related values in both, female (49.1 under 14, 48.6 under 16) and male players (58.0 under 14, 57.5 under 16, 59.5 under 18).

We conclude that the HTT is a valid and reliable procedure for endurance testing in tennis. Lmax seems to be a better performance predictor in young athletes than VO2max.

INFLUENCE OF PLANTARFLEXOR STRETCH TRAINING ON FASCICLE LENGTH AND STRAIN, H-REFLEX AMPLITUDE AND MUSCLE FORCE PRODUCTION

BLAZEVICH, A.J., MILLER, S., WAUGH, C., FATH, F., KAY, T., THORLUND, J.B., AAGAARD, P.

EDITH COWAN UNIVERSITY

Chronic stretching training is commonly performed by athletic and patient populations to improve joint range of motion (ROM), reduce injury risk and, possibly, enhance movement performance. In this study, we examined changes in resting gastrocnemius medialis (GM) fascicle length and fascicle strain during stretch (ultrasound imaging) and soleus H-reflex amplitude (stimulation of tibial nerve) after 3 weeks of twice-daily static stretches in 12 healthy men; 10 men acted as non-training controls. These changes were then related to changes in peak active joint moment, rate of torque development (RFD) and the moment-angle relation (MArel) of the plantarflexors.

In each stretch training session, four 30-s static stretches were performed to maximum stretch tolerance with the knee extended. Self-reported training adherence was 92%. All dependent variables except H-reflex were measured pre- and post-training at 5 joint angles: 20 deg (angle 1) and 10 deg (angle 2) of plantarflexion, and 3 further equidistant angles (angles 3-5) where angle 5 was defined as the angle where 80% of the peak passive moment was developed (~3-4 deg from maximum ROM). H-reflex was assessed at joint angles 2, 3 and 4.

There were no changes in any measure in the control group. Stretch training elicited a 20% (8.6 deg; $p<0.001$) increase in ankle ROM. This could not be explained by a change in resting GM fascicle length. However fascicle strain measured from angle 1-5 increased significantly (28.8% increase, $p<0.05$). This increased strain was associated with a significant post-training depression of the resting (2% MVC) H/M-wave ratio at joint angles 2 and 3, but not 4. Increases in fascicle compliance were related to ($p<0.05$) decreases in H/M ratio at angles 2 ($r=0.71$) and 3 ($r=0.54$), but not 4 ($r=0.18$). The decrease at angles 2 and 3 may partly explain the increased fascicle strain as a reduced reflex sensitivity, but the lack of change at angle 4 does not. These data are suggestive that the increased strain with stretch training resulted from decreased fascicle strain sensitivity, in which the observed decrease in spinal reflex input might have been influential. Despite these changes, there were no changes in RFD measured from contraction onset to 50, 100, 200 and 400 ms or from 200-400 ms at any joint angle and no shift occurred in MArel. These data are symptomatic of a lack of change in SEC compliance. There was also no change in peak active moment at any joint angle.

Chronic stretch of the plantarflexors is associated with an increased ROM due largely to an increased fascicle strain, which may be partly linked to increased parallel elastic, but not SEC, compliance. It may also be partly linked to a decreased spinal excitability. These changes did not affect peak active moment, RFD or alter the moment-angle relation. It is not yet clear whether dynamic force is affected, or whether performance changes might occur with longer periods of stretch training.

Invited symposia

IS-NU03 Nutritional interventions to increase fat oxidation

WHY IS A HIGH CAPACITY TO OXIDISE FAT IMPORTANT. CHAIR'S INTRODUCTION.

WAGENMAKERS, A.

THE UNIVERSITY OF BIRMINGHAM

Obesity is now regarded to be an epidemic in Westernized societies and is rapidly spreading at a global level. According to the WHO obesity is the consequence of a gradual reduction in physical activity in the last 20-30 years in combination with a calorie and/or high fat food intake that exceeds energy expenditure. With obesity comes a variety of adverse health outcomes. Endothelial and (micro)vascular dysfunction are now regarded as one of the earliest common metabolic defects, which subsequently lead to various forms of pathology to include insulin resistance, hypertension, metabolic syndrome, type 2 diabetes and cardiovascular disease.

Although initially viewed as an inert store for excess fats, it has more recently become clear that the adipose tissue stores play a crucial role in the buffering of plasma lipid levels, both in the period after meal ingestion and in the overnight fasted state. In addition to that excessive adipose tissue stores (especially visceral stores) become chronically inflamed (with macrophages contributing more than 20% of the cell content of adipose tissue) and are a constant source of inflammatory cytokine production. Chronic exposure to high systemic levels of lipid and inflammatory cytokines have both been implicated in the mechanisms that lead to endothelial dysfunction and insulin resistance of both the endothelial lining of the muscle microvasculature and the skeletal muscle fibres and also play a role in the mechanisms that lead to cardiovascular disease.

In this symposium the first two speakers will present an overview of exercise and nutrition interventions and nutritional supplements that might be useful in the prevention or treatment of obesity. The last speaker will present an overview of state-of-the-art immunofluorescent staining techniques methods that can be used 1) to investigate the molecular defects by which obesity leads to endothelial dysfunction, insulin resistance and related pathologies and 2) to investigate the therapeutic effects of exercise, modified nutrition and nutritional supplements.

NUTRITION AND EXERCISE AS MEANS TO INCREASE FAT OXIDATION AND CONTROL OBESITY

VENABLES, M.

THE UNIVERSITY OF BIRMINGHAM

It is well known that exercise is a potent stimulator by which metabolism can be modulated and that both exercise duration and intensity are two important factors leading to the modulation of fat oxidation.

This symposia presentation will discuss exercise related factors that can affect fat oxidation, more specifically in this presentation exercise related factors that affect maximal rates of fat oxidation (MFO) and FATmax, that is the exercise intensity which elicits maximal rates of fat oxidation. It will introduce the concept of FATmax and present data indicating that mode of exercise and training status can affect MFO and also how gender, training status and weekly physical activity can affect MFO and FATmax. Furthermore, the use of FATmax as a training intensity in obese individuals will be discussed and how this appears to be a more effective exercise protocol than an interval training program when investigating health related parameters such as fat oxidation and insulin sensitivity.

A potential mechanism thought to link the increase in fat oxidation following a 4 wk period of endurance exercise training with improvements in insulin sensitivity will be discussed. Insulin receptor substrate-1 (IRS-1) is a key protein involved in the insulin signaling cascade as it has been shown that without it IRS-1 associated PI3-kinase remains quiescent. The action of IRS-1 can be modulated in a post-translational manner not only by tyrosine phosphorylation but also by serine-threonine phosphorylation, which, depending on the specific site of phosphorylation, can either facilitate or inhibit insulin signal transduction. Moreover, it has been shown that phosphorylation on a specific serine site, serine 307, of IRS-1 can block the phospho tyrosine binding domain functions of the IRS-1 protein thereby inhibiting the downstream signaling events such as PI3-kinase activation and ultimately glucose uptake. Data will be presented that provides evidence for this mechanism.

NUTRITIONAL SUPPLEMENTS TO INCREASE FAT OXIDATION

JEUKENDRUP, A.

UNIVERSITY OF BIRMINGHAM

There are many nutrition supplements on the market that claim to increase fat oxidation. These supplements include caffeine, carnitine, hydroxycitric acid (HCA), chromium, conjugated linoleic acid (CLA), guarana, citrus aurantium, asian ginseng, cayenne pepper, coleus forskholii, glucomannan, green tea, psyllium and pyruvate. With few exceptions, there is limited to no evidence that these supplements marketed as fat burners actually increase fat oxidation during exercise. One of the few exceptions may be green tea extracts. We recently found that green tea extracts increased fat oxidation during exercise by about 20%. The mechanisms are not well understood but it is likely that the active ingredient in green tea epigallocatechin gallate (EGCG), one of most powerful polyphenol with anti-oxidant properties, increased the activity of the enzyme responsible for the breakdown of catecholamines (adrenaline and noradrenaline). This in turn may result in higher concentrations of catecholamines and stimulation of lipolysis making more fatty acids available for oxidation. Caffeine is another substance with the potential to increase fat oxidation. This talk will discuss the evidence (or lack thereof) for a stimulation of fat metabolism of various supplements.

IMMUNOFLUORESCENCE MICROSCOPY TO INVESTIGATE THE LINK BETWEEN FAT METABOLISM AND INSULIN ACTION

SHAW, C.S.

UNIVERSITY OF BIRMINGHAM

Immunofluorescence microscopy has provided unique insights into skeletal muscle fat metabolism and its role in the development of insulin resistance in skeletal muscle. Once transported across the sarcolemma, fatty acids can either cross the mitochondrial membrane and undergo β-oxidation or enter intramuscular triglyceride (IMTG) synthesis. The IMTG content of type 1 muscle fibres is approximately two-fold greater than type 2 fibres which appears to be related to a higher content of the IMTG synthesizing enzymes, namely mitochondrial glycerol-3-phosphate acyltransferase (GPAT) and diacylglycerol acyltransferase (DGAT). IMTGs are stored within lipid droplets (LD) which are preferentially located next to the mitochondrial network in trained individuals which enables the efficient oxidation of fatty acids liberated during periods of elevated metabolic demand (endurance and resistance exercise). Recent advances in LD research has shown that LDs contain a number of structural, enzymatic and membrane trafficking proteins and the protein composition of LDs depends on the cell type and its lipolytic state.

The expanded adipose mass in obese individuals results in increased delivery of circulating fatty acids to skeletal muscle. When fatty acid delivery exceeds fatty acid utilisation (oxidation or storage) the resultant accumulation of fatty acid metabolites, such as long chain acyl-CoA and diacylgycerol, appears to inhibit insulin-stimulated GLUT4 translocation. The accumulation of IMTG in the skeletal muscle of obese individuals does not appear to inhibit insulin action directly however IMTG metabolism plays an important role in determining the concentration of intracellular fatty acid metabolites. Low rates of fatty acid oxidation in obese individuals, at least partially due to low mitochondrial content, are likely to contribute to the accumulation of fatty acid metabolites. In addition, inadequate or incomplete IMTG synthesis could also potentially explain why fatty acid metabolites accumulate in the skeletal muscle of obese individuals.

Over recent years the elevations in plasma fatty acids and inflammatory cytokines associated with obesity have been implicated in the development of insulin resistance in the microvascular endothelium. Insulin-mediated synthesis of nitric oxide stimulates dilation of arterioles and a redistribution of blood flow to skeletal muscle fibres prior to insulin stimulation of the muscle fibres. There is evidence that microvascular dysfunction, typified by reduced NO-mediated vasodilation, occurs before impairments in insulin-mediated GLUT4 translocation. Immunohistochemistry allows visualisation of microvascular endothelial cells and could potentially provide further insight into the mechanisms behind obesity-related insulin resistance.

DOES HAEMOGLOBIN MASS INCREASE WITH SEVERAL YEARS OF ENDURANCE TRAINING? - A CROSS-SECTIONAL STUDY WITH U18, U23 AND ELITE NATIONAL TEAM CYCLISTS

WEHRLIN, J.P., CLÉNIN, G.E.

SECTION FOR ELITE SPORT

Introduction: It is unclear if haemoglobin mass (Hbmass) and red cell volume (RCV) increase with several years (ys) of training in endurance athletes (Sawka et al., 2000, Heinicke et al., 2001, Prommer et al., 2008). Especially, little is known about changes between junior and adult age. The aim of this study was to determine with a cross-sectional approach, whether national team endurance athletes in the age-related teams 'under 18' (U18), 'under 23' (U23) and 'elite' (>23 ys) are characterized by different Hbmass, RCV, plasma volume (PV) and blood volume (BV).

Methods: Blood volume parameters (CO-rebreathing method) and other blood, iron, performance and training parameters were measured in each a group of U18 (age = 16.9 ± 0.6ys; n = 15), U23 (age = 19.2 ± 1.2ys; n = 13) and elite (age = 27 ± 4.2ys; n = 14) male Swiss national team cyclists (road, cross-country and track).

Results: There were no differences in either body weight related Hbmass (U18 = 14.4 ± 1.2g/kg; U23 = 14.0 ± 1.3g/kg; elite = 14.6 ± 1.0g/kg), RCV (40.4 ± 3.4; 39.2 ± 3.9; 40.8 ± 3.2 ml/kg), PV (63.6 ± 7.1; 64.6 ± 7.1; 64.6 ± 8.1 ml/kg) and BV (104.1 ± 8.6; 103.8 ± 9.8; 105.4 ± 10.2 ml/kg) or absolute values. Absolute power at 4mmol/l blood lactate in the lactate threshold test was lower in the U18 than in the elite group (p = 0.043) whereas differences in maximal absolute power output did not reach statistical significance (p = 0.102). Training hours per week were lower (p = 0.032) in U18 than in the elite athletes.

Discussion: Our results indicate that several years of endurance training between the U18 and the elite age in national team cyclists do not increase Hbmass, RCV, PV and BV, but power at 4mmol/l blood lactate concentration. Interestingly, in another recent cross-sectional study with XC-skiers and triathletes (Steiner, Boutellier & Wehrlin, 2009), we found Hbmass to be lower at age 16 than at age 21 while it was similar at age 21 and 28. Perhaps, Hbmass can increase with endurance training in athletes younger than 17ys? However, when interpreting our results, one has to take into account, that although all our subjects where national team athletes, we used a cross-sectional design. This implies the risk of a possible selection bias. Studies with a longitudinal design are needed.

Conclusion: Hbmass can be similar in male U18, U23 and elite national team cyclists, what suggests, that Hbmass does not increase with several years of endurance training in athletes from the U18, to the U23 and the elite national team.

DOES HAEMOGLOBIN MASS INCREASE WITH SEVERAL YEARS OF ENDURANCE TRAINING? CONTROLLED CROSS-SECTIONAL STUDY WITH 16, 21 AND 28 YEARS OLD ELITE XC-SKIERS AND TRIATHLETES.

STEINER, T., BOUTELLIER, U., WEHRLIN, J.P.

1. SECTION FOR ELITE SPORTS, SWISS FEDERAL INSTITUTE OF SPORTS, MAGGLINGEN., 2. INSTITUTE OF HUMAN MOVEMENT SCIENCES AND SPORT, ETH AND INSTITUTE OF PHYSIOLOGY, UNIVERSITY, ZURICH

Introduction: Recent research results (Prommer et al. 2008) put into question, whether haemoglobin mass (HbM) - an important limiting factor of VO2max - unlike as guessed so far (Sawka et al. 2000) can be increased in endurance athletes with endurance training. Little is known about the effects of long lasting endurance training on HbM in adolescents. The aim of this controlled cross-sectional study was to evaluate if there are differences in HbM between endurance athletes at the age of 16 years, 20-23 years and older than 23 years.

Methods: In three endurance athlete groups at different age (AG16: 15.9±0.7 years, n=15, national top 15 ranking in XC-skiing and triathlon in 2008, no national team at this age; AG21: 21.3±0.9 years, n=14 and AG28: 27.5±3.0 years, n=16 from the national teams in XC-skiing and triathlon) as well as in three age matched control groups (< 2h endurance training per week; KG16: 15.9±0.3 years, n=16; KG21: 21.3±1.2 years, n=15; KG28: 28.1±4.0 years, n=16) we measured, among others, HbM (CO-rebreathing) and VO2max.

Results: In AG16 HbM (12.3 ±0.8 g/kg) as well as VO2max (66.1 ±3.6 ml/min/kg) was lower ($p<0.01$) than in AG21 (14.2 ±1.1 g/kg / 72.9 ±3.6 ml/min/kg) and AG28 (14.6 ±1.1 g/kg / 73.4±6.0 ml/min/kg), while there were no differences between AG21 and AG28 and among the control groups. Between AG16 and KG16 (12.0 ±1.0 g/kg / 58.9±5.0 ml/min/kg) only VO2max was different ($p<0.001$) but not HbM ($p=0.39$). In the AG21 and AG28 groups HbM and VO2max were higher ($p<0.001$) than in the matchable control groups (KG21: 12.5 ±1.0 g/kg / 57.5 ±6.6 ml/min/kg. KG28: 12.1 ±1.0 g/kg / 54.7 ±6.2 ml/min/kg).

Discussion: Our results indicate that HbM increases between the age of 16 and 21 in elite endurance athletes, but not between 21 and 28 years. Endurance training of adolescents seems to influence VO2max much more than HbM. That HbM doesn't change in older athletes we confirmed in another study (Wehrlin & Clénin, 2009), where we even didn't find a difference in HbM between U18, U23 and elite cyclists. Wherefore, HbM might have its biggest potential for development between the age of 16 and 18 in endurance athletes. When interpreting our data, we have to take into account that cross-sectional designs implicate always possible selection bias, although the selection guidelines for the athletes at the age of 16 have been clearly defined (top 15 ranking). However, data in adolescents from longitudinal studies are needed to verify our findings.

Conclusion: Our data suggest that with several years of endurance training HbM increases between the age of 16 to 21 years but not between the age of 21 to 28 years in endurance athletes.

A COMPARISON OF VΔ50 VS V 2MAX TRAINING INTENSITIES FOR OPTIMAL ENDURANCE RUNNING PERFORMANCE

LOUCAIDES, G., NIKOLAOU, K., MICHAELIDES, M., COCHRANE, T., PANAGIOTOU, G., THEOHAROUS, A.

1.CYPRUS SPORT ORGANIZATION

INTRODUCTION – AIM OF THE STUDY: Coaches, athletes and scientists debate as to which is the most efficient interval training intensity for optimizing the performance in endurance events. The purpose of this study was to compare the individualized training intensities termed as vΔ50 (the velocity at 50% of the difference between the velocity at lactate threshold and the velocity associated with maximal oxygen uptake) and v O2max (the minimum velocity that elicits maximal oxygen uptake) and to provide insight as to which of the two intensities leads to greater benefits in running performance in 1500m and 5000m TT (Time Trials), as well as to physiological parameters that are associated with success in endurance running events.

METHODS: 32 out of 45 male distance runners that gave a written consent for participation in the study completed the 9-month training intervention. The training included a 4-month aerobic base preparation period which was common for all participants. Then, after the runners were randomly assigned into one of two groups, differing only in the intensity of the interval training part of the training (vΔ50 for group Α and v O2max for group Β), completed another 3 months of training. Before and after the interval training intervention period, a 1-month testing period was imbedded where athletes performed 1500m and 5000 TT's on the track, as well as lab tests for the determination of vΔ50, v O2max, O2max, vLT4 (speed associated with a lactate concentration of 4 mmol/L) and ECR (Energy Cost of Running). The MANOVA statistical test was used for data analysis and the level of statistical significance was set at $p < 0.05$.

RESULTS: Group Α improved significantly in the 1500m TT (Test 1 = 309 ± 24s, Test 2 = 299 ± 21s), in the 5000m TT (Test 1 = 1163 ± 77s, Test 2 = 1139 ± 69s), as well as in the vLT4 and vΔ50 ($p < 0.05$). Group Β improved significantly in the 1500m TT (Test 1 = 312 ± 40s, Test 2 = 301 ± 36s) in the 5000m (Test 1 = 1191 ± 134s, Test 2 = 1162 ± 120s) as well as in the ECR, v O2max and vΔ50 ($p < 0.05$). No significant differences were observed were observed in the O2max in both Groups.

COCLUSIONS: Both vΔ50 and v O2max were equally effective in improving 1500m and 5000m TT performance, but each intensity seems to affect to a different degree the parameters that are associated with success in endurance running performance. Finally, it seems that v O2max affects marginally more positively most parameters related to endurance running performance (except for vLT4 and vΔ50).

EFFECTS OF FREQUENCY OF EXERCISE FOR IMPROVING AEROBIC CAPACITY: TRAINING AND DE-TRAINING

HATLE, H., STØBAKK, P.K., BRØNSTAD, E., STOLEN, T., TJØNNA, A.E., MØLMEN, H.E., INGUL, C.B., WISLØFF, U., ROGNMO, Ø.

NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY

BACKGROUND: Aerobic exercise performed as interval training is an effective way of improving maximal aerobic capacity (VO2max). We have previously shown that high-intensity exercise performed 2-3 times per week is superior to moderate exercise for improving VO2max when total exercise volume is equalized. This is valid both within highly trained individuals as well as in different patient groups. The aim of the present study was to investigate the rate of adaptation of VO2max in young, healthy individuals performing exercise at

either high frequency or moderate training frequency. We hypothesised that improvements of VO2max could be achieved to the same extent when exercising at high frequency compared to moderate frequency.

METHODS: Nineteen healthy students (23.5±2.0 yrs) carried out a total of 24 exercise sessions at either 3 times per week for 8 weeks, or 8 times per week for 3 weeks. All training was carried out as uphill treadmill running using heart rate monitors. VO2max was measured initially and after every 8th exercise session. During the de-training period, VO2max was measured 4, 14 and 24 day post exercise, and thereafter every second week over a total period of two months.

RESULTS: The moderate frequency group increased VO2max by 6.0±2.7 ml/kg/min ($p<0.001$) and the high frequency group by 4.1±3.1 ml/kg/min ($p=0.002$). Using the linear model with correction for baseline value, we found however no differences between the groups regarding the magnitude of elevating VO2max ($p=0.36$). Interestingly, while the moderate frequency group reached the highest measured VO2max-value 4 days post training, the high frequency group reached the peak value 14 days post training. This elevation was sustained 24 days post training in the high frequency group ($p=0.413$), while the moderate frequency group showed declined VO2max compared to peak level at this time point ($p<0.001$).

CONCLUSIONS: Improvements of VO2max after high-intensity aerobic interval training could be accomplished in reduced time with high frequency training compared to normal frequency training. VO2max may boost after ending a high-intensive, high frequency training programme, and this over-compensation may be sustained for over three weeks without training.

INSPIRATORY MUSCLE TRAINING AND LOADING ACCELERATES BLOOD LACTATE CLEARANCE.

SHARPE, G., BROWN, P., JOHNSON, M.

NOTTINGHAM TRENT UNIVERSITY

Introduction: Chiappa et al (2008) showed that pressure threshold inspiratory muscle loading during recovery from maximal exercise markedly reduced blood lactate concentration ([lac-]B). Using an identical protocol we examined whether 6 wks of inspiratory muscle training (IMT) would further accelerate blood lactate clearance

Methods: 18 subjects initially completed two maximal incremental cycling tests (20 W.min-1) followed by 20 min of static recovery with a constant inspiratory threshold load (15 cmH2O) or with purely passive recovery. The two protocols were separated by at least 48 hours. Throughout recovery acid-base balance was determined using the physicochemical approach by measuring the strong ion difference ([SID]) = [Na+] + [K+] - [Cl-] + [lac-]; the total concentration of weak acids [Atot-] and the partial pressure of carbon dioxide (PCO2). Individual [lac-]B decay curves were fitted to a bi-exponential time function using an iterative non-linear regression technique (Freund and Zouloumian 1981). Subjects were divided equally into either an IMT group that performed pressure threshold IMT at 50% maximal inspiratory mouth pressure (MIP) or a control group that experienced no intervention. After 6 weeks both protocols were repeated.

Results: Values are shown as mean (SD). MIP increased 34 (6) % ($p<0.001$) in the IMT group and remained unchanged in the control group. Peak [lac-]B after maximal exercise was reduced by 1.24 (1.32) mmol.L-1 ($P<0.05$) after IMT. Prior to the intervention addition of the inspiratory threshold load did not affect [lac-]B decay relative to passive recovery. However, following IMT, both the fast and slow velocity constants of [lac-]B decay were increased ($P<0.05$). At corresponding time points during the 20 min recovery period a mean reduction in [lac-]B of 0.66 (1.28) mmol.L-1 (trial × time interaction effect, $P<0.01$) was observed with the inspiratory threshold load relative to passive recovery. Relative to pre-IMT, inspiratory threshold loading reduced plasma [H+] which was accounted for by an IMT-mediated increase in [SID] due almost exclusively to a reduction in [lac-]B.

Conclusions: Whilst our findings contradict those of Chiappa et al (2008) we show that combining IMT with threshold inspiratory loading after maximal exercise accelerates [lac-]B decay relative to passive recovery. Our data support the notion that after training, the inspiratory muscles are capable of net lactate clearance which reduces plasma [H+]. These IMT-induced adaptations may improve tolerance of repeated spints and may also explain improvements in whole body performance following IMT.

EFFECTS OF AGE-RELATED AEROBIC FITNESS ON HEART RATE VARIABILITY AT REST, DURING EXERCISE AND DURING RECOVERY

MARTINMÄKI, K., RUSKO, H.

UNIVERSITY OF JYVÄSKYLÄ

Introduction: High aerobic fitness is associated with improved function of the autonomic nervous system (ANS) at rest and in response to exercise (1). Aerobic fitness and ANS function decrease with age (2,4) but physically active lifestyle can maintain high age-related aerobic fitness and may delay the age-related impairment of ANS function (1). We evaluated the effects of age-related aerobic fitness on autonomic heart rate (HR) control at rest, during low and high intensity exercise and during subsequent recovery.

Methods: Sixteen men and 16 women (age 25-55 yrs) were classified into high or moderate fitness group using predicted aerobic fitness (3) and age-related aerobic fitness norms (4). The gender and age were counterbalanced between the groups. The subjects performed an incremental maximal exercise test on a bicycle ergometer to verify their aerobic fitness and two 10-min constant load exercise sessions, one at low intensity (LI, 29±6% of maximal power) and another at high intensity (HI, 90±1% of individual anaerobic threshold). Low (LFP, 0.04-0.15 Hz) and high frequency power (HFP, 0.15-1.2 Hz) of heart rate variability (HRV) at rest, at the end of exercise and at each minute during subsequent 5-min recovery were assessed using short-time Fourier transform.

Results: Maximal oxygen uptake was higher ($P<0.001$) in the high (50±7, range 40-66 ml/kg/min) than moderate (39±7, range 30-53 ml/kg/min) age-related fitness group despite the ranges widely overlapped. At rest, HR was lower (62±8 vs. 72±8 bpm, $P<0.01$) and HFP was higher [7.73±1.39 vs. 6.56±1.13 ln(ms2), $P<0.05$] in the high than moderate fitness group. During HI exercise, there was no difference in HR but LFP [1.07±0.46 vs. 1.96±0.88 ln(ms2), $P<0.01$] and HFP [1.84±0.49 vs. 2.30±0.54 ln(ms2), $P<0.05$] were unexpectedly lower in the high than moderate fitness group. During the 5-min recovery period after HI exercise, HR decreased more rapidly ($P<0.01$) and HFP was higher ($P<0.01$) in the high than moderate fitness group. For LI exercise, only recovery HR was lower ($P<0.05$) and recovery HFP tended to be higher ($P=0.054$) in the high than moderate fitness group.

Discussion: The present findings suggest that, in addition to high aerobic fitness, high age-related aerobic fitness is associated with enhanced vagal HR control at rest and immediately after exercise. Lower HRV during HI exercise in the high than moderate fitness group may be related to greater absolute metabolic demand of HI exercise in the subjects with high age-related aerobic fitness.

AN ANALYSIS OF THE DIFFERENCE BETWEEN A JUDO SPECIFIC AND A GENERAL TREADMILL TEST

LOPEZ DIAZ DE DURANA, A., GARCÍA GARCÍA, J.M., NACLERIO AYLLÓN, F.

TECHNICAL UNIVERSITY OF MADRID

Introduction: In judo, treadmill running tests are commonly used for the physiological quantification of aerobic fitness in elite athletes. It should be noted however that the muscle mass used in a typical judo exercise is greater than in treadmill running. Therefore the aim of this study was to show the difference in the V˙O2max and hrmax observed in a treadmill test (Heck, 1985) and a new judo specifc protocol (López Díaz de Durana, 2009) which is a modification of that of (Sterkowicz, 1995).

Methods: 17 university judokas aged from 20 to 25 years, with a minimum of 3 years of judo practice were tested. All participants signed an informed consent, conistent with university guidelines concerning the testing of human participants. The teadmill test was an incremental step test and followed the protocol of (Heck, 1985). The judo test protocol (López Díaz de Durana, 2009) was similar to that of the treadmill and consited of incremental steps of 2 minute duration with a metronometer controlling the number and frequency of the throws (ippon seoi nage) for each step. After each step the heart rate and V˙O2 were recorded in the 1 minute before the next step began.

Results: The population average for the judo and treadmill V˙O2max was 64.2+10 mLkg-1min-1 and 58.23+7 mLkg-1min-1respectively. Whilst for the hrmax this was 195+9 bpm and 195+9 bpm respectively. However the mean individual differences between the judo and treadmill V˙O2max and hrmax were 5+10 mLkg-1min-1 and -1+10 bpm respectively. This showed that for the V˙O2max there exist substantial difference between the judo and treadmill tests. Such differences were not so apparent for the hrmax.

Discussion: Significant differences exist for the V˙O2max obtained in the judo specific test and the treadmill test, with the V˙O2max being greater in the judo test. This was due to that the muscular mass used in the judo specific test being greater than that used in treadmill test. In the case of the maximum heart rate the two tests predicted similar values. We conclude that for the prediction of V˙O2max in judokas a judo specific test is required so as not to underestimate this value.

EFFECT OF K1 FIGHT ON VERTICAL JUMP, REACTION TIME, AND LACTATE PRODUCTION.

CIMADORO, G., ALBERTI, G., BABAULT, N.

1. FACULTY OF SCIENZE MOTORIE; UNIVERSITY OF MILAN; ITALY, 2. UFR STAPS; UNIVERSITY OF DIJON, FRANCE.

Introduction: K1 is a combat sport with punches, kicks and knee blows. Two parameters may influence athletes' performance: injuries (e.g., Zazryn et al., 2003) and fatigue. Some studies were conducted to determine fighters physiological profile such as VO2max (Gosh et al., 1995; Guidetti et al., 2002). However, the effects of fatigue during official K1 fights remain unknown. Therefore, the aim of this study was to determine the effects of fatigue induced by an official K1 fight on vertical jump, simple visual reaction time, lactate accumulation and tactical behaviors.

Methods: Eight male volunteers were recruited during regional Italian K1-style amateur competition. Mean (± SD) age, height, weight and training experience were 24.3 ± 1.8 yrs, 173.8 ± 5.6 cm, 73.3 ± 9.4 kg, 5.6 ± 2.2 yrs, respectively. Subjects performed three rounds of 90 s with 60 s rest among rounds. Tests included counter movement jumps, simple visual reaction time (both were measured with an opto-jump system, Microgate, Italy) and blood lactate (Lactate PRO). They were performed before warm-up and after fights. Vertical jumps and simple visual reaction times were determined 8 minutes after the end of the third round due to judge's decision and prize giving. Blood lactate was collected 2 minutes after the end of the fight. A complete match-analysis was also made using a camcorder (blow numbers).

Results: Match-analysis showed 86 ± 23 total blows. No difference was found among rounds. However, punches (39 ± 16) and kicks (37 ± 16) number during fights was bigger ($p<0.001$) than knees (10 ± 10). While no difference among rounds was found for punches and kicks, knee blows were greater during the third round regarding with the first and second round (+4.8 ± 4.1, 2.8 ± 3.2, 2.4 ± 3.6, respectively, $p<0.05$). After the end of the fights, blood lactate was found to be on average 15.3 ± 1.6 mmol/L. Simple reaction times significant increased (+7.8 ± 5.6%; $p<0.01$) and no difference was found in vertical jump heights.

Discussion: Our data showed an altered number of blows among rounds. The increased knee blow number may be due to either or both tactical behaviors and technical economy. High values of blood lactate suggested a key role of anaerobic metabolism in K1 fights. Although high lactate values, vertical jump heights were surprisingly unchanged, this may be due to long rest duration between the end of the fights and post-tests. After the fight, simple visual reaction time was the only modified physiological parameter. It may be of interest during training to optimize cognitive process in fatigue conditions.

EFFECT OF KICKBOXING FIGHT ON VERTICAL JUMP, MUSCLE POWER, AND METABOLIC INDEXES.

CIMADORO, G., ROBINEAU, J., BABAULT, N., ALBERTI, G.
1. FACULTY OF SCIENZE MOTORIE; UNIVERSITY OF MILAN; ITALY, 2. UFR STAPS; UNIVERSITY OF DIJON, FRANCE.

Introduction: Combat sports alternate both anaerobic and aerobic efforts (Smith, 2006). Powerful and fast anaerobic actions are of paramount importance for explosive punch or kick attacks, feigns and defensive actions. Some authors examined the effects of fight on blood lactate production among different combat sports (Khanna et al., 2006). However, especially during kickboxing fights, the effects of fatigue on muscle power and metabolic indexes remain unknown. Therefore, the aim of this research was to determine the effects of fatigue induced by a kickboxing fight on vertical jump, bench press peak power, heart rate, and blood lactate accumulation.

Methods: Eleven athletes (5 females and 6 males) volunteered for the experiment. Females mean (± SD) age, height, weight and training experience were 29.6 ± 3.8 yrs, 164.8 ± 3.9 cm, 59.0 ± 2.4 kg, 6.4 ± 1.3 yrs, respectively. Males group was 26.5 ± 6.2 yrs, 178.3 ± 3.4 cm, 78.3 ± 10.5 kg, 8.0 ± 1.0 yrs, respectively. Subjects performed unofficial fights with three 120 s rounds with 60 s rest among rounds. Fights were conducted in accordance with kickboxing rules (low kick style). Athletes, referee, and coaches used their usual competition behavior. One day before fights, pre-tests were performed to determine bench press peak power using an accelerometer (Myotest, Switzerland), and vertical jump height during counter movement jumps (Optojump, Microgate, Italy). Just before fights and after warm-up, basal lactate (Lactate PRO, Japan) was collected. Heart rate (TMpro, Hosand Technologies, Italy) has been continuously recorded during fights. Finally, immediately after the end of the third round, bench press peak power, vertical jump height, and blood lactate values were evaluated for post-tests.

Results: At pre-test, a sex effect was found for both bench press peak power and vertical jump height, with males demonstrating greater values than females ($p<0.05$). During rounds, heart rate was on average 93 ± 1 % of the maximal heart rate. After fights, blood lactate concentration significantly increased until 13.6 ± 2.3 mmol/L ($p<0.001$). After fights no time effect was found for both bench press peak power and counter movement jump height.

Discussion: This study highlighted high heart rate and blood lactate values suggesting anaerobic metabolism plays a key role in kickboxing fights. However, aerobic power also plays an important role during recovery (e.g., lactate clearance). Neuromuscular indexes (vertical jump height and bench press peak power) were surprisingly unchanged although a fight-induced fatigue. These data could be explained by the non specific nature of these tests regarding with kickboxing skills.

NEUROMUSCULAR CONTROL DURING ROUNDHOUSE KICK WITH AND WITHOUT IMPACT IN TOP LEVEL KARATEKA

SBRICCOLI, P., CAMOMILLA, V., QUINZI, F., ALAIMO DI LORO, D., DI MARIO, A., FELICI, F.
UNIVERSITY OF ROME

Introduction: Karate practice requires a fine control of movement associated to a great ability to perform the main technical actions as fast as possible (Zehr et al., 1997; Sørensen et al., 1996; Mori et al., 2002). Because of its high speed and excellent accuracy, the roundhouse kick (RK) seems to be a good model to quantify the ability of a karateka to perform complex actions combining high movement velocities with high precision. This work was designed to characterize the neuromuscular activity pattern adopted by a top level karateka while performing the roundhouse kick (RK) using two different techniques: with impact (Impact RK) and without impact (No-impact RK).

Methods: Surface electromyographic (sEMG) signals have been recorded through a wi-fi transmission EMG amplifier (BTS Pocket EMG, Italy) from the Vastus Lateralis (VL), Rectus Femoris (RF), Biceps Femoris (BF), Gluteus Maximum (GM) and Gastrocnemious (GA) muscles of the kicking leg during the execution of Impact RK and No-impact RK. Six top level Karateka (K) and six graduated students practicing karate as amateurs (Controls, C) have been tested (25±1yrs; 1.78±0.03m; 73.8±4kg). Knee angular velocity has also been computed through magnetic field angular rate and gravity sensors (MTx, Xsens Motion Technologies, Enschede, The Netherlands) placed in correspondence with knee joint centre of rotation. Differences in knee angular velocity between C and K group during Impact and No-impact RK have been tested through an unpaired T-Test (level of significance: $p<0.05$).

Results: For K subjects, a typical EMG activity pattern was observed, consisting of by a biphasic and synergic activation of GM and VL muscles during both Impact and No-impact RK, the BF activation being shifted in time with respect to VL and GM muscles. A delayed activation of RF muscle was also observed. For C subjects, no typical EMG activation pattern was observed. Knee angular velocity obtained for both the Impact RK and No-impact RK was significantly higher in K group than in C group ($p<0.0001$) (Impact RK: 1948±67.2 °/s vs. 1295±74.87 °/s; No-impact RK: 1680±41.4 °/s vs. 922 87.4 °/s). For both K and C groups the peak knee angular velocity was higher for the Impact RK than for No-impact RK ($p<0.05$).

Discussion: The results obtained suggest the presence of a peculiar muscle activation strategy adopted by the Karateka with respect to amateurs during the execution of the RK. This was associated with a higher execution speed in K with respect to C subjects. Following our results, the different RK technique doesn't act as a confounding factor in terms of neuromuscular control as no relevant differences have been detected in the execution of Impact and No-impact RK.

THE IMPACT OF DIFFERENT COOLING STRATEGIES ON THE PHYSIOLOGICAL STRAIN ASSOCIATED WITH FIREFIGHTING ACTIVITY IN THE HEAT

BARR, D., GREGSON, W., REILLY, T.

LIVERPOOL JOHN MOORES UNIVERSITY

Introduction: Performing firefighting activity in the heat imposes a high degree of physiological stress (Rossi, 2003). The provision of effective cooling methods is important for the health and safety of firefighters. Cooling via the application of ice vests combined with hand/forearm water immersion (~19oC) reduces the physiological strain incurred during firefighting activities (Barr et al., 2009). However, the relative contribution of these two cooling methods is unclear. The aim of this study was to compare the effectiveness of an ice vest relative to hand/forearm water immersion on the physiological responses during firefighting activity in the heat.

Methods

On four separate occasions under high ambient temperatures (49.1 ± 1.3 oC, RH 12 ± 1%), seven male firefighters (mean + s: age 40, s = 6 years, maximal oxygen uptake 50.6 s = 4.6 mlkgmin-1, % body fat 19, s = 4 %), completed two 20-min bouts of treadmill walking (5 kmh-1, 7.5% gradient) separated by a 15-min recovery period. During each exercise bout, firefighters wore standard protective clothing, including self-contained breathing apparatus (SCBA). During the recovery period, participants removed their helmets, tunics, anti-flash hoods, gloves and SCBA, consumed a controlled amount of water (temperature ~19oC) (5 mlkg-1 body mass) and were either cooled via an ice vest (VEST), hand/forearm immersion (W; ~19oC), ice vest combined with hand/forearm immersion (VEST+W) or remained seated without cooling (CON).

Results: During the first bout of exercise physiological variables were similar under all conditions. Core temperature was lower at the end of the 15-min recovery period in W (37.96 ± 0.19oC) and VEST+W (37.97 ± 0.23oC) compared to the VEST (38.21 ± 0.12oC) and CON (38.29 ± 0.25oC) and remained lower throughout the second bout of exercise ($p < 0.05$). Mean skin temperature was higher in CON compared to the three cooling conditions ($p<0.01$). At the end of the recovery period heart rate (HR) was lower in W and VEST+W compared to VEST and CON ($p<0.05$). During the second bout of exercise maximum HR was lower in the VEST+W and W conditions, compared to the VEST, and CON condition. Prior to bout 2, firefighters perceived themselves to be 'cool' in the three cooling conditions compared to 'warm' in the CON condition. Firefighters perceived bout 2 to be 'hot' in the VEST+W and W conditions compared to 'very hot' in the VEST and CON conditions.

Discussion: These findings demonstrate that hand/forearm immersion is more effective than ice vests in reducing the physiological stress during firefighting activity in the heat. Furthermore, combining ice vests with hand/forearm immersion provides no additional benefits compared to hand/forearm immersion alone.

POST ACTIVATION POTENTIATION - CHANGES IN POWER DEVELOPMENT IN UPPER BODY PULLING, FOLLOWING MAXIMAL FORCE EXERCISE

OLSEN, R., SØRENSEN, H.

AARHUS UNIVERSITET

Introduction: The contractile response in skeletal muscle depends partly on the contractile history, which can have both a fatiguing and a potentiating effect. The balance between these decides whether the muscle's contractile response in the post phase is increased (post activation potentiation, PAP), decreased, or unchanged (Rassier & MacIntosh, 2000). Young et al (1998) and Gilbert & Lees (2005) have shown that PAP can comprise increase in rate of force development (RFD) and maximal power (Pmax). Various intervention protocols have been used to examine PAP in the lower body and in the upper body pushing muscles, i.e. shoulder flexors and elbow ectensors, with varying results. However, no one has so far investigated PAP in the upper body pulling muscles, i.e. shoulder extensors and elbow flexors.Thus, the purpose of this study was to examine RFD and Pmax in the upper body pulling muscles following a bench-pull intervention.

Methods: 8 elite (national medal takers) male sprint canoeing and sprint swimming athletes, whit 3-14 years of continued strength training experience, where chosen, all had employed the exercise used in the study as a main exercise in their strength training for at least 6 month prior to the study.

The participants visited the lab on two occasions separated by 1-4 days. On the first occasion the subjects´ 1RM bench-pull was determined. On the following test occasion, an intervention of 5x1RM was performed whit 5min rest in between.

Pre and at 1,7,13, and 19min post the intervention, the subjects performed 3 explosive bench-pulls with 1min rest in between with 40% 1RM. The Pre and post tests were high speed filmed and subsequently Pmax from each pull was calculated. The mean value from each set of 3 pulls were used for further analysis. A one way ANOVA with repeated measures was used to test for significant differences among pre and post intervention Pmax.

Results: None of the participants could complete all the lift successfully during the intervention protocol, only 2 of the participants could complete more than 1 lifts successfully. Results showed no significant difference in Pmax from pre to any of the post measurements.

Discussion: The results in this study conflict with the earlier results found in the lower body by Gilbert & Lees, but is similar to result found by (Farup & Sørensen,2008) in upper body, both using the exact same intervention. It could be speculated if it for elite athletes is possible to reproduce a true 1RM 5 times whit only 5min break in between. Or if different tolerance for maximum intensity levels in the upper body vs. the lower body could explain the conflicting results.

In conclusion, the results shows that an intervention of 1RM is not applicable, to elicit post activation potentiation

PS-PL03 Sport, Body and Mind: Towards a New Understanding?

EVIDENCE FROM RANDOMIZED TRIALS: EFFECTS ON MENTAL DISEASE OUTCOMES

DUNN, A.L.

KLEIN BUENDEL

Recent randomized clinical trials demonstrate the role of exercise and physical activity in the treament of a wide variety of mental pathologies. Using depression illness as a primary focus and severe mental illness as a secondary focus, this discussion will highlight how exercise could be used in the treatment of depression and severe mental disorders.

A number of randomized trials suggest that exercise could serve multiple functions in the treatment of depression disorders and severe mental illness. One randomized trial examining different doses of exercise to treat diagnosed Major Depressive Disorder (MDD) as a monotherapy found that an amount equivalent to public health guidelines for physical activity was effective in reducing symptoms, while a lower dose was not. Furthermore, several studies now show response and remission rates of exercise to treat depression disorders appear to be equivalent to standard therapies of antidepressant medication and cognitive behavioural therapy (CBT). Exercise could also be used to augment pharmacotherapy or CBT in patients who might not be achieving complete remission of symptoms, and there is some evidence to suggest the use of exercise to augment traditional treatments is similar to findings from multi-site trials. Finally, recent trials demonstrate that exercise could be used as adjunctive therapy with both depression and severe mental disorders to improve health outcomes related to co-morbid diseases, like cardiovascular disease and diabetes.

Most studies of exercise have had relatively small sample sizes in comparison to standard treatment studies of pharmacotherapy and CBT. There is a need to demonstrate the efficacy and effectiveness of exercise treatments in well controlled studies with larger sample sizes of diagnosed patients. Further, there is a need for better understanding of the potential mechanisms underlying treatment effects in both primary and secondary prevention studies. This includes understanding: 1) short-term treatment effects of acute bouts of exercise; 2) long term treatment effects to prevent relapse; 3) key factors that might influence response to treatment, e.g., why do some individuals respond to exercise treatment; 4) the role of exercise in preventing the onset of a wide variety of mental disorders; and, 5) development of programs that will enhance motivational factors for individuals with mental disorders to engage in regular exercise.

THE BRAIN : HOW DOES THE INTEGRATION OF SIGNALS OCCUR ?

MEEUSEN, R.

VRIJE UNIVERSITEIT BRUSSEL

Brain research is a rapidly developing field and new understandings emerge on the interaction between the brain, motor action, and even motivation and emotion.

Recently there has been more interest in the effects of exercise on brain processes. These new experiments arise mostly from animal studies where the basic knowledge on possible underlying physiological mechanisms are explored. Much progress has been made in identifying the various hormonal and neural mechanisms by which the brain informs itself about signals from the periphery, and, in turn, generates behavioural, autonomic, and endocrine output. Several brain nuclei play crucial roles in homeostatic functions such as food intake, and in processing prior experience with food, reward, exercise etc. From these animal studies it is known that exercise might be a 'natural' antidepressant, and that some neurotransmitters are influenced by regular exercise. Training will induce other neurochemical reactions, that might explain possible underlying neurophysiological arguments for the use of training in degenerative neurological diseases such as Parkinson's disease and Alzheimer disease.

Exercise can be a powerful tool in the treatment of neurological diseases. There have been a number of studies that examined the exercise effect on a wide variety of pathological situations, and it seems that exercise works, although there is a general need for controlled trials.

EFFECT OF REST DURATION BETWEEN RESISTANCE TRAINING SETS ON MARKERS OF MUSCLE DAMAGE IN TRAINED MALES

GHADERI, M., RAHIMI, R., AGHA ALINEJAD, H.

AZAD UNIVERSITY OF MAHABAD

Abstract:

The purpose of the present study was to evaluate the effects of rest duration between resistance training sets on markers of muscle damage in trained men. Therefore, ten male athletes (Mean ± SD, age=20.37± 2.24 years, body mass= 65.5 ± 26.70 kg) voluntarily participated in four sessions with 48 h recovery time who were performing different resistance trainings. At the first session, one repetition maximum (1RM) of participants evaluated. The subjects from the second session up to the fourth, each session, performed four sets of squat and bench press to failure with 85 % of 1RM and one of rest intervals of 60s, 90s and 120s between the sets used randomly. Also, there were taken three blood samples from the subjects before, immediately after, and 30 min after the training, to determine serum

enzymes concentration (CK، CK-MB and LDH). For statistical analysis of data, one-way repeated measures and LSD post hoc were used. No significant differences were found in the increase of serum enzymes concentration (CK، CK-MB and LDH) between three groups. However, there were significant increase in serum enzymes concentration immediately after and 30 min after exercise in the three groups. It wasn't observed a significant difference among the three programs in lactate concentration. Although, the ability of keeping the repetition (training volume) by using 90s and 120s rest intervals has been more than that of 60s, but statistically it wasn't observed a significant difference in training volume. The results of the present study showed that 60, 90, and 120 sec rest duration between resistance training sets don't affect on markers of muscle damage such as CK، CK-MB and LDH and also don't affect on training volume.

EFFECTS OF CONCURRENT AND RESISTANCE TRAINING ON CALCITONIN GENE-RELATED PEPTIDE (CGRP) CONTENT IN SLOW AND FAST MUSCLES OF WISTAR RATS

PARNOW, A., GHARAKHANLOU, R., HEDAYATI, M., MAHDIAN, R., GORGIN, Z.

UNIVERSITY

Calcitonin Gene-Related Peptide (CGRP), a 37-amino acid peptide generated by alternative processing of primary transcripts from calcitonin gene, is broadly distributed in the peripheral and central nervous systems of vertebrate and invertebrate species. The purpose of the present study was to investigation the effects of Concurrent (Resistance and Endurance) and Resistance Training on the content of CGRP in Slow and Fast Muscles of Wistar Rats. A number of twenty -three male Wistar rats (10 mo of age, 220 ± 15 gr, Iran Pasteur Institute) randomly were divided to three groups (control (n=7), concurrent training (n=8), and resistance training (n=8)) and followed 12 weeks training according protocols. Animals of the resistance group were housed in metal cage with a wire-mesh tower, with two water bottles set at the top. Concurrent group did a combine of both resistance and endurance training (5 days a week, 60 min/day, 30 m/min speed). Forty-eight hours after last session of protocols, animals were anaesthetized with a mixture of KetamineTM and Xylazine. The right soleus (as slow muscle) and anterior tibialis (AT, as fast muscle) were removed under sterile condition via an incision on dorsolatral aspect of the hindlimb. After remove, tissues were quickly frizzed in liquid nitrogen and kept at -70 ° C for later useage. For CGRP assay, ELISA kit was used. For data analyses, One-way ANOVA was used. Data analysis showed that there was a significant difference between control and concurrent training groups in slow muscle CGRP. Also, the content of CGRP in both fast and slow muscles was significantly difference in resistance training group with control group. Both resistance and concurrent training increased the content of CGRP in the fast and slow muscles. Therefore, CGRP increase depends on the nature of activity and probably duration and intensity of it, but not the type of muscle. Finally, CGRP content is depending on activity and stimulus more than muscle type so that concurrent training has caused CGRP increase in both slow and fast muscles.

EFFECTS OF STRENGTH TRAINING ON CALCITONIN GENE-RELATED PEPTIDE (CGRP) CONTENT IN SLOW AND FAST MUSCLES OF WISTAR RATS

GHARAKHANLOU, R., ESLAMI, R., PARNOW, A.H., VAHIDPOUR, SH., MADIAN, R.

UNIVERSITY

Calcitonin Gene-Related Peptide (CGRP), a 37-amino acid peptide, generated by alternative processing of primary transcripts from calcitonin gene, is broadly distributed in the peripheral and central nervous systems of vertebrate and invertebrate species. The purpose of the present study was to investigate the effect of Strength Training on the content of CGRP in Slow and Fast Muscles of Wistar Rats. A number of 12 male Wistar rats (10 mo of age, 220 ± 15 gr) randomly were divided to tow groups (control (n=7) and strength training (n=5)). The strength training protocol consisted of climbing a 1- meter–long ladder set at an 85° angle, with a weight attached to a tail. For CGRP assay, ELISA kit was used. Data showed that there was not a significant difference between slow and fast muscle CGRP of control group. Nonetheless, the strength training leaded to increase in CGRP content of slow muscle and decrease in CGRP content of fast muscle that both increase and decrease were not significant compare with control group (respectively, p= 0.155 , p=0.083). In conclusion, the results of current study show that slow and fast muscle CGRP content changes with strength training which the quantity and the direction of this changes may depend on duration and intensity of training protocol.

EFFECTS OF 8 WEEKS OF RESISTANCE TRAINING ON HAEMATOLOGICAL VARIABLES IN MEN

HASSANLOEI, H., AHMADIZAD, S., IBRAHIM, K., ASLANKHANI, M.A.

AALBORG UNIVERSITY, DENMARK & SHAHID BEHESHTI UNIVERSITY G.C., TEHRAN, IRAN.

Resistance exercise or weight training is used extensively to improve physical fitness, enhance performance, prevent injuries, increase muscle size and also is used in rehabilitation programmes (1). The acute effects of resistance exercise on selected haematological variables have been recently investigated (2,3). However, no information is available regarding the chronic effects of resistance exercise haematological parameters. Therefore, the present investigation was designed to examine the effects of 8 weeks of resistance training on red blood cell and platelet indices. Training group (N = 9; age, 22 ± 1.5 y) undertook a strength-training programme three days a week for 8 weeks, while the control group (N = 6; age, 23 ± 1 y) were asked to avoid any regular physical activity during this period. Resistance exercise protocol included the performance of 3 sets of 8-10 repetitions of six exercises at 80% of 1RM. After 4 weeks of training subjects performed another 1RM test and the exercise intensity was set at 80% of new 1RM for the remaining 4 weeks. Four resting blood samples were taken before training, after 4 and 8 weeks of training and after 4 days of recovery and were analysed for RBC count, haemoglobin, haematocrit, mean corpuscular volume (MCV), mean corpuscular haemoglobin (MCH), mean corpuscular haemoglobin concentration (MCHC), red blood cell distribution width (RDW), fibrinogen, platelet count, plateletcrit, mean platelet volume (MPV), and platelet distribution width (PDW). No significant difference between pre and post-training values was observed in the control group for all measured platelet variables. Resistance training resulted in a significant increase in muscular strength by 20% to 35%. Statistical analyses of the data indicated that RBC count, haemoglobin, and haematocrit decreased significantly during first 4 weeks of training and increased significantly ($P < 0.01$) between weeks 5 to 8 to nearly pre-training level. However, the other RBC indices did not change significantly in response to resistance training. A significant effect of training was found for platelet count and plateletcrit ($P < 0.01$). Post-hoc analyses revealed a significant increase in platelet count and plateletcrit during first 4 weeks of training with no significant changes between weeks 5 to 8. However, MPV, PDW, and fibrinogen did not change significantly in response to resistance training. It was concluded that resistance training doesn't change red blood cell parameters, while increases platelet count and PCT. Therefore, it could be

suggested that the performance of resistance exercise in patients with impaired cardiovascular function should be considered with caution when prescribing exercise.

RESISTANCE TRAINING IMPROVES SOME CARDIOVASCULAR RISK FACTORS IN OBESE WOMEN DESPITE A DECREASE IN SERUM ADIPONECTIN LEVELS

IBÁÑEZ, J., IZQUIERDO, M., MARTÍNEZ-LABARI, C., GARCÍA-UNCITI, M., FORGA, L., GRIJALBA, A., FERNÁNDEZ-REAL, J.M., GOROSTIAGA, E.M.

STUDIES, RESEARCH AND SPORTS MEDICINE CENTER, GOVERNMENT OF NAVARRA, PAMPLONA

Objective: The purpose of this study was to examine the relationships of plasma adiponectin and different body composition variables with insulin resistance and lipid profile when a resistance training program (PRT) is applied to a group of hyperholesterolemic obese women with a concomitant weight-loss diet.

Design and methods: Thirty four hypercholesterolemic obese (BMI: 30-40Kg/m2) women, aged 40-60y, were randomized to 3 groups: a control group (C; n=9); a diet group (WL; n=12) with a caloric restriction of 500Kcal/d; and a diet plus resistance training group (WL+RT; n=13) with the same caloric restriction as group WL and a 16-week supervised whole body PRT of 2 sessions/week.

Results: In the WL+RT group significant improvements in different cardiovascular risk factors (insulin sensitivity, baseline insulin levels, total cholesterol or LDL-C) was observed in spite of a significant decrease of serum adiponectin levels. The decrease in circulating adiponectin being observed in 11 over 13 subjects. However, in the WL group, a similar diet in terms of caloric content and nutrients composition and a loss of body mass and adipose tissue of similar magnitude was accompanied by no changes in serum adiponectin levels or in lipid profile, although an increase in insulin sensitivity and a decrease in baseline insulin levels were observed.

Conclussion: In hypercholesterolemic obese women a PRT plus a weight-loss diet is accompanied by significant improvements in different cardiovascular risk factors in spite of a significant decrease of circulating adiponectin. Overall, the data suggest that a decrease in circulating adiponectin levels may not be always a negative health marker.

NEURAL ADAPTATIONS FOLLOWING STRENGTH TRAINING IN CHILDREN AND ADOLESCENTS: A TMS PILOT STUDY.

PEARCE, A.J., GRIKEPELIS, L.A., KIDGELL, D.J.

1. VICTORIA UNIVERSITY, 2. DEAKIN UNIVERSITY

Introduction: It has been suggested that when an individual participates in strength training, much of the initial increase in strength is attributed to adaptations (plasticity) in the central nervous system (CNS; Griffen and Cagarelli, 2005). It has been proposed (Adkins et al., 2006) that strength training is comprised of a form of motor skill learning, to explain short-term improvements in strength in children and adolescents (Faigenbarum et al., 1999) This preliminary study examined strength changes and central nervous system (CNS) adaptations following a four week training of the biceps brachii (BB) muscle in healthy children and adolescents who were novice to strength training.

Methods: Ten participants (five male, five female; 12-17 years of age) completed 12 strength training sessions (two sets, increased to three sets of 15 repetitions at individualised prescribed weights) over a four week period. Prior to and post-training period participants were tested for BB maximal voluntary contraction (MVC) strength (via hand-held dynamometry) and sub-maximal strength (10 RM test); relaxed and flexed upper arm girths; and motor evoked potential (MEP) excitability, using single–pulse transcranial magnetic stimulation (TMS).

Results: Significant improvements (p=.01), in both arms, were shown post-training in group mean MVC (9.7 ± 3.7% and 12.8% ± 5.0% left and right arm respectively) and 10 repetition max strength test (22.7 ± 5.6% and 21.6 ± 4.0 % left and right arm respectively). Conversely, no changes were shown in group mean upper arm girths in both arms, for the relaxed and flexed conditions. Group mean corticomotor excitability projecting from the motor cortex to the BB showed significant increases (p=.001) post-training. Mean MEP amplitudes projecting from the motor cortex to the right arm increased from 1.7 (± 1.3 mV) to 2.4 (± 1.3 mV) and to the left arm from 1.2 (±.6 mV) to 1.6 (±.8 mV).

Discussion: The data in this study provides further evidence of rapid strength increases and CNS changes that may account for rapid increases in strength without associated muscle hypertrophy. The study further demonstrates the safety of single-pulse TMS use in children and adolescents. However, this is the first time CNS plasticity, following a period of strength training, has been demonstrated in children and adolescents. Further study will aim to investigate longer training period durations.

CORTICO-SPINAL MECHANISMS OF THE REGULATION OF CONCENTRIC AND ECCENTRIC MUSCLE CONTRACTIONS

PETROV, D., GORODNICHEV, R.

VELIKIYE LUKI STATE ACADEMY OF PHYSICAL EDUCATION AND SPORTS

Introduction: Concentric and eccentric muscle contractions make up the essential part of motor activity of humans. There are a lot of researches devoted to studying of EMG changes, activity and specific modulation of motor units at concentric and eccentric contractions (Pasquet et al., 2006; Semmler et al., 2007). The purpose of the present research was to study parameters of motor evoked potentials (MEP) and the EMG silent period of skeletal muscles under transcranial magnetic stimulation (ТМS) in the process of concentric and eccentric muscle contractions.

Methods

Subjects aged 19-23 took part in the research. All the subjects were informed about conditions of the research and gave a written consent to participation, and it conformed to the Helsinki Declaration. The subjects performed concentric and eccentric muscle contractions (plantar\dorsi flexion) making 50 % of maximal voluntary contraction. The MEP parameters, EMG silent periods of lower extremities mus-

cles during ТМS of the brain were registered by the magnetic stimulator «Magstim 200», the dynamographic system «Biodex Multi-Joint System Pro-3» and the electroneuromyograph «Neuro-МЕР-8».

Results: It was revealed, that MEP amplitude of the researched muscles during contractions considerably increased in comparison with that at rest. It is marked that the most significant growth of the MEP amplitude of m. gastrocnemius med. and m. soleus at the concentric contraction, exceed the values at rest in 5-8 times. The greatest MEP amplitude was registered in the middle of concentric contraction, and minimal was at the moment preceding the final part of it. At the eccentric contraction the MEP amplitude of the m. tibialis anterior was higher, than that of the other muscles. The silent period of the researched muscles was longer at the performance of concentric contraction, the maximum of the silent period duration was achieved in its final part.

Discussion: The MEP amplitude increase at muscle contractions is explained by the MEP facilitation phenomenon which is determined by change of excitability of elements of the nervous system (Mills et al., 1996). We have every reason to believe that the MEP amplitude increase of m. gastrocnemius med. and m. soleus at the concentric contraction proves higher excitability of the cortical neurons.

Conclusion

The revealed facts testify variability of descending cortical currents during voluntary concentric and eccentric muscle contractions.

DIURNAL VARIATION IN THE H-REFLEX IN HUMAN

YAMAGUCHI, H.

KIBI INTERNATIONAL UNIVERSITY

The monosynaptic Hoffmann (H)-reflex that is evoked by Ia afferents from muscle spindle to homonymous MNs (excitability of spinal α-motoneurons) is widely used as a tool for investigating the changes in excitability of the MN pool. Diurnal variation in the H-reflex amplitude has been identified primarily in rats, mice and monkeys. H-reflex amplitude in the rat is the largest in the late morning and the smallest around midnight. In contrast, the primate H-reflex and spinal stretch reflex amplitude are the largest at midnight and the smallest in the morning. These results suggest that the central nervous system activity and reflex function vary with the time of the day. This phenomenon could be observed in human, nevertheless little is known about diurnal H-reflex in human. The purpose of this study was to investigate H-reflex on the diurnal variation in human. Six healthy males were voluntarily participated in this study. H-reflex of soleus muscle (SOL) and rectal temperature were recorded at 7:00, 11:00, 16:00, 20:00, 22:00, 3:00, and 7:00 h. Participants were allowed to sleep for 8 hours, from 23:00 to 7:00. H-reflex and rectal temperature were measured after a 20 minute rest period. Subjects maintained the prone position to minimize the variation of the H-reflex caused by changes in position or muscle activity. H-reflex of SOL was evoked by electrical stimulation at the tibialis nerve in the popliteal fossa continuously, once per 4 second interval. The stimulus to elicit the H-reflex was delivered as 1-ms square pulse. With the maximal H wave, there was a small M-wave (10% of the maximal M wave) and the amplitude of this M-wave was monitored to maintain constancy of nerve stimulation during the experiment. We measured the peak-to-peak amplitude of the H-reflex, which indicates the excitability of spinal α-motoneurons. Also, we compared the time interval between the time on positive peak of M and H wave (loop time), which indicates the recruitment threshold of motor units. Rectal temperature significantly changed during 24 hours ($p < 0.05$); natural circadian rhythms were seen in all participants. Rectal temperature was significantly lower in the morning and midnight compared to the daylight ($p < 0.05$). In contrast, the loop time was significantly shorter in the daylight than in the morning and midnight ($p < 0.05$). In fact, the rectal temperature and loop time varied in a mirror image. These results suggest that the recruitment threshold of motor unit is low in the early morning and midnight. H-reflex amplitude did not show any diurnal variation. These results were varied from the previous studies. We consider that it is because of the discrepancy in method for evaluation of excitability of spinal α-motoneurons. In conclusion, the data shows that the diurnal variation is present in the time interval between the time on positive peak of M and H wave.

IGF-I AND HORMONAL RESPONSES TO ARM CURL EXERCISE UNDER DIFFERENT HYPOXIC CONDITIONS

KUROBE, K., HUANG, Z., OZAWA, G., TAMAKI, H., OGITA, F.

NATIONAL INSTITUTE OF FITNESS AND SPORTS

Introduction: It has been reported that several hormonal responses including growth hormone (GH) and catecholamine are enhanced by exercise in a hypoxic condition compared that in a normal condition. The present study aimed to examine the effects of arm curl exercise under different hypoxic conditions on insulin-like growth factor-I (IGF-I) and hormonal responses, which relate to muscle hypertrophy.

Methods: The subjects were 8 healthy male adults (23±2 yrs, 171.9±4.2cm, 68.3±13.5kg). They performed an exhaustive arm curl exercise in three different conditions, that is, 1) normal condition (N), 2) hypoxic condition corresponding to 3000m (H1), and 3) to 5000m above sea level (H2). Arm curl exercise was done at the load of pre-determined 8 RM to the exhaustion in each set, and it was repeated 3 sets with 1 min rest between sets. The range of elbow joint motion was from 10 to 100°(0°at full extension), and the exercise was performed at a fixed cadence (flexion action 3-s, extension action 3-s). Before the exercise, the subject rested in a sitting position for 30 min breathing the gas of each condition. Blood samples were obtained before, and immediately, 15min, and 30min after the exercise to determine serum IGF-I, GH, cortisol, and blood lactate concentrations (BLa).

Results: Mean values of BLa at immediately after the exercise were significantly higher than those before the exercise in the all conditions ($P<0.05$). Furthermore, BLa in H2 kept significantly higher until 15 min after the exercise when compared to that before the exercise. When time course of serum GH were compared in each condition, no significant changes were observed in all conditions. However, when those were compared among conditions, the values at 15 min and 30 min after the exercise were significantly higher in H2 than those in N and in H1 ($P<0.05$). Time course of serum cortisol did not change significantly in all conditions, either. In the comparison among conditions, the values of serum cortisol at 15 min and 30 min after the exercise were significantly higher in H2 condition compared to that in N ($P<0.05$). In serum IGF-I, neither time course of changes in each condition nor differences among conditions were found.

Discussion/Conclusion: These results suggest that hypoxic stimulus could enhance the hormonal responses which relate to muscle hypertrophy but that mild hypoxic stimulus corresponding to 3000m above sea level would not be strong enough to induce such hormonal responses. On the other hand, it is suggested that serum IGF-I would not change within 30 min after the exercise by the hypoxic and exercise stimulus used in this experiment.

THE EFFECT OF STRETCHING ON MUSCLE FORCE PRODUCTION IN HAMSTRING MUSCLES

MOE, V., AUNE, T.K.

NORD TRONDELAG UNIVERSITY COLLEGE

The purpose of this study was to explore the acute effect of proprioceptive neuromuscular facilitation stretching (PNF) on maximal voluntary contraction (MVC), rate of force development (RFD) and power in both isometric and dynamic contractions of hamstring (knee flexion).

10 volunteer male kickboxers participated in the experiment. The subjects underwent two days of testing, and randomly the subjects were tested with or without stretching the first or the second day of testing. The day without PNF was used as a control condition for the day with PNF.

Each experimental condition conducted of a 10min warm up on at treadmill at 60% of the subjects HFmax. Immediately after warm up the day without stretching the dependent variables in both the isometric and dynamic contractions of the hamstrings were tested. After warm up the other day the subjects underwent a controlled PNF sequence of the hamstring that was immediately followed by a test of the dependent variables. The subjects hamstring flexibility was controlled by the "sit and reach test" after warm up both days of testing, and after PNF. Only the dominant leg was tested.

The results indicate that PNF increases hamstring flexibility, but has an acute negative effect on MVC, RFD and power in both isometric and dynamic contractions of hamstring muscles.

Therefore it is concluded that PNF has an acute negative effect on muscle force production measured as MVC, RFD and power in both isometric and dynamic tasks, and is not a type of stretching that should be recommended in before performing activities that require high force production.

SCALING OXYGEN CONSUMPTION TO BODY MASS IN REAL ELITE CROSS-COUNTRY SKIING PERFORMANCES

CARLSSON, T., CARLSSON, M., HAMMARSTRÖM, D., TONKONOGI, M.

LIVI

Introduction: Maximal oxygen consumption (VO2max) is a frequently evaluated test parameter in cross-country skiing. Most often the units L min(-1) and mL min(-1) kg(-1) are used as performance ability markers, but earlier research have suggested that VO2max divided by body mass raised to 2/3 power would theoretically better reflect the physiological demands in cross-country skiing (Bergh and Forsberg, 1992). Changes in cross-country skiing in the last decades might place different physiological demands regarding VO2max. The purpose was therefore to find the optimal body mass exponent for test parameter VO2max for real elite cross-country skiing performances and ranking points.

Methods: Four to seven days prior to the first ski race twelve highly motivated male Swedish national elite cross-country skiers (age 23.9+/-4.2 years; weight 76.2+/-5.8 kg; VO2max 5.34+/-0.34 L min(-1)) completed an incremental treadmill roller skiing test in diagonal technique determining VO2max.

Performance data were collected from the Swedish National Championship (SNC) in cross-country skiing (13-17 March 2008): 15-km with individual start in classical technique (SNC15); 30-km double pursuit with mass-start (SNC30) also divided in the two halves in classical technique (SNC30:15c) and free-style technique (SNC30:15f); sprint prolog in free-style technique (SNCsprint). In addition to ski races, overall seasonal ski ranking points were collected from International Ski Federation's (FIS) 3rd Cross-Country Points List 2007/2008 published before SNC for distance (FISdist) and sprint (FISsprint) races.

Body mass scaling of VO2max for each of the skiing performances was determined using Pearson´s correlation analysis. Optimal mass exponent was set to the scaling value between zero (L min(-1)) and one (mL min(-1) kg(-1)) where Pearson's product-moment correlation coefficient showed highest correlation for the relationship between VO2max and the ski performance parameter.

Results: Optimal body mass exponents for VO2max regarding ski performances SNC15, SNC30, SNC30:15c SNC30:15f and SNCsprint were 0.49, 0.57, 0.55, 0.58 and 0.31, respectively. Optimal scaling factor for FISdist was 0.63 and corresponding value for FISsprint was 0.25.

Discussion: This study indicates that optimal body mass exponents for maximal aerobic power depends mainly on work intensity of the actual skiing performance. Sprint skiing performance places higher metabolic demands than distance races which are reflected by a lower scaling factor. The fact that SNC15 had a lower optimal body mass exponent than SNC30:15c despite both were performed in the same course and technique supports the work intensity theory because in double pursuit the physiological resources should be sufficient to go 15-km more resulting in lower work intensity. Summarizing the reasoning above heavier skiers are favored in shorter race distances with higher metabolic demands.

PHYSIOLOGICAL DEMANDS OF REAL ELITE CROSS-COUNTRY SKIING PERFORMANCES

CARLSSON, M., CARLSSON, T., HAMMARSTRÖM, D., TONKONOGI, M.

LIVI

Introduction: Which are the main physiological differences between a successful and less successful cross-country skier? To our knowledge no previous studies have examined a real elite cross-country ski competition. Main purpose of this study was therefore to validate commonly used test parameters to skiing time and to International Ski Federation (FIS) overall seasonal ranking points and to create multiple regression models to predict skiing performances.

Methods: Twelve highly motivated male Swedish national elite cross-country skiers completed a test battery consisting of: isokinetic knee extensor peak torque tests at three different velocities; three different vertical jumps tests; two-part treadmill roller skiing test determining lactate markers, maximal oxygen consumption (VO2max) and time to exhaustion; 60 and 360 s double poling tests determining mean upper-body power (DP60Pmean) (DP360Pmean) and mean oxygen consumption (DP60VO2mean) (DP360VO2mean).

Performance data were collected from the Swedish National Championship (SNC) in cross-country skiing (13-17 March 2008): 15-km with individual start in classical technique (SNC15); 30-km double pursuit with mass-start (SNC30); sprint prolog in free-style technique (SNCsprint). In addition to ski races, overall seasonal ski ranking points were collected from FIS 3rd Cross-Country Points List 2007/2008 published before SNC for distance (FISdist) and sprint (FISsprint) races.

Correlations between test parameters and performance data were established using Pearson´s correlation analysis. Prediction models were created using standard multiple linear regression analysis.

Results: Time to exhaustion during the incremental treadmill roller ski test is best correlated with both SNC15 ($r = -0.86$, $p < 0.001$) and SNC30 ($r = -0.81$, $p < 0.01$). For SNC15 significant correlations were shown with VO2max both absolute and relative to body weight, lactate markers, DP60Pmean and DP60VO2mean. Corresponding correlations for SNC30 were: lactate markers, DP60VO2mean and percentage decrease in mean knee extension peak torque when comparing highest and lowest velocities. Highest correlation coefficient for SNCsprint was found for DP60Pmean ($r = -0.93$, $p < 0.05$). Significant correlations for SNCsprint was also detected for DP360Pmean as well as DP360VO2mean and jump height in squat jump.

Prediction models explain 68, 91, 68, 77 and 82% of the variance in performance for SNC15, SNC30, SNCsprint, FISdist and FISsprint, respectively.

Discussion: Correlations found in this study have validated several commonly used physiological tests with real elite cross-country skiing performances. Frequently investigated test parameters like VO2max and anaerobic thresholds are of great importance for success in cross-country skiing. Many recent research studies have focused on upper-body capacity and we could confirm that high mean power production in double poling is necessary to be successful as elite skier in both sprint and distance races.

INTERACTION BETWEEN OXIDATIVE STRESS AND ANTIOXIDANT MARKERS IN ELITE FEMALE PLAYERS FOLLOWING A SOCCER GAME.

ANDERSSON, H., KARLSEN, A., BLOMHOFF, R., RAASTAD, T., KADI, F.

SCHOOL OF HEALTH AND MEDICAL SCIENCES

Introduction: Exhaustive exercise may produce an excessive amount of free radicals leading to oxidative stress. Under normal conditions, the production of free radicals is in a fine-tuned equilibrium with the antioxidant defence system (Blomhoff, 2005). During a soccer game the aerobic energy system is highly taxed and increased free radical production is expected. Thus, we aimed to investigate the interaction between biomarkers of oxidative stress and antioxidants levels in elite female soccer players in response to a 90-min game.

Methods: Blood samples were taken from 16 field players (22±3 yrs, 167±5 cm, 64±2 kg, 54±3 ml•kg-1•min-1) before, immediately and 21 h after a 90-min game. Plasma oxidised glutathione (GSSG), the ratio of reduced to oxidised glutathione (GSH:GSSG) and lipid peroxidation measured by D-Roms test were used as biomarkers of oxidative stress. Plasma endogenous (uric acid, total glutathione–TGSH) and dietary antioxidants(α-tocopherol, ascorbic acid- AA, total carotenoids, and polyphenols) were analysed using liquid chromatography and the Folin-Ciocalteu method. The food intake was standardised for all players during the study and secured an optimal intake of macro nutrients.

Results: Immediately after the game GSSG significantly increased, GSH:GSSG decreased and D-Roms levels were unchanged. Uric acid, TGSH, AA and α-tocopherol significantly increased immediately after the game whereas total polyphenols decreased and total carotenoids remained unchanged. GSSG and GSH:GSSG ratio returned to baseline at 21 h whereas D-Roms levels remained unchanged. Uric acid, TGSH and AA returned to baseline 21 hrs after the game. In contrast, total polyphenols remained significantly reduced whereas α-tocopherol remained elevated. Significant increases above baseline were observed in total carotenoids only at 21 h.

Conclusion

A soccer game in elite female soccer players induced a transient increase in GSSG and reduction in GSH:GSSG ratio accompanied by a robust response of the antioxidant defence systems. The orchestrated endogenous and dietary antioxidant responses in well-trained players helped to prevent the occurrence of lipid peroxidation after a soccer game. These results differ from that observed following soccer games in males where increased lipid peroxidation occurred for several days following the game (Ascensao et al., 2008; Ispirlidis et al., 2008). The differences may be related to the antioxidant functions of the female hormone estrogens. Furthermore, as polyphenols are only found in the circulation and not stored in the tissue, we suggest that the reduction in polyphenols following the game may be used as a marker of increased free radical production.

THE SHORTEST TIME TO REACH MAXIMAL OXYGEN UPTAKE WITHOUT PRIOR WARM UP IN PROFESSIONAL SOCCER PLAYERS

GATTERER, H., FAULHABER, M., KLAUSNER, F., BURTSCHER, M.

UNIVERSITY INNSBRUCK

Introduction: In very heavy exercise, preceded by adequate warm-up, VO2max and HRmax can be attained within one minute (Astrand et al., 2003). However, with a restricted warm up, VO2 during short exhaustive treadmill runs of ~2min duration (i.e. 800 m run) was shown to plateau at different levels below VO2max depending on pacing strategies (Sandals et al., 2006). The question arises about the shortest time to achieve VO2max with optimal pacing and without a preceding warm up.

Methods

Eight professional male soccer players, accustomed to sprint training, performed a progressive paced field test to exhaustion consisting of two laps on a track (first lap 50%, half lap 70% of the self estimated maximal performance capacity followed by an all-out sprint to the finish line) and an incremental treadmill test (work increments of 1 km/h per minute). Oxygen uptake, minute ventilation and heart rate

were measured with a portable spirometric-telemetric device (Oxycon mobile, Jäger, Germany). In the 3rd minute after cessation of work, blood lactate concentrations were determined.

Results: The highest VO2 values in the field test were achieved after 230±17s. When using 30 s averages of data collection VO2max values differed significantly between the field and the lab test, however no differences were found for the 15 s averages (r=0.824 ($p<0.05$)). The total errors of estimation for the field test were 2.6 and 1.8 ml/min/kg for the 30 and 15 s averages, respectively. Lactat concentrations in the lab test were significantly lower than in the field test.

Discussion: These results demonstrate that a test duration of approximately 230s without warm up is sufficient for eliciting VO2max in professional soccer players, provided a progressive pacing strategy is applied. An explanation for the rapid attainment of VO2max may be that the relative intensive "warm up" run (first 1.5 laps) speeds up (Gerbino et al., 1996) or increases the primary VO2 response amplitude (Burnley et al., 2001) of the 200 m run to exhaustion. Furthermore the progressively increasing speed in contrast to other pacing strategies lengthens running time so that the slow component of the VO2 increase can occur and possible O2 delivery limitation due to reduced muscular temperature or pH changes is avoided (Burnley et al., 2001).

PRE-SEASON CORRELATIONS BETWEEN SPRINT, 1RM AND RUNNING ECONOMY IN PROFESSIONAL SOCCER PLAYERS

NYMARK, B.

LILLEHAMMER UNIVERSITY COLLEGE, NORWAY

Pre-season correlations between sprint, 1RM and running economy in professional soccer
players

Bernt Sivert Nymark1, Bent Rønnestad1 and Truls Raastad2

1Lillehammer University College, Lillehammer, Norway

2Norwegian School of Sport Sciences, Oslo, Norway,

Strength training has the potential to improve sprint performance and running economy in athletes[1,2], but it is uncertain whether it is the increase in maximum strength per se or other factors affected by strength training which accounts for these findings. Therefore, the aim of this study was to investigate the relationship between strength in leg extensors, measured as one repetition maximum (1 RM) in squat, and sprint abilities as well as running economy in professional soccer players.

METHODS: Fifteen professional Norwegian soccer players (±SD) age 25±5 years, height 184±5 cm, weight 77.3±7.8 kg and maximal oxygen uptake 64.2±5.0 ml·kg-1·min-1 (range: 56.4-71.4 ml·kg-1·min-1)

were tested for 1 RM in half squat, sprinting performance (0-40m) and running economy, measured while running on 5.5% incline at 10 km/h.

RESULTS: The 1 RM in half squat was 149.2 ±17.3 kg (range: 100-180kg), 10m sprint time was 1.78±0.06 sec, 30-40 meter sprint time was 1.16±0.05sec and total sprint time (0-40m) was 5.37±0.16sec. Relative strength in half squat (1RM/body weight) was correlated with both 10m

acceleration (r=0.70) and total time on the 40m sprint (r=0.75). Running economy was 47.2±0.6 ml·kg-1·min-1 (range: 0,265-0,303). Relative strength in half squat was not correlated with running economy (r=0.16).

DISCUSSION: The results of this study confirm that relative strength is important for performance in activities like sprint where athletes accelerate their own body weight [1]. Earlier studies [2,3] has indicated that an increase in 1RM increase running economy. However, in the present study running economy was not correlated with 1RM. This might indicate that maximal

strength per se is not important for running economy. It may be that the rate of force development (RFD) and muscle-tendon stiffness are more important for running economy than maximum strength. A tight musculo–tendinous system, and consequently a higher degree of stiffness, may be advantageous for running economy and strength training has been

reported to increase muscle-tendon stiffness [4]. In conclusion, our results confirm that relative strength in leg extensors is important for the performance in sprint, but no relation was found between relative strength and running economy.

COMPARISON BETWEEN SOCCER AND BASKETBALL PLAYERS IN STRENGTH, AEROBIC AND ANAEROBIC CAPACITY

SOTIROPOULOS, A., ALEXIOU, V., JAMURTAS, A.

UNIVERITY OF THESSALY

The aim of this study was to compare the strength, aerobic and anaerobic capacity of elite soccer and basketball players prior to the beginning of a pre-season training period. Thirty nine soccer players (S) and thirty basketball (B) players participated in an exercise capacity assessment two days prior to the beginning of their pre-season training. Their strength (quadriceps and hamstrings) was assessed in an isokinetic apparatus, the aerobic capacity using a metabolic cart and their anaerobic capacity via the wingate test. The anaerobic capacity was assessed first, then the strength and finally the aerobic capacity. The results showed that there was no difference between the two groups in anaerobic (S = 10.66 + 1.0 W/kg, B = 10.28 + 1.0 W/kg) and aerobic capacity (S = 52.1 + 4.8 ml/kg/min, B = 50.5 + 4.3 ml/kg/min). However, there was a significant difference between the two groups in hamstring strength, with the S exhibiting higher relative values compared to B. The fitness level of both players was not at a high level and this is something that trainers should give a closer attention.

REDUCTION IN HIGH INTENSITY ACTIVITY DURING SENIOR ELITE RUGBY LEAGUE MATCHES

SYKES, D., TWIST, C., LAMB, K., NICHOLAS, C.

UNIVERSITY OF CHESTER

Introduction: The amount of high intensity activity (HIA) performed by players has been shown to discriminate between playing standards in soccer (Mohr et al., 2003). Moreover, irrespective of playing standard, fatigue during competitive match play will manifest itself as a reduction in HIA during the final 15 min of play (Mohr et al., 2003). However, in the only study to-date investigating the changes in movement intensities in competitive rugby league (RL) matches, the researchers reported findings that were inconsistent and seemingly dependent on playing standard (Sirotic et al., 2009). Therefore, the aim of the present study was to clarify the changes in movement intensities observed during senior elite RL matches.

Methods: Following ethical approval, a semi-automated match analysis image recognition system (ProZone 3, ProZone®, Leeds, England) was used to track players (n = 78) during three senior elite matches. The players' movements were classified into locomotive categories of standing: <0.2 m/s; walking: 0.2-1.9 m/s; jogging: 2.0-3.9 m/s; running: 4.0-5.4 m/s; high intensity running: 5.5-6.9 m/s and sprinting: ≥ 7 m/s (low intensity activity – LIA: 0-3.9 m/s; HIA: ≥ 4.0 m/s). The distance covered in each of the locomotive categories was calculated per half, for every 20 min of the match and for the whole match. To prevent the effects of clock stoppages, only data obtained from the first 40 min of each half was used for analyses.

Results: Distances covered in running and sprinting were significantly lower in the second half in comparison to the first ($P<0.05$). Furthermore, mean distance covered in HIA was 14.4% lower in the second half (708 ± 146 m) than the first (827 ± 117 m; $P<0.05$). In addition to a reduction in HIA during 20-40, 40-60 and 60-80 min compared to 0-20 min, there was also a reduction in HIA during 60-80 min compared to 40-60 min ($P<0.05$). Conversely, mean total distance covered was only 1.4% (-56 m) lower in the second half due to HIA accounting for only 24.1% of the overall distance covered and a non-significant 2.0% increase in LIA in the second half ($P>0.05$).

Discussion: The finding of this study that senior elite players exhibit an inability to maintain HIA in the second half (- 14.4%), especially toward the end of a match (60-80 min), is in-line with previous research reporting significant reductions in running and sprinting in the second half of senior elite RL matches (Sirotic et al., 2009). Furthermore, evidence from the current study suggests distance covered in HIA is more effective at detecting fatigue than total distance covered. Therefore, coaches should implement appropriate training interventions to ensure that players are capable of maintaining HIA for the duration of a match.

A COMPARISON OF EXERCISE PERFORMANCE USING DIFFERENT TYPES OF ERGOMETERS IN COMPETITIVE CYCLISTS, RUNNERS, ROWERS AND SWIMMERS.

MICHAELIDES, M., LOUCAIDES, G., NICOLAOU, K., SCHIZAS, K., HADIGEORGIOU, M.

CYPRUS SPORT ORGANIZATION

PURPOSE: The purpose of the study was to compare physiological responses during different modes of maximal exercise testing.

METHODS: Twenty competitive athletes and five recreational athletes performed incremental exercise tests using Bicycle, Treadmill, Rowing and Swim-Bench Ergometers.

Physiological variables (O2 max , O2 pulse , Anaerobic Threshold, Maximum Lactate, Heart Rate, Blood Pressure , R. Q ,) were measure using a Quark b2 gas analyzer, Polar Heart Rate monitors and a Dr. Lange lactate analyzer). Blood lactate was measure post-exercise. Outcome variables were analyzed with repeated measures ANOVA.

RESULTS: The data suggested differences in measured variables obtained using different modes of exercise. Caution is suggested when training guidelines and physiological assessment is made with athletes of different event specialization tested on various exercise modes.

THE EFFECT OF CARRYING A PORTABLE RESPIRATORY GAS ANALYSIS SYSTEM ON ENERGY EXPENDITURE DURING RUNNING

SPARKS, S.A., ORME, D.

EDGE HILL UNIVERSITY

Introduction: Improvements in respiratory gas analysis technology have made the availability of portable gas analysers widely available. Previous studies have shown that the majority of these systems are a valid and reliable method of determining respiratory responses during intense (Meyer et al., 2005) and light exercise (Ingle et al., 2007). Whilst these systems have been widely used, little is known of the impact on energy expenditure (EE) on individuals that are required to carry them during exercise bouts. Method: Eight male participants of mean (SD) age 25.0 (9.47) y, body mass 78.5 (8.39) kg, and height 1.83 (0.08) m, completed two randomly ordered incremental exercise bouts on a motorised treadmill. Following a period of four minutes of standing, participants were required to walk at 4km/h for four minutes. Thereafter the treadmill increased in speed every four minutes in order to induce a variety of exercise intensity demands (7, 10, 12, 14, km/h and maximal exercise). The experimental trial required participants to complete the exercise bout whilst wearing a portable (PT) respiratory gas analysis system (Metamax 3B, Cortex, Germany) in a harness on the chest. During the control trial (CT) the weight of the gas analyser was supported by a harness adjacent to the treadmill. Throughout each exercise trial respiratory gases, heart rate (HR) and rating of perceived exertion (RPE) were measured. Respiratory gases were used to calculate EE via indirect calorimetry (Frayn 1983). All data were analysed using a General Linear Model ANOVA with Repeated Measures, significance was accepted at $p< 0.05$. Results: During the exercise bouts, the rate of EE increased as the intensity of exercise increased ($p<0.001$). There was a significantly greater rate of EE during PT between the running speeds of 7 – 14 km/hr ($p=0.048$), but no significant differences were observed during standing, walking or at maximal exercise ($p>0.05$). Conversely there were no significant effects of wearing the gas analyser on VO2 max. (4.10±0.53, and 4.28 ±0.75 for the LC and PT trials respectively), HR or RPE ($p>0.05$). Conclusion: The use of portable gas analysis systems have no effect on the energy expended during standing or walking for short periods, but caution may need to be taken, particularly if exercise bouts are both submaximal and prolonged in nature.

UPPER BODY AEROBIC AND ANAEROBIC CAPACITY IN CANOE AND KAYAK PADDLERS: ASPECTS OF AGE AND GENDER

HELLER, J., VODICKA, P.

FACULTY OF PHYSICAL EDUCATION AND SPORT, CHARLES UNIVERSITY,

Introduction: Canoe and kayak flat water paddling are upper-body sports that make varying demands for upper body aerobic and anaerobic capacity. There is only little evidence on the upper body aerobic and anaerobic capacity data in paddlers across the different age categories and/or males and females using the same methods and test protocols (Bishop, 2000). Therefore, the aim of the present study was to evaluate the physiological parameters obtained in upper body aerobic and anaerobic exercise tests in young (youngster, youth junior and junior) and adult (senior) trained male and female paddlers and evaluate the results from point of view of age and gender.

Methods: Altogether 306 elite flat water paddlers (99 female kayak paddlers, 135 kayak and 72 canoe male paddlers) were tested by a 30-s Wingate anaerobic arm test at a resistance load 4 W.kg-1 (=0.069 kg.kg-1) in males and 3.3 W.kg-1 (=0.057 kg.kg-1) in females, and an incremental maximum aerobic arm-cranking test. The results were compared in canoe paddlers and in male and female kayak paddlers in four age categories 13 to 14 ("youngster"), 15 to 16 ("youth junior") and 17 to 18 and years of age (junior) and in seniors (19 years and older), respectively. Statistics included correlation analysis and a 2-way ANOVA was used to determine the effects of gender and age.

Results: Maximum aerobic performance in male canoe and kayak paddlers increased from 13-14 to 15-16 age category and was not different in junior (17-18 years) and senior paddlers. However, in the anaerobic arm test, both peak power and mean power output increased with age from the youngest to the oldest age categories. These anaerobic capacity indices were strongly related to the amount of fat-free mass (PP: r= 0.69 and r= 0.62; MP: r= 0.72 and r= 0.71 for the canoe and kayak paddlers, respectively). In female kayak paddlers, the indices of upper body aerobic and anaerobic capacity also increased with age, however the differences among the age groups were smaller than in male paddlers. In contrast to male paddlers, in female kayak paddlers the upper body aerobic and anaerobic capacity indices (relative to body mass) were unrelated to the amount of fat free mass.

Discussion: The results of the present study seem to be comparable with the previous reported data in paddlers including gender differences in aerobic and anaerobic performances of paddlers (Bishop, 2000; Fry and Morton, 1999). It could be concluded that aerobic upper body capacity in canoe and kayak paddlers is increasing from the youngster to the junior age category. Higher upper body anaerobic capacity, lower body fat and a higher amount of fat-free mass may account for the main physiological differences between senior and junior flat water paddlers.

SECRET CLOCK MANIPULATION AFFECTS TIME-TO-TASK FAILURE DURING HIGH-INTENSITY EXERCISE

DE VRIJER, A., BISHOP, D.

UNIVERSITY OF VERONA

SECRET CLOCK MANIPULATION AFFECTS TIME-TO-TASK FAILURE DURING HIGH-INTENSITY EXERCISE

Introduction: Task failure is an important feature of performance, ageing and many diseases. While there is currently considerable debate regarding the principal cause(s) of task failure, some of the more popular hypotheses include a failure of skeletal muscle motor unit recruitment, the depletion of muscle energy stores, and metabolite accumulation (1). Recently, it has been suggested that exercise tolerance in humans may be limited by self-perceived ratings of exertion (2). As poorer performance has also been associated with the perception of time slowing (3), we decided to test the hypothesis that secretly manipulating the clock calibration would influence time-to-fatigue (TTF).

Methods: Eight healthy males each performed an incremental test on a cycle ergometer to determine their power at VO2max (P100%), followed by a familiarisation trial and 3 identical time-to-fatigue tests at P120%. During all tests a large digital clock with the time of the test was shown to the subjects. During test 3 and 4, the speed of the clock was either manipulated by a factor 0.9 (slow clock) or 1.1 (fast clock). The subjects were unaware of the time manipulation and the tests with the slow and fast clock were conducted double blind and in a random, counter-balanced order. Manipulated clock times were later converted to real times.

Results: Analysis of the results showed that TTF with the fast clock (182 ± 44 s) was significantly longer compared to the slow clock (156 ± 46 s). The average TTF of the normal clock was 168 ± 38 s and was not significantly different from the other two conditions. Heart rate at task failure was significantly higher in the trial with the fast clock (178 ± 7 bpm) compared to the slow clock (174 ± 10 bpm), but was not different from the normal clock (177 ± 9 bpm). There was no significant difference in VO2 between the three conditions (49.5 ± 5.5, 50.5 ± 5.5 and 49.8 ± 6 ml/kg/min for the normal, fast and slow clock respectively).

Discussion/Conclusions: The results show that subjects were able to increase TTF when they were looking at the fast compared to the slow clock. We hypothesise that the perception of time speeding may have motivated subjects to continue exercising. These results provide strong evidence that task failure is not only related to physiological factors, but is also influenced by perception. This has important implications for both research and for coaching.

TREADMILL EXERCISE ENHANCES ABCA1 EXPRESSION IN RAT LIVER

SAFARZADEH, A., GHANBARI-NIAKI, A., EBRAHIMI, M., RAHBARIZADEH, F.
TARBIAT MODARES UNIVERSITY

ATP-binding cassette transporters (ABCs) belong to a large family of the mammalian transmembrane transporters that play a crucial role in plasma HDL-C remodeling. The purpose of this study was to investigate the expression of ABCA1 in rat liver in response to treadmill exercise. Ten adult Wistar male rats (300-322 g) were used for this purpose. Animals were divided into control (n = 5) and Training (n = 5) groups. Training group was given exercise on a motor-driven treadmill at 25 m/min (0% grade) for 60min/day, 5 days/week for 12 weeks. Rats were sacrificed 48h after the last session of exercise. A portion of the liver were excised, immediately cleaned, washed in ice-cold saline, and frozen in liquid nitrogen for extraction of ABCA1 mRNA expression and ATP measurement. Plasma collected for plasma lipids, lipoproteins, apolipoprotein A-1, LCAT, and pre β-HDL measurements. Liver ABCA1 mRNA expression was significantly (P <0.024) higher in trained rats compared to control rats. Liver ATP concentrations remained unchanged. Plasma HDL-C and HDL2- C and, Apo A-1, pre ß-HDL, and LCAT concentrations were significantly higher in trained rats at the end of treadmill exercise. In conclusion, an elevated plasma HDL-C was accompanied by higher ABCA1 mRNA expression in liver tissue, Apo A-1, LCAT, pre β-HDL concentrations, but not in liver ATP concentrations.

EFFECT OF ENDURANCE AND RESISTANCE TRAININGS ON SALIVARY IGA, CORTISOL, DHEA AND DHEA: CORTISOL CONCENTRATION RATIO IN UNTRAINED FEMALES

HOSSEINI, M., YAZDANPARAST, B., FARZANEGI, P.
ISLAMIC AZAD UNIVERSITY BRANCH OF QYAMDASHT.,ISLAMIC AZAD UNIVERSITY: VARAMIN., ISLAMIC AZAD UNIVERSITY :SARI

Introduction:
Moderate, Regular physical training is associated with improved health including decreased blood pressure and body weight and possibly a decreased sensitivity to upper respiratory tract infection(URTI) (1).Mucosal immune of URT is the first defense of the body that by salivary IgA protect the body against the pathogenic factors(1,2). DHEA has anabolic effects on several tissues. excessive trainings increase DHEA concentration(3).
Methods: 28 untrained female students (aged; 24 2.58 yr, height; 161  8.2 cm, weight; 56.8  14.61 kg) were randomly divided into three groups; Control (C; n=8), Endurance (E; n=10), resistance (S; n=10). E training consisted of running %65 MHR for 16 minutes during the first week, reaching %80 MHR for 30 minutes during the 8th week. S training consisted of having four leg-press, bench-press, pull down curls, and legs curls. During the first week, the training were done at %50 1RM in two sets with 10 repetitions. The intensity of training was increased to %80 1RM in 3 sets and 6 repetitions, during the 8th week.
Before and after of 4 and 8 weeks of trainings unstimulated saliva samples were collected at 8 o'clock in the morning. Samples were assayed using an ELISA.
Results:
ANOVA for repeated measures showed IgA,DHEA and DHEA :cortisol ratio in S group compared with another groups had meaningful increase (p 0.05) that In between group comparison differences were meaningful .there was no alterations in cortisol concentration of groups and significant correlation was not found between IgA and cortisol (p 0.05).
Discussion: This finding indicated that resistance training by increasing IgA, DHEA and DHEA :cortisol ratio caused improvement of immune function and anabolic status of the body but had no effect on cortisol.

EFFECT OF ENDURANCE, RESISTANCE AND CONCURRENT TRAININGS ON THE HEART FUNCTION IN FEMALE STUDENTS

HOSSEINI, M., PIRI, M., AGHA ALINEJAD, H.
ISLAMIC AZAD UNIVERSITY BRANCH OF QYAMDASHT.,ISLAMIC AZAD UNIVERSITY BRANCH OF CENTRAL TEHRAN., TARBIAT MODARES UNIVERSITY

Introduction: Regular and long term training causes physiological adaptation of the heart that opposite pathological adaptation (2). impact of physical training on cardiac function depends on the type, intensity and duration of training as well as previous physical fitness, heredity and gender(1,3).
Methods:

39 untrained female students (aged; 25 2.8 yr, height; 165  7.2 cm, weight; 55.8  11.63 kg) were randomly divided into four groups; Control (C; n=9), Endurance (E; n=10), Strength (S; n=10) and concurrent (SE; n=10). E training consisted of running %65 MHR for 16 minutes during the first week, reaching %80 MHR for 30 minutes during the 8th week. S training consisted of having four leg-press, bench-press, pull down curls, and legs curls. During the first week, the training were done at %50 1RM in two sets with 10 repetitions. The intensity of training was increased to %80 1RM in 3 sets and 6 repetitions, during the 8th week. The SE training included a combination of two S and E training in the same manner of each respective group.

Pre and post of training heart rate, QT and PR intervals, the distance of ST segment from isoelectric line, deceleration time, ejection fraction percent measured by electrocardiography and echocardiography.

Systolic and diastolic blood pressure and vo2 max (through Bruce protocol and treadmill) also gauged.

Results: According to the finding of inter_group comparison, decrease of heart rate, systolic blood pressure and increase of PR interval, vo2max, decrease of diastolic blood pressure of endurance group was meaningful which in between group comparison in four parameters of first, differences were meaningful. (p 0.05) on the other hand, in resistance group, the parameters of heart rate and systolic blood pressure showed meaningful increase which in between group differences were meaningful. (p 0.05)

And in concurrent group parameter of vo2max, showed meaningful increase which in between group comparison this difference was also meaningful. (p 0.05) .

Discussion: It is suggest that performing of endurance training after resistance training creations combine of cardiac adaptation with due of endurance or resistance training alone and causes to eliminate some side effects of resistance training on heart.

DOES LEFT VENTRICULAR DIMENSIONS FURTHER INCREASE BY CONTINUING EXERCISE TRAINING IN ALREADY WELL-TRAINED ENDURANCE ATHLETES?

KINOSHITA, N., OGUMA, Y., KATSUKAWA, F., ONISHI, S., YAMAZAKI, H.

KEIO UNIVERSITY

Introduction: Left ventricular (LV) dilatation/hypertrophy is commonly observed in endurance athletes. However, there are few evidences about whether LV dimensions can further increase by continuing intensive training. The aim of the study was to evaluate long-term changes in LV dimensions in already well-trained athletes.

Methods: The subjects were Japanese 16 female middle/long distance runners (15-16 y/o) in a competitive high school team with the national level of achievements. They had had >3 years of experience as competitive runners before recruited but in the high school team the intensity and distance of running increased (at a speed of 12-20km/hr for 200-500km/month). Echocardiography, underwater weighing, blood and maximal exercise tests were performed mostly at the beginning of the first semester and repeated after 20+/-6 months. LV mass (LVM) was calculated according to Devereux RB, et al (1) and LVM and LV end diastolic dimension (LVDd) were indexed to height (ht)^2.7, body surface area (BSA), and fat free mass (FFM). The changes in variables were tested by paired t-test ($p<0.05$ was considered significant).

Results: Many had no or a few menstruations during the follow-up period. Ht, FFM, and maximal oxygen uptake (VO2max) significantly but slightly increased (159.5 to 160.3cm, 39.5 to 41.1kg, and 59.8 to 60.8ml/kg/min, respectively) and the records of 1500 and 3000m track races were significantly improved (4'50" to 4'42" and 10'18" to 9'59", respectively). There were no differences in weight (46.6 vs 47.2kg), fat% (14.9 vs 13.0%), hemoglobin concentration (13.0 vs 12.7g/dl), blood pressure (100/62 vs 99/61mmHg), and resting heart rate (55 vs 50 bpm). Although LVDd, LVM, LVM/ht^2.7, and LVM/BSA significantly increased (48.7 to 50.1mm, 135.2 to 146.2g, 38.4 to 41.1g/m^2.7, and 93.4 to 100g/m^2, respectively), LV septal/posterior wall thicknesses, LVDd/ht^2.7, LVDd/BSA, LVDd/FFM, and LVM/FFM did not change (8.2 vs 8.4mm, 8.3 vs 8.5mm, 13.8 vs 14.1mm/m^2.7, 33.7 vs 34.3mm/m^2, 1.24 vs 1.23mm/kg, and 3.44 vs 3.58g/kg, respectively).

Discussion: Body scales, particularly FFM, were the most powerful predictor for LV dimensions (2). The subjects trained hard enough to improve the performance but without substantial increase in body scales. Their energy availability should be low to become a/oligomenorrhea and they were supposed to be under the least hormonal influence. These backgrounds yielded an optimal model to evaluate the independent effect of training to the LV dimensions. They had already large left ventricles as compared to the former published data at the beginning and LVDd and LVM increased further by keeping training. However, the changes did not persist when indexed to FFM. In conclusion, LV dimensions hardly increase further beyond expected from FFM increase along with training continued in already well-trained athletes.

EFFECT OF INTERMITTENT HYPERCAPNIC GAS INHALATION ON VENTILATORY RESPONSE IN TRIATHLETES

KATO, T., SAKATA, Y., SUGIURA, Y., YAMASHITA, N., TSUKANAKA, A., MATSUMOTO, T.

TOYOTA NATIONAL COLLEGE OF TECHNOLOGY

Introduction: Hypercapnic stimulation has a strong power to ventilatory response. Therefore, the application of hypercapnic stimulation may provide a novel impact on sports training. We have recently demonstrated the physiological responses during exercise under hypercapnic condition (Kato et al. 2005, 2006, 2007). However, there is no study to address the effect of hypercapnic stimulation on sports training. Thus, the purpose of this study was to investigate the effect of hypercapnic stimulation on sports training, and we tested the intermittent hypercapnia (IHC) on ventilatory response in endurance athletes.

Materials and methods: Six male and one female triathletes volunteered to participate in the present study. As an IHC, each subject performed hypercapnic gas (21%O2, 3%CO2, N2=balance) inhalation for one hour each day for two weeks. Hypercapnic ventilatory response (HCVR) and hypoxic ventilatory response (HVR) were determined four times in each subject; 1) before IHC; 2) after one week of

IHC; 3) after two weeks of IHC; 4) one week after the cessation of IHC. The maximal exercise performance test was also carried out before and after IHC.

Results: HCVR and HVR did not significantly change throughout the experiment period. On the maximal exercise test, maximal minute ventilation tended to increase from 146.0 ± 29.0 l/min to 155.4 ± 34.2 l/min by IHC (P = 0.059). But maximal workload (255.7 ± 36.4 W vs. 255.7 ± 40.4 W), exercise performance (891 ± 109 sec vs. 904 ± 130 sec), VO2max (58.9 ± 7.4 ml/kg/min vs. 60.9 ± 8.1 ml/kg/min), maximal respiratory rate (67.9 ± 17.8 f/min vs. 71.7 ± 21.3 f/min), and maximal heart rate (188.3 ± 8.7 beats/min vs. 189.1 ± 8.2 beats/min) did not differ between before and after IHC.

Conclusion: Our present results suggested that IHC for two weeks may promote ventilation capacity, but could not lead to the change in HCVR and HVR.

Acknowledgements: This research was supported in part by a Grant-in-Aid for Young Scientists (B) from the Japanese Ministry of Education, Culture, Sports, Science and Technology (Grant No. 20700518).

EFFECT OF CONCURRENT TRAINING SESSION ON RECOVERY HYPOTENSION AND ITS HEMODYNAMIC AND NEURAL MECHANISMS

FORJAZ, C.L.M., TEIXEIRA, L., DIAS, R.M.R., MION JR, D., TINUCCI, T.

UNIVERSITY OF SÃO PAULO

Introduction: Post-exercise hypotension and cardiac sympathetic activation have been reported after a single session of aerobic as well as resistance exercise. Nowadays, concurrent training has been recommended for healthy maintenance. Nevertheless, the effects of the association between aerobic and resistance exercise on post-exercise hemodynamics and autonomic modulation have been poorly studied. Thus, the objective of this study was to evaluate the isolated and combined effect of aerobic and resistance exercise on post-exercise hypotension and its hemodynamic and neural mechanisms.

Methods: Twenty-three normotensive young subjects (12 men, 26±1 yr, 113±1/75±1 mmHg) were submitted to 4 experimental sessions: Control (C) - seated rest; Aerobic exercise (A) – cycle ergometer, 30 min, 75% of VO2peak; Resistance exercise (R) – 6 exercise, 3 sets, 20 repetitions, 50% of 1RM; and aerobic followed by resistance exercise (AE). Before and after each intervention, blood pressure (BP- auscultatory), heart rate (HR – ECG), cardiac output (CO - CO2rebreathing), and HR variability (HRV- spectral analysis) were measured. Data were compared by a 2-way ANOVA for repeated measures. Data are shown as mean±SE.

Results: Systolic BP decreased significantly after all the exercise sessions, and this decrease was similar between A and AR (A=-12±1 and AR=-11±1 mmHg), and greater than at R (-7±1 mmHg). Diastolic BP decreased significant and similarly in all exercise sessions. CO decreased similarly in all the exercise sessions, while systemic vascular resistance (SVR) increased in all the sessions, but this increase was greater in AR than in R and A (AR=+7±2 vs. R=+4±1 and A=+4±1, $P<0.05$). Stroke volume decreased in all the exercise sessions, and this response was significantly greater in the AR than in the other sessions. On the other hand, HR and cardiac sympathovagal balance increased in all the exercise sessions, and these responses were also greater in the AR session (AR=+22±2 vs. R=+15±2 and A=+15±2 bpm, and AR=+1.4±0.2 vs. R=+0.9±0.2 and A=+0.9±0.2, respectively, $P<0.05$). In the C session, most of the variables did not change after intervention, except for SVR and diastolic BP that increased significantly.

Conclusion: The association of aerobic and resistance exercise in the same training session do not produce any increase in post-exercise hypotension, but this association results in a greater and longer maintenance of cardiac sympathetic activation and tachycardia during the recovery period. Since blood pressure lowering reflects a reduction in cardiovascular risk, but cardiac sympathetic activation reflects an increase in this risk, the association of aerobic and resistance exercise brought out a controversial effect on cardiovascular risk that might be considered when thinking in concurrent training for subjects with cardiovascular disease or risk factors.

PHYSIOLOGICAL REPONSE DURING TIME LIMIT AT VO2 MAX PLATEAU.

PETOT, H., HAMARD, L., SARRE, G., BILLAT, V.L.

UBIAE UNITÉ INSERM 902, LEPHE EA 3872

According to Hill and Lupton (1923), during a physical test, subject had 1) an upper limit to oxygen uptake and 2) this VO2 max was limited by ability of the cardio respiratory system to transport O2 to the muscles. But, actually, only 50% of the subjects showed a plateau of VO2 at the end of a graded exercise test(Howley. and al 1995). In addition, if the subject had a poor anaerobic capacity, the v peak and the V VO2 max were the same. In fact, the subject stopped the exercise because he attained the V peak and not because he attained the v VO2 max. he hadn't a VO2 max plateau(Noakes. 1998);

In other hand, Billat et al 2000 showed that all the subject had a plateau of VO2 max if they did a test between 90% and 140 % PMA. In addition, it was possible to obtain a plateau of VO2 max more longer if the subject did a intermittent test (Billat. and al 1999). But, this test was very difficult and we didn't controlled exactly the VO2 at the upper limit.

We put forward the hypothesis that the plateau at VO2max can be maintained more longer significantly, reducing the power after VO2 maximum achievement. The delay of exhaustion at VO2 max does not depend on cardiac output but on the power output.

They realized 3 tests on ergocycle in moderation of the VO2. The first one was a test raised to determine the VO2max, the power in the lactic threshold (Psl) and the smallest power that elicit VO2max (PMA).

The second one was a test of limited time at VO2max with variation of the power. The initial power was PMA, then from VO2max reach, the power was adjusted to maintain the VO2 to it maximum as long as possible. Finally the last test was a time limit to maintain PMA with no variation of the power.

The time limit at VO2max during the second test was significantly longer than the time limit at VO2max during the PMA test ($p=0.0057$). On the other hand, stroke volume and the cardiac frequency were not significantly different between the second and the third test. Furthermore, the average power of VO2max plateau during the second test corresponded to the power at lactate threshold which represents 80% of PMA.

We showed that decreasing the muscular mechanical demand allowed to maintain the VO2max for 15 min 57 sec +/- 6 min 6 sec, in men and women of different fitness levels.

The physiological response during a VO2 max plateau were correlated with the power and not with the cardiac output.

These results thus open towards new training protocols , which remain to be defined, allowing to work on VO2 max much longer while decreasing the risks of damage and the recovery time.

EFFECTS OF PRE-SLEEP INTENSIVE EXERCISE ON SLEEP IN YOUNG MEN

KOHEI, S., YUGO, U., YUKIKO, N., HIKARU, T., KAZUSHIGE, G., SUNAO, U.

WASEDA UNIVERSITY

Introduction: There are various researches concerning the effect of aerobic exercise on sleep (Youngstedt et al. 1997 ;Dworak et al. 2008). However, few researches have been conducted with focus on the effect of anaerobic exercise. The purpose of the present study is to examine the effect of high-intensity exercise on sleep components evaluated by electroencephalogram (EEG).

Method: Seven male adults participated in the experimental condition consisting of three consecutive days. The first night was set for acclimatization. Subsequent two nights were set as "no-exercise day (second night, control condition)" and "exercise day (third night, exercise condition)", respectively. On the exercise day, the subjects performed ten sets of 5 sec maximal pedaling exercise with 25 sec rest periods between sets. An applied load for maximal intermittent exercise was equivalent to 7.5 % of each subject's body weight. The exercise was then repeated after 30 min. Respiratory parameters and blood lactate concentration were measured before and after exercises. During sleep (bedtime from 23:30-07:30), EEG, heart rate, and rectal temperature were continuously recorded.

Results: Exercise caused acute increases in resting oxygen uptake, blood lactate concentration, and heart rate ($p<0.01$). The average of maximum heart rate during exercise was 172 bpm. At the point before bedtime, heart rate was significantly higher in the exercise condition than in the control condition ($p<0.05$). However, no significant differences were observed in sleep variables (i.e., sleep efficiency, sleep onset latency, REM latency, sleep stages) between control and exercise condition.

Conclusion: Although intensive exercise showed significant increase in heart rate immediately before bedtime, it did not affect sleep variables. These results suggest that intensive exercise during the night does not have strong impact on sleep in young individuals.

CHANGE IN BLOOD PROPERTIES BEFORE AND AFTER CLIMBING OF HIGH MOUNTAINS

KOHNO, T., FUJIYA, H., YATABE, K., SUGA, E., TERAWAKI, F.

ST. MARIANNA UNIVERSITY SCHOOL OF MEDICINE

High mountain climbing places a great deal of stress on climbers. Body composition and blood tests before and after climbing were examined in climbers who scaled 8,000m or higher two times over a two year period.

Methods: Examinations were conducted on four climbers: A (26 years old), B (27), C (28) and D (29). Body weight and body fat were measured. Particular items involved in the blood test included measuring red blood cell count (RBC) and haemoglobin (Hb), hematocrit (Ht), serum iron, ferritin, total cholesterol, triglyceride, and total protein levels.

Results: The mean RBC (106/mm3) levels before and after climbing were 4.87±0.14 and 5.73±0.49 ($p<0.05$), respectively. The mean Hb (g/dl) levels before and after climbing were 15.4±0.60 and 17.6±1.3 ($p<0.05$), respectively. The mean Ht (%) levels before and after climbing were 45.6±0.8 and 53.0±4.4 ($p<0.05$), respectively. In looking at each subject on an individual basis, we found that although in three of the subjects the figures for Hb, Ht, and serum iron had all increased after high mountain climbing; in one of the subjects we were unable to find any significant changes in these indices between before- and after-ascent levels.

Discussion: In a hypoxic atmosphere, oxygen-carrying capacity decreases. Because of this, hematopoietic function becomes hyperactive to improve oxygen-carrying capacity and as a result RBC increases. In all of these two times of climbing, 4 climbers stayed at more than 2,500m for more than 60 days, and generally gained altitude during the period and finally reached more than summit of 8,000m. We did a blood test for three to four weeks after descending to less than 2,500m, and three out of four climbers had an increase of RBC compared to what they had before climbing and also had an increase in Hb, Ht and serum iron. Three to four weeks after descending the mountain, the effects of high altitudes were still apparent. Their reticulocyte count decreased after going down the mountain, which means there was no hyperactivity of the hematopoietic function at this time.

On the other hand, the fourth climber didn't see any changes in RBC, Hb, Ht and serum iron after descending the mountain, compared to before climbing. He also didn't have experience any changes in reticulocyte count before and after climbing. This means he didn't have any changes of hematopoietic function in a hypoxic atmosphere. However, there was no decreased ability to exercise and he succeeded in climbing to more than 8,000m two times. This means there was no decreased ability to exercise in a hypoxic atmosphere.

Conclusions

Under low oxygen and low pressure conditions the effects of climbing activity showed themselves in the increase after climbing rates of RBC, Hb, and Ht. We did, however, see individual differences among the subjects regarding these increases.

HEMATOLOGICAL RESPONSES TO TWO DIFFERENT INTERMITTENT HYPOXIC TRAINING REGIMENS

DEBEVEC, T., AMON, M., KERAMIDAS, M.E., KOUNALAKIS, S.N., MEKJAVIC, I.B.

INSTITUTE JOZEF STEFAN

Introduction: Hypoxic training has been reported to enhance athletes' altitude and sea level performance by augmenting oxygen carrying capacity of the blood, as a consequence of increases in hematocrit (Hct) and hemoglobin (Hb) concentrations (Friedmann-Bette, 2008). However the effect of intermittent hypoxic training on hematological responses remains unresolved (Muza, 2007). The present study investigated the effect of two intermittent hypoxic training regimens on the response of hematological indices.

Methods: Twenty seven healthy male subjects (mean+SD age=21.5 ± 3 yrs, height=181 ± 5 cm, body mass=74.8 ± 8 kg, VO2max= 47.8 ± 7.5 ml•kg-1•min-1) were equally assigned to either a control group (CON), a live low-train high (LL-TH) or a intermittent hypoxic exposure (IHE) group. All subjects conducted a 1 hour submaximal endurance exercise on a cycle ergometer, 5 days per week for 4 weeks, at an intensity corresponding to 50% of normoxic peak power output (PPO) for the CON and IHE groups, and to 50% of hypoxic PPO for the LL-TH group. Thus, all groups trained at the same relative work rate. The absolute work rate during the training was 18-20 W lower for the LL-TH group compared to the CON and IHE groups. All groups lived at an altitude of approx. 300 m above sea level. The CON and IHE groups also trained at this altitude, whereas the LL-TH group performed their training in a hypoxic chamber, breathing a hypoxic mixture (FIO2=12%). In addition to the daily exercise training, the IHE group also inspired a hypoxic gas mixture at rest, prior to the cycle ergometry. The intermittent hypoxic training comprised breathing a hypoxic mixture during 7 phases. Each phase consisted of 5-min breathing a hypoxic mixture, followed by 3-min breathing a normoxic gas mixture. Prior to, during, at the end, and ten days after the training period, blood samples were taken from all subjects in order to measure Hb, Hct, Erythrocytes, Ferrittin and Transferrin concentrations. The blood analyses were performed using the cythochemical impedance method (Pentra120; Horiba ABX Diagnostics) for hemogram, and the turbo-bidiametrical method (Hitachi 912; Roche Diagnostics) for transferrin analysis.

Results: No significant differences were observed between groups in any measured hematological variables. Similarly, no significant differences were found within groups at different testing periods.

Discussion: Although it has previously been reported that both LL-TH and IHE protocols provide hematological benefits (Hamlin and Hellemans, 2007; Hendriksen et. al 2003), this was not confirmed by our study. The tested protocols did not induce any changes in the measured hematological variables; therefore no improvements of the oxygen carrying capacity of the blood should be expected following this type of hypoxic training.

OXYGEN CONSERVATION BY THE DIVING RESPONSE IMPROVED AFTER 2 WEEKS OF APNEA TRAINING

LODIN-SUNDSTRÖM, A., ENGAN, H.,3, RICHARDSON, M., SCHAGATAY, E.,2

1 DEPT OF ENGINEERING AND SUSTAINABLE DEVELOPMENT, 2 SWEDISH WINTER SPORTS RESEARCH CENTRE; 3 DEPT OF HUMAN MOVEMENT SCIENCE. FACULTY OF SOC. SCIENCE AND TECHNOLOGY MANAGEMENT, NTNU, TRONDHEIM, NORWAY

Introduction: Physiological long-term effects of apnea training have previously been demonstrated, including an increased cardiovascular diving response (Schagatay et al 2000), but the effect of this improved diving response on arterial oxygen saturation after apneas has not been studied. Another response to apnea is spleen contraction and elevation of haemoglobin concentration (Hb), but it is not known from any longitudinal studies whether this response can be altered by training. We aimed to reveal if 1) two weeks of apnea training increases cardiovascular and spleen responses during apnea, and 2) if any effects result in a higher SaO2 after apneas of the same duration after training – which could indicate adaptive changes e.g. by an increased diving response-related oxygen conservation or enhanced splenic erythrocyte ejection.

Methods: Four females and 6 males of mean age 25 years performed 10 apneas per day for at least 12 days within a 2-week period. Apneas were divided into two series of 5 maximal duration apneas with resting pauses of 2 min, and with 10 min rest between series. Each apnea was preceded by 1 min of hyperventilation in order to maximize duration, which was recorded for all training apneas. Before training, subjects performed a test including 3 maximal duration apneas without hyperventilation. After the training period subjects performed one series of 3 apneas mimicking the duriations from the pre-training test as well as one series of maximal duration apneas, in weighted order and spaced by 20 min of rest. Heart rate (HR), venous Hb, SaO2 and spleen volume (ultrasonic imaging) were recorded.

Results: After training, maximal apneic duration had increased from 142 sec to 185 sec (by 30 %; $P<0.01$). Self-recorded durations indicated a steady increase until training day 8. The phase without CO2-induced involuntary breathing movements had increased by 20 sec during maximal duration apneas (22%; $P<0.05$). Apneic HR had decreased after training by 12 % in the time-mimicked series ($P<0.01$). SaO2 after apnea was 84% before training but 89% after the time-mimicked apneas after training ($P<0.05$). In the maximal apnea series after training SaO2 was 72 % ($P<0.05$). Spleen contraction and Hb increase during apnea tended to be attenuated in the time mimic series, but were of a similar magnitude in the maximal duration series after training.

Discussion: The cardiovascular diving response was increased after apnea training in accordance with previous studies (Schagatay et al 2000). As no increase of the spleen contraction or Hb increase was observed after the training, we concluded that the elevated SaO2 after the time mimic apneas indicates improved oxygen conservation by the enhanced cardiovascular diving response. The 2-week apnea-training period may have been too short for adaptive changes in spleen contraction to occur.

EFFECT OF FATIGUING PEDALING EXERCISE AT MAXIMAL POWER ON NOCICEPTIVE WITHDRAWAL REFLEXES IN THE UPPER AND LOWER LIMB MUSCLES

FUMOTO, M., SASADA, S., FUTATSUBASHI, G., MIYAO, J., KOMIYAMA, T.

1. SEIWA UNIVERSITY, 2. TOKYO GAKUGEI UNIV, 3. CHIBA UNIVERSITY, 4. CHIBA UNIVERSITY

High-intensity electrical stimulation of peripheral nerves can give rise to withdrawal reflexes, which are thought to be protective reflexes involving coordinated muscle contractions meditated by polysynaptic pathways. To date, it remains unknown how muscle fatigue modifies the withdrawal reflex. Therefore, we investigated the effect of fatiguing pedaling exercise (PE) at maximal power on the nociceptive withdrawal reflex (NWR) in the upper and lower limb muscles in the present study. NWR was elicited by delivering electrical stimulation (1 ms duration) to the superficial radial nerve at the wrist (SR, 4 pulses at 250 Hz) and the sural nerve at the ankle (Sur, 8 pulses at 250 Hz). Stimulus intensity was set at 7–10 times the perceptual threshold, which was sufficient to induce a painful sensation at each innervation area. Electromyographic (EMG) signals were recorded from the right brachioradialis (BR) and biceps femoris (BF) muscles with bipolar surface electrodes. Subjects performed three sets of PE using a bicycle ergometer (Power Max VII, Combi Co Ltd., Japan) with ~10 min rest. One set of PE consisted of five bouts of pedaling for 7 s at maximum effort, and the PE was repeated five times with 40-s intervals. The PE load was determined beforehand using the built-in program of the ergometer to perform maximum power. During the rest period, blood lactate was measured with a conventional sensor (Lactate pro, Arkray Co Ltd., Japan). NWRs were elicited before and immediately after three sets of PE. The level of pain sensation for the electrical stimulation was measured by visual analogue scale (VAS, 100 mm). We found that the magnitude of NWR for BR was significantly increased after the first set of PE. This increase was retained after the second and the third sets. In contrast, the magnitude of NWR for BF did not show any significant change. The level of blood lactate before the first set of PE was 2.2±0.8 mmol/l and increased significantly after the first set of PE (12.2±0.6 mmol/l), reaching a plateau thereafter (15.1±1.1 mmol/l). The VAS for SR stimulation tended to increase after the first set of PE, and this increase was retained after the second set of PE. Interestingly, both the VAS for SR stimulation and the magnitude of NWR for BR returned to the pre-PE level 20 min after the end of the third set of PE with a similar time course. These results suggest that fatiguing PE at maximal power increases NWR in non-exercising upper limb muscles.

MODULATION OF MOTOR REFLEX EXCITABILITY IN MONOSYNAPTIC CIRCUITS DURING DOSED MUSCLE EFFORT

POVARESCHENKOVA, Y., EKATERINA ANDRIYANOVA, E., PETROV, D., LAPCHENKOV, A.

VELIKIYE LUKI STATE ACADEMY OF PHYSICAL EDUCATION AND SPORTS

Introduction. Most researchers study the peculiarities of the spinal control of excitability of leg muscles in the athletes specializing in cyclic sports requiring endurance. The change of motor neurons excitability of leg muscles was studied at an isometric assigned effort. Multisegmental monosynaptic responses (MMRs) were evoked (G Courtine et al., 2007) by stimulating afferent fibre roots of the peripheral nerves between the T11-Т12 spinous processes to evaluate alpha-motoreuron reflex excitability.

Methods. Ski-racers and racing cyclists aged 20, with the height of 175 sm and weight – 68 kg, who have achieved some results in sports, took part in the research. The athletes (adapted to endurance work) made an isometric effort in the ankle joint.

The subject was seated with the right leg fixed at 110° of the knee and 90° of the ankle joints; the left foot was propped with the knee and ankle joints at 90°. An electric stimulus of 80 mA was delivered at sustained muscle effort of 25%; 50%; 75% of the maximal and during a maximal isometric effort performance in a sitting position. The period of the applied stimulation was 1 minute. The MMR amplitude and latency of the shin and rectus femoris muscles were registered.

Results. The latent period of MMRs of the proximal leg muscles is shorter than that of the distal ones at rest, which is consistent with the original method data (G Courtine et al., 2007) and proves the identity of the monosynaptic reflex nature.

It is determined that the MMR amplitude of rectus femoris, medial gastrocnemius, tibialis anterior and soleus of the right leg, an active one, increases with growth of effort, and the latent period has some tendency to shortening. At the same time some of the subjects demonstrate a decrease of alpha-motoneuron reflex excitability of the inactive leg muscles while others have some increase. The subjects of the research showed significant differences of quantitative changes of the MMR amplitude of the muscles studied.

Discussion. The received results allow to assume that modulation of alpha-motoreuron reflex excitability of leg muscles is defined by a degree of the applied effort, a function of the leg in the test task (active/inactive), motor preferences (the right leg is pushing off or swinging) and peculiarities of muscle interaction during the motor task.

CORTICO-SPINAL MODULATION OF ANTAGONIST COACTIVATION DURING DIFFERENT INTENSITIES OF CONTRACTION

LEVENEZ, M., GROSBELLET, X., DUCHATEAU, J.

UNIVERSITÉ LIBRE DE BRUXELLES

Introduction: During a voluntary contraction of a muscle group, antagonist muscles are usually active. This concurrent activation is referred to as coactivation. The aim of the current study was to investigate the control mechanisms, at cortical and spinal levels, of antagonist coactivation during different intensities of contraction of the ankle dorsiflexor muscles.

Methods: Changes in surface electromyogramme (EMG) of the tibialis anterior and of two antagonist muscles, the soleus and medialis gastrocnemius, were investigated during ten different levels of contraction, ranging from 0 to 100% of maximal voluntary contraction (MVC). Furthermore, we recorded motor evoked potentials (MEP) in response to transcranial magnetic stimulation of the motor cortex, as well as the Hoffmann reflex (H-reflex) and maximal M-wave (Mmax) elicited by electrical stimulation of the tibial nerve.

Results: The results showed that the average EMG (aEMG) of the tibialis anterior and antagonist muscles, normalized to their respective MVC, increased linearly (r2=0.99; r2=0.97 and r2=0.97, respectively; P<0.001) with the augmentation of the agonist torque. While the MEP (normalized to Mmax) of the tibialis anterior increased (~ 71%; P<0.01) up to 60% MVC and then plateaued, the responses in both the soleus and medialis gastrocnemius increased gradually throughout the different intensities of contraction, respectively, from 3.8 ± 2.5% to 5.5 ± 2.2% (~ 44%; P< 0.01) and from 1.7 ± 1.1% to 3.4 ± 1.7% (~ 98%; P< 0.01). In contrast to the increase of the antagonist MEP, the H-reflex amplitude (normalized to Mmax) of the antagonist muscles declined linearly from 64.8 ± 12.6% to 8.7 ± 9.9% (P< 0.01) and from 22.9 ± 10.3% to 3.1 ± 1.9% (P< 0.001) in the soleus and medialis gastrocnemius, respectively. The Mmax evoked in both muscles did not change significantly.

Discussion: In conclusion, the results indicate that the level of antagonist coactivation increases linearly with the torque produced by the agonist muscles. Because the changes of the H-reflex were observed when the MEP and aEMG are increasing, the reduction in H-reflex cannot be due to a decreased excitability of the motor neurone pool of the antagonist muscles. In contrast, our results suggest that the decrease of the H-reflex in the antagonist muscles during the increased intensity of contraction of the ankle dorsiflexor muscles, is likely caused by modulation of presynaptic inhibitory mechanisms (Leonard et al., 1999; Stein et al., 2007).

MODULATION OF THE CUTANEOUS REFLEXES INVOLVING LOWER LIMB MUSCLES IN SUBJECTS WITH FUNCTIONAL INSTABILITY OF THE ANKLE JOINT

FUTATSUBASHI, G., SASADA, S., TAZOE, T., FUMOTO, M., KOMIYAMA, T.

1. CHIBA UNIVERSITY, 2. TOKYO GAKUGEI UNIV, 3. CHIBA UNIVERSITY, 4. SEIWA UNIVERSITY

Ankle sprains are known as one of the most common injuries in sports activities. Furthermore, ankle sprains frequently recur if not given adequate and continuous treatment. Many persons with ankle sprain complain of a degradation of the ability to control the ankle joint. We hypothesized that cutaneous afferents about the ankle joint and foot are influenced by ankle sprain with functional instability, hence cutaneous reflexes of the lower limb muscles may be modified in the subject with ankle sprains. Therefore, the present study investigated the extent to which cutaneous reflexes in the lower leg muscles are modified in subjects with ankle sprain who reported functional instability of the ankle. The participants were 9 males with unilateral ankle sprain and functional instability (5 right and 4 left). In addition, the Functional Instability Score which investigates pain, swelling, instability, stiffness and so on, was determined using the responses to a survey questionnaire. The subjects were asked to perform different levels of isometric dorsiflexion, plantarflexion and eversion while sitting (5 - 40% of maximum EMG amplitude). The cutaneous reflexes were elicited by applying non-noxious electrical stimulation to the sural nerve at the ankle joint (333Hz, 5pulses). Stimulus intensity was set to 2.5 times the perceptual threshold for all cases. EMG signals were recorded from both sides of the tibialis anterior (TA), medial gastrocnemius (MG) and peroneus longus (PL). The EMG signals were full-wave rectified and averaged (20 times). The middle latency component (~70-120msec, MLR) of the cutaneous reflex was analyzed by off-line analyses. For all muscles tested, an inhibitory MLR was identified on EMG following stimulation of the sural nerve. The amplitude of the MLR was well graded with the background EMG activity for all muscles. It is worth noting that in PL, the slope of the regression line between the magnitude of the MLR and background EMG activity was significantly increased on the injury side compared to that on the intact side ($P < 0.05$). In TA and MG, there was no significant difference between the slopes for the injured and intact side. These findings suggest that ankle sprain with functional instability may increase the excitability of the inhibitory MLR pathways for PL. Since PL has the functions of stabilizing and increase the stiffness of the ankle joint, an increase in inhibitory MLR may lead to instability of the ankle joint in response to tactile sensation given to the lateral margin of the foot.

CHANGES OF THE LATENT TIME OF H WAVE IN HUMAN GASTROCNEMIUS MUSCLE TO ARM CRANK EXERCISE AT DIFFERENCE OF EXERCISE INTENSITY.

SEKI, K., TAKAHARA, T., YAMAGUCHI, H., ONODERA, S.

KAWASAKI UNIVERSITY OF MEDICAL WELFARE

INTRODUCTION: The sthenia of the autonomic nervous system influences the activity of spinal cord α-MN. We defined that the interval between the latent time of M wave and H wave (loop time) of medial gastrocnemius (MG) significantly shortened after arm crank exercise which intensity was 60% peak oxygen uptake (ECSS 2006). Additionally, the loop time returned to the pre-exercise level with recovery examination. The loop time depended on change of cardiac parasympathetic nervous system activity. It is identified that the recovery examination of cardiac autonomic nervous activity is slower after high-intensity exercise than after low-intensity exercise. In addition, the difference of exercise intensity has an influence on activity of spinal cord α-motoneuron. The purpose of this study was to investigate the effects of low-, middle- and high-intensity arm crank exercise on the loop time in MG. METHODS: Nine young males volunteered to participate in this study. After the H-reflex was elicited at rest, subjects performed 10 min arm crank exercise trials at low- and middle- (30% and 60% peak oxygen uptake) intensity. High-intensity condition was encouraged until exhaustion. After exercise, subjects kept lying in a prone position, and H-reflex in MG was measured immediately after exercise and during recovery. We measured Heart rate (HR), cardiac parasympathetic nervous system (CPNS) modulation, rectal temperature (RT) and H-reflex. The analysis of CPNS modulation examined the R-R interval data for 30 seconds, which was calculated by the MemCalc methodology before each H-reflex. log HF was an index of CPNS modulation. The H-reflex was evoked by the electrical stimulation of the tibialis nerve in the popliteal fossa continuously for 10-20 times in all of once per four seconds interval. Analysis of the H-reflex signal showed an average 4-8 times wave patterns, the amplitude of the M wave was maintained the same. The latent time of M wave was not influenced by exercise. Therefore, we compared loop time. RESULTS and DISCUSSION: HR, log HF and RT indicated the response that depended on exercise intensity. Amplitude of H-reflex indicated that as much as exercise intensity becomes higher, variation trend cause large. The loop time of immediately post exercise was significantly shorter than loop time of the pre-exercise (P<0.05, middle condition, -0.30±0.27 ms; high condition, -0.50±0.28 ms), however the loop time of low condition did not short. The loop time gradually returned to the pre-exercise with the recovery examination (ANOVA: P<0.05, middle and high conditions). The loop time depended on exercise intensity with recovery examination and returned to a value before the pre-exercise from low intensity sequentially. Similarly, CPNS modulation and RT also depended on exercise intensity with recovery exami-

nation. These data suggests that recovery response of different to exercise intensity between CPNS modulation and RT has a meaningful influence on loop time.

USING TMS TO MEASURE THE EFFECT OF HYDROTHERAPY IN ATTENUATING CENTRAL FATIGUE FOLLOWING REPEATED EXERCISE.

PEARCE, A.J., CASSSAR, S., KIDGELL, D.J.

1. VICTORIA UNIVERSITY, 2. DEAKIN UNIVERSITY

Introduction: Hydrotherapies such as cold water immersion (CWI) and contrast hot/cold water therapy (CWT) are commonly used by athletes, following competition or training, to assist in the recovery process and to return the athlete to normative physiological state as quickly as possible. To date, investigations on recovery have focussed on peripheral variables to measure the effectiveness of hydrotherapies. Conversely, limited study has been completed to investigate the role of the central nervous system (CNS) fatigue (known as central fatigue) during the post-exercise recovery period. Using transcranial magnetic stimulation (TMS), we investigated the CNS in subjects following repeated exhaustive exercise bouts followed with hydrotherapy based recovery modalities.

Methods: Eight trained subjects (6 m; 20 to 35 years of age; mean VO2max 59.43 ± 3.73 ml.kg-1.min-1) participated in a cross-over design of three interventions (CWI, 12-14° C for 14 mins; CWT of alternating one min hot, 38 – 40° C, and cold immersion, 12-14° C, repeated seven times; and passive rest at room ambient temperature 22° C for 14 mins) following exhaustive performance conducted over five days. Measures included excitability of the CNS (motor evoked potential amplitude or MEP) assessed using TMS, time to fatigue (TTF) performance, blood markers for muscle inflammation (lactate dehydrogenase and c-reactive protein) and damage (myoglobin and creatine kinase), and visual analogue scales (VAS) for soreness and fatigue.

Results: No changes were observed with muscle damage or markers of inflammation when compared to pre-exercise values. All subjects, participating in all conditions, showed a progressive reduction in performance and MEP amplitude (p=0.04). However, greater cumulative decrements in TTF performance and MEP amplitude were demonstrated in the passive condition (30.8% decrease in performance by day five) compared to the CWI or CWT conditions (17.7% and 13.5% decrease by day five respectively). Further, MEP amplitude was associated with performance (r=0.83; p=0.01) and VAS for fatigue (r=0.75; p=0.01).

Discussion: Although no differences were observed between the two hydrotherapy conditions, the results showed that hydrotherapy modalities, compared to the passive recovery, were more effective in reducing repeated performance decrements and MEP amplitudes. However, immediate changes in MEP amplitudes post recovery were not observed.

EFFECTIVE RECOVERY STRATEGIES FOR ATHLETES RUNNING SEVEN MARATHONS ON SEVEN CONTINENTS IN SEVEN DAYS <7MM>

GLASGOW, P., GAMBLE, D., WEBB, M., JENNINGS, D., MADIGAN, S.

SPORTS INSTITUTE NORTHERN IRELAND

A blind athlete and his guide runner ran seven marathons on seven consecutive days on seven continents. The challenge involved circumnavigating the globe, travelling more than 35,000 miles through 24 time zones, experiencing widely variable environmental conditions (Range: 60C, 40% humidity to 370C, 90% humidity) and disrupted sleep patterns.

PURPOSE: To assess the effectiveness of recovery strategies during a unique extreme endurance event. METHODS: Indices of physiological and psychological stress and recovery were measured immediately before and after each marathon. Muscle condition, mood state, quality of sleep, appetite, mental and physical fatigue (scale: Fantastic, OK, Poor) as well as illness and injury (scale: 0=none, 5=extremely) were measured using a questionnaire. Blood creatine kinase (CK) levels were assessed prior to the start of the event, at the mid-point (pre-marathon 4) and at the end of marathon 7. Body mass (kg) and hydration (usg) were also measured. Recovery strategies incorporated: hydration and nutrition, ice bath immersion, pool sessions, massage, compression leggings and acupuncture. RESULTS: Following each of the marathons both athletes reported muscle condition as Poor or OK (Athlete 1 (A1), poor x 4; Athlete 2 (A2), poor x 3); however, prior to each marathon the athletes reported muscle condition as Fantastic or OK indicating an improvement in muscle condition. Similar improvements in mood state and fatigue levels were also observed; indeed physical fatigue levels improved from an average of 3.3 post-marathon to an average of 1.9 pre-marathon.

During the event both athletes gained between 1-2 kg body mass and hydration levels were maintained throughout (usg < 1.01). After an initial rise in CK levels from baseline (A1: 567 u/l vs. 2650 u/l and A2: 183 u/l vs. 2627 u/l) both athletes experienced a marked decline in CK levels by the end of the event (A1: 885 u/l, A2: 1639 u/l). CONCLUSION: These results reveal that the specific strategies employed enhanced recovery; muscle condition and fatigue were improved between marathons and, perhaps surprisingly, CK levels had fallen markedly by the end of the event when compared to mid-event levels. Beyond this, maintenance of body mass and appropriate hydration levels demonstrate the effectiveness of the hydration and nutritional strategies.

CORRELATION BETWEEN URINARY STEROIDS LEVELS WITH MUSCLE MASS, BMC AND BMD

TIMON, R., TOMAS-CARUS, P., OLCINA, G., MUÑOZ, D., TORIBIO, F., RAIMUNDO, D., MAYNAR, M.

SPORT SCIENCE FACULTY, UNIVERSITY OF EXTREMADURA

The muscle and bone development is influenced directly by the quantity of steroid hormones produced in the body. Purpose. The aim of this study was to correlate the urinary steroids concentration with the muscle mass, the bone mineral content (BMC) and the bone mineral density (BMD). Methods. 17 university males [age: 24.1 (2.61), height: 1.75 (0.06), weigh: 72.05 (8.33)], who did not perform strength training, were evaluated by DXA. Muscle mass, BMC and BMD were analyzed. Moreover, the first urine of the morning was taken. Testosterone, DHEA, androstenedione, androsterone, ethiocolanolone, cortisol, cortisone, tetrahydrocortisol, tetrahydrocortisone levels were performed by gas chromatography-mass spectrometry. Results. Was observed that the urinary concentration of Testosterone and Cortisol correlated negatively with the level of muscle mass (r =-0,441 and r = - 0,487). At the same time, the urinary concentration of Cortisone and Cortisol also correlated negatively with the BMC (r =-0,401 and r =-0,502) and with the BMD (r =-0,427 and r =-0,448). Any more significant correlations were found. Conclusions. On the one hand, these results suggest that the muscular development depends on the endogenous levels of androgens and corticosteroids, being able to be evaluated through the urinary steroid excretion. On the other hand, low cortisol and cortisone endogenous levels can contribute to a major muscle mass and BMC and BMD.

THE CHANGES OF THYROID HORMONE AND STIMULATING THYROID HORMONE AFTER AEROBIC RUNNING EXERCISE

SHAHSAVA, A., POURVAGHAR, M.J.
ISLAMI AZAD UNIVERSITY OF TEHRAN GHARB, DEPARTMENT OF PHYSICAL EDUCATION, FACULTY OF HUMANITIES, UNIVERSITY OF KASHAN, KASHAN, I. R. IRAN

Triiodothyronine (T3) and thyroxine (T4) are both secreted by the thyroid gland in response to thyroid-stimulating hormone (TSH) secreted by the anterior pituitary gland. This research has been conducted in order to study the changes of secretion of thyroid hormone i.e. (T4), (T3), and (TSH) following an aerobic physical activity. A group of 10 male university athletes with over three years experience in different fields of sport participated in this semi- experimental research. The obtained average and standard deviations of factors such as age, height, weight and body mass index (BMI) are as follows: (23.1±1.65), (171.1±4.51), (68.5±4.8) and (21.4±1.1). The exercise training of this research consisted of 20 minutes of running around the track and field, each being 10 rounds in two minutes.

The results showed that aerobic activities did not have any significant effect on amount of T3 and TSH secretion, although the results proved a significant difference in concentration level of serum T4 after 20 minutes (4000 m) aerobic physical activity ($p = 0.002$). So, it seems that aerobic activities can have different reactions on the secretion of thyroid hormone while factors like hematocrit, plasma decrease, as well as changes in PH of blood and also mental conditions may lead to a significant change in concentration of hormone.

STEROID PROFILE CHANGES AFTER SUBMAXIMAL EXERCISE IN TRAINED MALES

MUÑOZ, D., TORIBIO, F., OLCINA, G., TIMÓN, R., ROBLES, M.C., SAYAVERA, J., MAYNAR, M.
UNIVERSITY OF EXTREMADURA

Some research has shown that exercise can induce physiological stress which alter hormonal profile. Urinary excretion of these hormones and its metabolites can be used in order to evaluate physical exercise load. Testosterone and its metabolites as well as suprarenal androgens are in relation with anabolic status, while cortisol´s metabolites and cortisone are determined for assess catabolic status PURPOSE: the aim of this study is to analyze if submaximal efforts (75-80% VO2 max) provokes changes in urinary steroids profile in endurance trained subjects.METHODS: Twenty male cyclists participated in this study (age: 23,83 2,32 years; height: 176,00  3,65 cm; weight: 66,94  3,59 kg; body fat %: 8,57  1,22; VO2 max: 65,53 ± 9,35 ml/kg/min). The trial performed was a submaximal ergometric test during 30 min, at 75-80% VO2 max. Urine samples were collected before and after the text. All tests were conducted in a physiology laboratory, room temperature was 23 - 25ºC, humidity was 45 - 55%. Urinary samples were analyzed by gas chromatography techniques in order to determine testicular androgens, suprarenal androgens and corticosteroids values. Sample urinary density was in the range of 1,005-1,025 g/mL, pH was between the normal range of 4,7-7,8. Creatinine levels of all samples were determined in order to report the steroid concentrations relative to this urinary parameter. The Wilcoxon test was performed for statistical analysis. A $p<0.05$ was used to determine statistical significance. RESULTS: We obtained no changes in testicular androgens and corticosteroids We obtained statistically significant decresases ($p<0.05$) in androstenedione (43.98 ± 21.87 to 32.74 ± 19.32 ng/mg creatinine) and total suprarenal androgens (250.54 ± 117.29 to 163.09 ± 59.01 ng/mg creatinine), and in DHEA/THC (0.04 ± 0.01 to 0.01 ± 0.005 ng/mL) and DHEA/THCol (0.026 ± 0.008 to 0.015 ± 0.004 ng/mL) ratios. CONCLUSION: Results suggest a immediately response in adrenal glandule following submaximal exercise while there were not changes in hypophisary-testicular axis. It could be due to the short duration and intensity of exercise. The DHEA/THC and DHEA/THCol ratios are some markers of the subjects' anabolic/catabolic status following the exercise session.

RELATIONSHIP BETWEEN TORQUE VALUES OF HIP JOINT MUSCLES AND CROSS-SECTIONAL AREAS OF PSOAS MAJOR AND ERECTOR SPINAE MUSCLES IN OLDER MALES

KITA, T., MOCHIZUKI, K., YAMAMOTO, T., AOYAMA, H., AKITA, K., MIURA, K., MIURA, M., TAMURA, M., YOSHIHARA, S.
MUSASHINO ART UNIVERSITY

Introduction: The relationship between the cross sectional areas of the psoas major and erector spinae muscles, which are deep muscles not readily accessible for muscle strength evaluation, and the torque values of hip joint muscles, which are relatively easy to measure, was studied in three older (age: 66 – 68 years) males who exercise regularly. The torque values of hip joint muscles during inward and outward rotations and the left and right cross-sectional areas of the psoas major and erector spinae muscles were each measured 11 times over a period of two years using magnetic resonance imaging (MRI) and an exclusively developed torque measuring device for hip joint muscles.

Experiment Outline

Period: March 2006 – March 2008

Location: Bodily Movement Study Laboratory, Nippon Sports Science University

Subjects: three males aged 66-68 years No. of experiments: 11times (at 2-month intervals)
MRI device: AIRIS II (Hitachi Medicon, Inc.)
Analytical software: Aquarius NetStation Version 1.1 (Terarecon Inc.)
Measuring instrument for hip-joint muscle strength: Newly developed exclusively for the study
Results: The study revealed significant correlations between abductor force during outward rotation of the hip joint muscles and the left and right psoas major and erector spinae muscles ($r = 0.595$, 0.514, 0.611 and 0.726 respectively; $p < 0.01$).
Observations
the study indicated the possibility that the torque values of hip joint muscles can be used effectively as a substitute measure for evaluating the strengths of the psoas major and erector spinae muscles, which are not readily accessible for muscle strength evaluation.

QUANTITATIVE ULTRASOUND OF THE GASTROCNEMIUS MUSCLE ARCHITECTURE IN CHILDREN: VARIABILITY, RELIABILITY, AND COMPARISON BETWEEN PORTABLE AND STATIONARY MACHINES

LEGERLOTZ, K., SMITH, H.K., HING, W.A.
QUEEN MARY, UNIVERSITY OF LONDON

Muscle architecture is believed to be affected by muscular disorders, including the chronic spasticity associated with cerebral palsy. Although there is clear evidence that muscle thickness is reduced with spastic cerebral palsy in children and adults, the effects of spasticity on other parameters of muscle architecture remain unclear. However, a high biological and/or methodological variability might explain why differences in muscle fiber length or pennation angle between groups of individuals might be difficult to detect. This may be particularly important in children due to their smaller muscles and potential difficulty in remaining still. The first aim of this study was therefore to determine the inter-leg and inter-individual variability in ultrasound measurements of gastrocnemius muscle architecture in young children. Our second aim was to establish within-session and between-session reliability of measurements for the same child. Third, we compared measurements obtained using a stationary ultrasound (Phillips HD11) with those obtained using a less costly and portable machine (Chison 8300) to evaluate the appropriateness of a more widely accessible and practical option for the quantification of gastrocnemius muscle architecture in children.
Muscle thickness, pennation angle and fiber length of the medial gastrocnemius were determined in healthy children (13 boys, 8 girls) aged 4-10 years. Ultrasound images were obtained from each leg, twice at each of two ankle positions (90º and maximal plantar flexion), and with each of the two machines in succession, within the same session. The same measurements were made on a second occasion, between 4 and 6 weeks later, in 4 of the children.
There was no significant difference between the absolute values, coefficients of variation (CV) or intra-class correlation coefficients (ICC) of measurements determined by the two ultrasound machines. The CV and ICC of duplicate images taken during the same session for the same leg, ankle position, and machine ranged from 2.1-3.1% and 0.94-0.98 for muscle thickness, 4.1-6.0% and 0.85-0.96 for pennation angle, and 4.5-6.3% and 0.87-0.96 for fiber length, similar to that reported previously for adult muscle architecture. CV for variables for the same child measured on two separate sessions were within the same ranges. There was wide inter-individual variability at both ankle positions for pennation angle (range 11-22°), fiber length (26-68mm) and muscle thickness (26-68mm).
Since the CVs for repeated measurements within a subject (2.3-6.3%) were much less than the group SD relative to the mean for the same measurement (13-25%), we suggest that the variability attributable to the methods is acceptable given the biological variation seen. We conclude that the portable ultrasound is suitable to determine muscle architecture and that thickness, pennation angle and fiber length can be reliably determined in the gastrocnemius muscle of young children.

TRI-AXIAL INERTIAL MAGNETIC TRACKING DETECTS CHRONIC ANKLE INSTABILITY.

MARTÍNEZ, A., LECUMBERRI, P., GÓMEZ, M., MORANT, M., MENDIGUCHÍA, J., IZQUIERDO, M.
CENTRO DE ESTUDIOS, INVESTIGACIÓN Y MEDICINA DEL DEPORTE

Introduction: Ankle sprains are one of the most common lower extremity injuries. Real time human motion tracking is an accurate, inexpensive and portable system to obtain kinematic and kinetic measurements (2). The purpose of this study was to discriminate between subjects with chronic ankle instability (CAI) and subjects with stable ankles through inertial/magnetic tracking technology.
Methods: Twelve subjects (23.16 ± 5.32 years, 174.83 ± 8.78 cm, and 73.58 ± 17.10 kg) with stable ankles and thirteen (24.69 ± 5.91 years, 173.31 ± 9.07 cm, and 69.61 ± 15.32 kg) with chronic ankle instability performed the Star Excursion Balance Test (SEBT) (1). The SEBT is a dynamic postural control task that may hold promise in detecting deficits related to CAI (1). The subjects complete anterior (A), posteromedial (PM), and posterolateral (PL) reaching directions of the SEBT. Static force platform (IBV, Valencia, Spain) and a body-mounted sensor MTx (Xsens Technologies B.V. Enschede, Netherlands) were used to record simultaneously force, acceleration and orientation data. The inertial motion tracking was placed close to the centre of mass, which is located within the pelvis with the aim of study ¨whole-body¨ movements. Wavelet analyse based on time–frequency information was used for analysing all signals (2-3).
Results: CAI group showed greater (81%) values than the stable ankle group both in the peak amplitude of the approximation signal of the rotation around the z-axis ($p=0.053$) in the A direction and in the peak amplitude of the approximation signal (102%) of the rotation around the x-axis ($p=0.086$) in the PM direction. No significant differences were observed in the other orientation parameters. The approximation of the z acceleration coordinate signal ($p=0.014$) showed significant differences between groups. In addition, there were significant differences in the sum of the coefficients of the details 1 ($p=0.02$) and details 2 ($p=0.007$) of the y acceleration coordinate signal. When the corresponding analyses were performed from the force plate measurements no significant differences were observed between groups.
Discussion: The rotation around the z-axis and the x-axis acquired from the MTx unit discriminated differences between groups. The wavelet details of the y acceleration coordinate signal were the most accurate parameters discriminating between ankle groups. How-

ever, these differences were not observed from the force plate signals. This may indicate that different aspects of the movement may be measured by each monitoring system of human motion. The real motion human tracking is a promising technique of evaluating and distinguishing between CAI and stable ankles which may be also applicable in clinical settings outside a laboratory.

APPLICATION OF A CONTACT-TYPE MUSCLE HARDNESS METER DURING VOLUNTARY ISOMETRIC CONTRACTION

MURAYAMA, M., ITO, R., UCHIYAMA, T., YONEDA, T.

1. INST. OF PHYSICAL EDU., KEIO UNIV., 2. FAC. OF SCIENCE & TECHNOLOGY, KEIO UNIV., 3. SCHOOL OF HEALTH & SPORTS SCIENCE, JUNTENDO UNIV.

Muscle hardness is a possible index of muscle conditioning. Several methods of evaluating muscle hardness have been reported, for instance, the indentation method. Previous studies have demonstrated that a high correlation between muscle contractile tension and muscle hardness is obtained when the indentation method is used for evaluation in humans (1, 2, 3). However, it is difficult to assess the real-time change in hardness, e.g., during muscle contraction. Furthermore, joint movement or muscle shaking that occurs during a contraction increases the difficulty in evaluating hardness by the indentation method. We developed a contact-type muscle hardness meter using an ultra-slim pressure sensor which assesses the change in muscle hardness continuously. The purpose of the present study was to compare the change in muscle hardness during isometric contraction evaluated by the new contact-type device and the conventional indentation device.

Contact-type muscle hardness (CMH) meter: The hemisphere hard rubber tip was bonded with the front of the ultra-slim pressure sensor and then bonded with a metal plate. This hardness meter was set on the muscle belly of the biceps brachii and bound with adhesive non-elastic surgical tape. Therefore, it could continuously detect the internal pressure change with muscle activation. Indentation type muscle hardness (IMH) meter: The muscle hardness meter was connected to the stage controller system. Mechanical indentation with 25 mm amount was performed with a remote control. The muscle hardness value with indentation was calculated by measuring the slope of the force/displacement relationship that ranged from the length eliminated the thickness of subcutaneous tissue up to 15% muscle thickness (4). Measurement of 2 types of muscle hardness during isometric contraction: Six healthy males performed isometric contractions in the range 20–100% of the maximal voluntary contraction (MVC). Two types of muscle hardness in the elbow flexor muscles, namely, CMH and IMH, were simultaneously measured while the target contraction level was sustained.

The measured mean relative CMH was linearly related to the isometric force (r = 0.856). On the other hand, the relationship between the mean relative IMH and the isometric force was non-linear even when IMH was increased up to 90% MVC. The mean relative CMH also showed a non-linear relationship with the mean relative IMH (r = 0.862). Therefore, it was suggested that CMH could be used to assess the extent of muscle contraction at a higher intensity than IMH. We conclude that the contact-type muscle hardness meter can be used to quantitatively evaluate muscle hardness during isometric contraction, and CHM can be used to estimate the extent of contraction.

THE EFFECT OF DYNAMIC STRETCHING ON MUSCLE PERFORMANCE AFTER FATIGUING EXERCISE

KUNO-MIZUMURA, M.

OCHANOMIZU UNIVERSITY

Stretching is one of common exercise widely performed during warm up or cool down. It is also widely accepted that stretching would be useful strategy to recover from muscle fatigue; however, it was not fully elucidated by scientific evidences. The purpose of this study was to examine the effect of dynamic stretching on muscle fatigue using EMG analysis. Subjects were eleven healthy females. Subjects visited our laboratory three times including familiarization for testing protocol as the first visit. On the second and the third visit, subjects were performed 30% maximal voluntary contraction (MVC) of isometric plantar flexion until exhaustion (1st EX) with active dynamic stretching (ST) and without stretching (CON). After 1st EX, subjects performed active dynamic stretching for five minutes for ST. One minutes after active dynamic stretching, subjects performed 30%MVC of isometric plantar flexion again until exhaustion (2nd EX). On the other visit, subjects were asked to keep resting instead of dynamic stretching for CON. MVC forces of isometric plantar flexion were recorded before and after 1st and 2nd EX for both ST and CON. MVC force decreased significantly after 1st and 2nd EX compared to the baseline. Exercise time of 2nd EX decreased significantly than that of 1st EX for both ST and CON. However, % decline in the exercise time of 2nd EX was significantly smaller for ST. Integrated EMG of lateral heads of gastrocnemius, medial heads of gastrocnemius, soleus, and tibialis anterior muscle increased significantly with time for both 1st and 2nd EX during both ST and CON, while mean frequency of EMG signals evaluated by FFT analysis decreased significantly with time for all exercise. Integrated EMG of soleus muscle during first 10% of exercise time showed significantly lower level for ST than that for CON. In addition, mean frequency of medial heads of gastrocnemius decreased earlier than that of iEMG increase with time for ST, although those two parameters of medial heads of gastrocnemius muscle changed simultaneously for CON. From the results of this study, it is indicated that active dynamic stretching would be effective to reduce muscle fatigue by modifying neuromuscular activity by active stretching.

THE RELATION BETWEEN EXERCISE STYLE AND ACTIVATED AREA DISTRIBUTIONS WITHIN HUMAN MEDIAL GASTROCNEMIUS

EDAMATSU, C., IKEBATA, H., KAWAKAMI, M.

KURASHIKI UNIVERSITY OF SCIENCE AND THE ARTS

The purpose of this study was clarifying the relation between exercise style and activated area distributions within human medial gastrocnemius(MG).

Method: Eight healthy young male participated in this study. Each subject performed a calf-raise exercise (104bpm), submaximum hopping and maximum hopping with measuring EMG activity. EMGs were recorded from the proximal and distal area of the MG. The EMG and goniometer signals sampled at 2kHz. The EMG signals were full-wave rectified and then determined as the RMS value. RMS during submaximum hopping and maximum hopping was expresses as percentage of the corresponding values (%calf-raise) obtained during the calf-raise exercise.

Result : In submaximum hopping, the %calf-raise of the proximal area (92±15%) was larger than the distal area (60±11% ; P<0.05). In maximum hopping, the %calf-raise of the proximal area (148±10%) was larger than the distal area (88±12% ; P<0.05). These findings indicate that the proximal area of MG performed major role in hopping, in contrast, the distal area of MG performed major role in calf-raise exercise.

Discussion : Tibial nerve forks off into two branches of nerve which innervating the proximal area and the distal area of the MG. In addition, the Pennation angles at proximal area of the MG are larger than that at distal area (Kawakami et al., 2000). Furthermore, the proximal compartment of rat MG had higher oxidative capacity than the distal (De Riuter et al.,1995). Therefore, from innervation, architectural and biochemical properties of MG, it is expected that the function of proximal portion differ from that of distal portion. In the present study, EMG data suggested that muscle activation was distributed unequally along the longitudinal axis in the MG. The proximal area activated higher in hopping, It develop the advantage for lengthening the tendon and aponeuroses to calcaneus.

In conclusion, individual areas of the MG play different functional roles during exercise.

IN VIVO BEHAVIOR OF MUSCLE TENDINOUS COMPLEX OF GASTROCNEMIUS DURING REBOUND DROP JUMP : COMPARISON BETWEEN THE JUMPER AND THE GENERAL ADULT MALE

IKEBATA, H., EDAMATSU, C., KAWAKAMI, M.

KURASHIKI UNIVERSITY OF SCIENCE AND THE ARTS

Introduction : The explosive power is demanded by dynamic movement in sports. In research for the mechanism of explosive power, the importance of the tendinous tissue(TT) during movement was clarified by the research that uses the ultrasonography in recent years. In this research, it aimed to examine the mechanism of the explosive power by comparing jumper (RDJindex=3.0) and general adult male (RDJindex=1.0) with observing the behavior of muscle tendinous complex during rebound drop jump (RDJ).

Method : Jumper(n=1, age 22 yr) and general adult male(n=1, age 21 yr) performed RDJ. Change of TT-length during RDJ was measured by the high speed camera and the ultrasonography. In addition, The electromyography and the ground reaction force were measured in synchronized with camera and ultrasonography.

Result and Discussion : Jumper pre-activated the gastrocnemius medialis (GM) muscle and did not change the TT-length in pre-contact phase with the ground. In contact phase, TT-length was elongated in the braking phase and shorten in the subsequent push-off phase. On the other hand, the general adult male's GM was hypoactivate and TT-length shorten during the just before the contact with the ground to the braking phase. Therefore, the general adult male could not elongate the TT-length sufficiently in the braking phase. Why was the general adult male's GM hypoactivate? One possibility is that, the hypoactivity of GM is possible to reduce the stress which exert on the TT in the braking phase. In contrast, the jumper's GM elongated TT with never hypoactivity during the just before the contact with the ground to the braking phase.

In conclusion, the jumper prepared the jump motion by preactivation of GM in pre-contact phase with the ground. Moreover, his TT-length was elongated in the braking phase, and rapidly shortening in the subsequent push-off phase. These results suggest that the jumper achieve the explosive power by functional strategy for use of TT.

TENDON STRUCTURAL PROPERTIES AND THE DEVELOPMENT OF PATELLAR TENDINOPATHY

COUPPÉ, C., KONGSGAARD, M., HANSEN, P., AAGAARD, P., BOJSEN-MØLLER, J., VINTHER, A., BOESEN, M., KJÆR, M., MAGNUSSON, S.P.

INSTITUTE OF SPORTS MEDICINE, BISPEBJERG HOSPITAL AND CENTER FOR HEALTHY AGING, FACULTY OF HEALTH SCIENCES, UNIVERSITY OF COPENHAGEN, DENMARK.

Introduction: Patellar tendinopathy (jumper's knee) is a disabling overload injury of the patellar tendon. The prevalence rate of patellar tendinopathy is very high in sports involving repeated jumping. Tendon stress and elongation during loading is related to tendon structural and mechanical properties. However, very little is known about potential predisposing mechanical and structural tendon properties in the development of tendinopathy.

Purpose: To examine the in vivo structural and mechanical properties of the patellar tendon, in elite male badminton players with and without patellar tendinopathy.

Material & Methods: Seven players with unilateral patellar tendinopathy (PT-group) (22±1yrs, 83±3kg, 1.87±0.03m) on the dominant-side (DOM) and 9 players with no current or previous patellar tendinopathy (CT-group) (26±1yrs, 76±2kg, 185±0.02m) were included. Clinical assessments and ultrasonography were used to confirm the presence or absence of patellar tendinopathy both on the DOM and non-dominant side (NDOM). MRI was used to assess whole patellar tendon structural properties bilaterally. Whole patellar tendon mechanical properties were assessed using simultaneous ramped isometric (MVC) knee extension and ultrasonography on both knees.

Results: Tendon cross-sectional area (CSA) normalized for body weight (mm2/BW2/3) was greater in the CT-group compared to the PT-group on both the NDOM (7.3±0.3 vs. 6.0±0.3, P<0.01) and DOM (8.2±0.4 vs.6.5±0.5, P<0.05). In addition, greater DOM-CSA compared to NDOM-CSA was observed in the CT-group (p<0.05), but not in PT-group Tendon stress was lower in the CT-group compared to the PT-group for both the NDOM (20.3±0.7 vs. 23.4±1.1MPa, P<0.05) and the DOM (17.9±0.9 vs. 24.6±2.0MPa, P<0.01). Again, stress was lower on the DOM compared to the NDOM in CT-group (P<0.01), but not in PT-group. No other differences were found between PT-group and CT-group.

Conclusion: PT subjects had a smaller tendon CSA on both the injured (DOM) and uninjured side (NDOM) compared to the CT group. The smaller CSA yielded a greater tendon stress for a given force, which may be related to the etiology of patellar tendinopathy. Further, the smaller tendon CSA on both sides may indicate that it is a predisposing factor.

GENDER DIFFERENCES IN STIFFNESS DURING THE LANDING MOVEMENT FROM A VERTICAL JUMP

MARTÍN-CASADO, L., ALEGRE, L.M., MÁRQUEZ, G., MARTÍN-ACERO, R., ELVIRA, J.L.L., AGUADO, X.

1. UNIVERSITY OF CASTILLA-LA MANCHA, TOLEDO, 2. UNIVERSITY OF A CORUÑA, A CORUÑA, 3. MIGUEL HERNÁNDEZ UNIVERSITY, ELCHE

Introduction: Women athletes have shown higher injury rates than their male counterparts in the anterior cruciate ligament, in sports where vertical jumps are common. Besides the anatomical and mechanical gender differences some authors have attributed the greater injury rate in women to kinetic and kinematic differences in the landing technique. Previous studies have found gender differences in the kinetic behaviour during the landings from jump tests (Abián et al., 2008), and others have also described differences between young and adult subjects in the stiffness of the push off and landing phases of a counter movement jump (CMJ). Although these two factors have been related to the injury rate, the gender differences in stiffness during CMJs remain to be studied. Therefore, the purposes of this study were to describe gender differences in vertical ground reaction forces, path of the center of gravity and vertical stiffness in the push off and landing phases of maximal CMJs, in applicants to a Sports Sciences university degree.

Methodology: 110 young subjects (19.1±2.7 years), 24 women and 86 men, volunteered for the study. A Quattro Jump force platform (Kistler, Switzerland) with a sample rate of 500 Hz was utilized for the jump tests. All the subjects have been previously informed of the jump test protocols, and received a previous demonstration of the test in situ. They were allowed for a 10-minute warm up, and had two trials to reach a minimum jump height of 21 cm and 29 cm, for the women and the men, respectively.

Results: The men's group showed greater jump performance than their female counterparts, with greater jump heights (men 34.1±4.5 cm; women 25.1±4.3 cm, P<0.001) and peak power during the push off phase (men 50.8±5.7 W/kg; women 41.9±5.1 W/kg, P<0.001). During the landing phase, men showed greater peak forces than women. However, the relationship between peak forces during landing and jump (landing) height was low (r=0.23, P<0.05). Women's group lowered more their center of gravity during the landing, although the difference only reached significance when it was expressed as percentage of standing height (men 18.8±4.2 cm, women 19.7±5.7 cm, not significant; men 10.7±2.4%, women 12.0±3.4%, P<0.05). Women also showed greater stiffness values during the landing phase (men 7.67±1.64 kN/m; women 9.24±1.92 kN/m; P<0.001).

Discussion-Conclusion: The gender differences in vertical stiffness during the landing phase from a vertical found in the present study can improve the understanding of the different landing technique between men and women. This could be applied to the design of injury prevention programs that focus on the landing technique.

Aknowledgements

EFFECT OF PEDAL FORCE TO ANAEROBIC POWER GENERATION CAPACITY DURING CYCLING EXERCISE.

TANAKA, S., TAKAHASHI, Y., KUMAGAWA, D., TSUNODA, N.

KOKUSHIKAN UNIVERSITY

Introduction: Anaerobic power generation capacity is important factor in any athletic activities. Its power output capacity effected by muscle size and athletic training mode were many reported previously. Whereas, it was not cleared that the pedal force effect to the anaerobic power generation capacity during cycling exercise with different loads. Therefore, the purpose of this study was to investigate effect of pedal force on the anaerobic power generation capacity during cycling exercise with different loads.

Methods: The subjects were thirty-one collegiate male athletes of physical education. The anaerobic power generation capacity was obtained by bicycle ergometer (Power max VⅡ, Combi co. Japan) in all the subjects. Subjects were performed ten seconds with the maximal efforts intermitted of three steps load, and requested to have warm-up and two minutes rest. The load of first trial was 4.0±0.4kp, second trial was 6.2±0.6kp, third trial was 8.2±0.7kp. The peak pedal force and clank angle of the peak pedal force on each pedaling were measured by bicycle ergometer with custom-made measurement system. The pedal force and its impulse during first to fifth pedaling were analyzed on all the trials. Moreover, the ratio of anaerobic power to pedal force and impulse were calculated in each trial.

Results: Significant differences of the peak pedal forces were observed in fourth and fifth pedaling among the three trials. The clank angles of the peak pedal force were differed by trials with different loads. The pedal force and impulse were showed significant difference among the three trials (first trial < second trial < third trial, p<0.05). In first and second trials, significant correlation coefficients were observed between pedal force and anaerobic power. In addition, pedal impulses for fifth pedaling were closely related to the anaerobic power in first and second trials. However, pedal force and impulse in third trial were not observed significant correlation to the anaerobic power. The ratio of anaerobic power to pedal force and impulse on first and second trials were significantly higher than that of third trial.

Discussion: In this study, it was considered that the pedal force was effected by increase of load. And, significant correlation was obtained between the pedal force and anaerobic power during cycling exercise with light work load. Whereas, the pedal force was not related to the anaerobic power generation capacity in case of high load. From these results, it was cleared that relationship between pedal force and anaerobic power generation capacity in cycling exercise with different loads.

EMG ANALYSIS AND METABOLIC EXPENDITURE IN TAI CHI CH'UAN (YANG STYLE) PRACTITIONERS

ZORZI, E., ZAMPARO, P.

UNIVERSITY OF VERONA - SCHOOL OF SPORT AND EXERCISE SCIENCE

Introduction. Tai Chi Ch'uan (TCC) is a branch of traditional Chinese martial arts; its metabolic intensity can be defined as low to moderate and depends on the adopted style (e. g. Yang, Wu or Ch'en), posture (semi-squat) and on the exercise duration [1]. The characteristics of the classical Yang style (investigated in this study) are: extended and natural postures, slow and even motions, light and steady movements. TCC involves long duration of co-activation of the lower limb muscles that continuously change their action from concentric to isometric to eccentric [2]. Aims. The aim of this study was to investigate the relationship between the metabolic requirement of TCC and the co-contraction of the lower limb muscles in expert practitioners and beginners. Material and Methods. Experiments were performed on 14 subjects (41.4±7.3 yrs of age, 67±13 kg body mass 171±8 cm stature, 10M and 4F) 10 experts, practising TCC for 15±5 yrs, and 4 beginners (3±1 yrs of experience). On these subjects we measured the oxygen consumption (VO2) of the first sequence of movements (Tai Chi Ch'uan Ti I Lu) by means of a portable gas analyzer (K4b2, Cosmed, I) and we recorded the electrical activity (at a sampling frequency of 1000 Hz) of selected lower limb muscles (VL: vastus lateralis; BF: biceps femoris: GM: gastrocnemius medialis; TA: tibialis anterior) by means of a surface EMG analyzer (Zerowire, Aurion, I). The duration of the co-contraction between VL and BF and between GM and TA was calculated by means of the software Chart (AD Instruments, NZ); the sum of the co-contraction times (left and right limb) was then expressed in percentage of total exercise duration (% co-co-leg and % co-co-thigh). Results. Expert practitioners had a lower net VO2 (above resting) compared to beginners (11±2 vs. 14±6 ml.min-1.kg-1) and were able to perform the sequence of movements at a slower speed (229±45 vs. 180±9 s). A significant relationship was found between the metabolic requirement and the level of co-contraction of the thigh: net VO2=6.2+23.8% co-co-tight (n=14, R=0.650, $p<0.01$). A similar relationship was found between net VO2 and the level of co-contraction of the lower limb as a whole (R=0.634, $p<0.05$). Discussion. Longer co-contraction times are thus related to higher metabolic demands, as expected. However, data of experts and beginners are not clustered but interspersed. This finding can be tentatively explained as follows: expert practitioners assume a lower squat posture but are capable of a smoother transition from one movement to the other while beginners adopt a less pronounced squat that compensate, at least in part, for their still imperfect postural control and fluidity of movement.

SYMMETRY OF MUSCLE ACTIVITY DURING ABDOMINAL EXERCISES

RUTKOWSKA-KUCHARSKA, A., SZPALA, A., PIECIUK, E.

UNIVERSITY SCHOOL OF PHYSICAL EDUCATION, WROCLAW

Introduction: Studies indicated that 50% of working adults have symptoms of low back pain (van Tulder et al., 1997). To prevent low back pain, abdominal-lumbar equilibrium is needed. Normally, abdominal muscles are weaker than muscles of the back. Therefore in order to maintain abdominal-lumbar equilibrium it is required to strengthen the abdominal muscles by executing strength exercises (of these muscles). The aim of the experiment was to determine whether symmetrical exercises actually produce symmetrical muscular action.

Methods: In this study, symmetry of EMG activity of right and left part of muscles: rectus abdominis, erector spinae, rectus femoris have been tested during isometric exercises.

The analysed exercises consisted in isometric action of abdominal muscles in a precisely specified position - lying on the back with the shoulders raised above the floor and the lumbar part of the spine contacting the floor. Individual exercises differed in the position of the lower and upper limbs in relation to the trunk. Three positions of the lower limbs and three positions of the upper limbs were selected, thus making nine exercise combinations.

Results: Differences in EMG activity between specific exercises for left and right part of each muscle were tested for significance with a one-way ANOVA. It was concluded that EMG activity of left and right side of m. rectus abdominis and m. rectus femoris does not differ significantly; nevertheless statistically important differences were noticed between left and right side of m.erector spine.

Discusision: In our study m. rectus abdominis showed symmetry in its activity while the m. erector spine showed activity in the right side higher than in the left one. The asymmetry of lumbar muscles was also reported in a study examining the EMG activity of m. erector spinae and m. trapezius (Furjan-Mandic et al., 2002). In all the analysed exercises, the dominance in the electrical activity of the right side of the muscles was observed. On the other hand, Axler and McGill (1997) reported a different pattern of asymmetry. Muscle rectus abdominis showed higher activity in its left side than in the right one. Our study indicates symmetry in the activity of the m.rectus abdominis and asymmetry (dominance of the right side) of m.erector spine irrespective of external load. This may result from the fact that the experiment test subjects were previously active sportsmen.

MUSCLE ACTIVITY DOES NOT CHANGE IN RESPONSE TO DIFFERENT LOADS DURING BENCH PRESS

KIN ISLER, A., ASCI, A., ARITAN, S.

1. BASKENT UNIVERSITY, 2. HACETTEPE UNIVERSITY

Introduction: Among the exercises used in heavy-resistance training programs, bench press is one of the most popular upper body lifts. Myoelectrical activity of upper-body muscles during bench press exercise has attracted a great deal of interest (Clemons & Aaron, 1997; Welsch et al. 2005) however limited research have been found related with the effects of different loads on electromyographical activity of upper body muscles during the bench press. Therefore the aim of this study was to determine if muscle activation changes in response to different loads during non-bar release concentric bench press motion.

Methods: Seventeen male handball players volunteered to participate in this study. Subjects performed five explosive non-bar release concentric bench press motions at 50, 60, 70, 80 and 100 % of their 1-RM at 200 % of their biacromial distance (BAD). The EMG activity of clavicular pectoralis major (CPM), sternocostal pectoralis major (SPM), anterior deltoid (AD) and triceps muscles of dominant side were recorded by using surface electrodes. For each muscle at each different loads, root mean squares of EMG signals were calculated spontaneously from the beginning of the lift until the maximum force formation and all root mean squares values were summed to get a total muscle activation value. Maximum force for each lift at different loads was calculated by inverse dynamics Methods: Results: Results of one way ANOVA with repeated measures did not indicate any significant differences in muscle activation at different loads in non-bar release concentric bench press motion ($p>.05$).

Discussion: The present study suggested that different loads did not result in differences in muscles' activation patterns during non-bar release concentric bench press motion at 200 % BAD. This implicates that CPM, SPM, AD and triceps muscles are similarly activated during the bench press at different loads.

MUSCLE ACTIVATION AND LOADING OF THE SHOULDER JOINT IN HUMERAL EXTERNAL ROTATION BY PULLEY AND VARIABLE RESISTANCE

PELTONEN, H., AROKOSKI, J., KALLINEN, M., PULLINEN, T.

UNIVERSITY OF JYVÄSKYLÄ

Introduction: Free weights, such as dumbbells and rubber bands and cable pulley devices are traditionally used for rehabilitation of shoulder disorders (Reinhold et al. 2007). Also the weight of the arm itself has been used as resistance. The aim of the study was to evaluate the differences in the loading of the muscles and the glenohumeral joint between a cable pulley machine (CP) and variable resistance machine (VR) during axial humeral external rotation.

Methods: Eleven healthy male subjects took part in the study. Intramuscular electromyography from five muscles of the shoulder (medial and posterior parts of deltoideus, supraspinatus, upper part of trapezius and infraspinatus), torque and power output were measured with different rotation angles and different loads (10%, 50% and 100% of 1RM). Also the compressive and shear force in the glenohumeral joint was analysed (Harms-Ringdahl et al. 1985) at the horizontal level at particular angles of rotation. External rotation was self-paced and performed in the scapular plane.

Results: The range of the movement (ROM) when using the CP reduced compared to the VR along with the increasing workload ($P<0.05$). The activity of infraspinatus did not increase in the CP after 50% load, while it did in the VR ($P<0.01$). The upper part of trapezius was activated less in the CP than in the VR ($P<0.01$) when using the high loads (50% and 100%). In comparison with the CP, the shear forces that retract the head of the humerus were more evenly distributed in the VR than in the CP at through the ROM ($P<0.001$).

Discussion: We conclude that since the VR exercise makes it possible to utilize a larger range of motion, activates the infra- and supraspinatus muscles more at the end of the movement range, and the shear forces in the joint are more constant throughout the motion than in CP, it is especially suitable for glenohumeral rehabilitation. However, it is necessary to controlled to the position and form of the exercise, otherwise the upper part of trapezius is also highly activated, which is not desirable. Activity of the upper part of trapezius has been linked to headaches in some patients with neck and shoulder pain (Ashina et al 1999). In people suffering from frontal joint instability, it is important for rehabilitation that the shear forces in the joint are steady throughout the motion (Lugo et al 2008), such as in the VR machine. Thus, it is possible to control the stress of the anterior side of the joint and it's stability by adjusting the resistance.

THE INFLUENCE OF BREATHING PATTERN ON ABDOMINAL MUSCLE ACTIVATION DURING TRUNK CURLS

TINMARK, F., BJERKEFORS, A., EKBLOM, M., UCHIYAMA, S., WELIN, L., THORSTENSSON, A.

THE SWEDISH SCHOOL OF SPORT AND HEALTH SCIENCES (GIH)

Introduction: Abdominal muscles serve a multitude of functions in controlling posture and movement, providing stabilization for the spine and participating in breathing. Exercises for the abdominal muscles are an integral part of most training programs in sports and rehabilitation. The purpose here was to further elucidate the multifunctional role of abdominal muscles by investigating the effects of systematic breathing interventions during a commonly used training exercise, the trunk curl.

Methods

Ten healthy habitually active young females performed straight trunk curls from a supine position with bent knees. The movement speed was set by a metronome and the upward and downward phases each lasted approximately 2 s. Five different variants were carried out: 1) spontaneous breathing 2) inspiration during the upward and downward phases 3) expiration during the upward and downward phases 4) breath-holding on a maximal inhalation level and 5) breath-holding on a maximal exhalation level. Kinematics was recorded

with a position transducer and air flow with a respiratory flow-meter. Intramuscular electromyography (EMG) was recorded via bipolar fine-wire electrodes placed under the guidance of ultrasound in the Transversus Abdominis (TrA), Obliquus Internus (OI), Obliquus Externus (OE), and Rectus Abdominis (RA) muscles on the right side. EMG amplitude was calculated for 1 s intervals in the middle of the upward and downward phases and expressed as % of the EMG obtained in an isometric maximal voluntary trunk curl in a supine position.
Results: The overall range of relative EMG-levels was 6-72%. The activation of TrA was lower than that of the other muscles (6-29% vs 19-72%). All muscles showed higher activation during the upward than downward phase (ranges: 13-72% vs 6-56%). A significant effect of an intervention was present only for breath-holding in exhalation, which showed higher EMG-values than the spontaneous breathing situation for OE and RA both in the upward (difference OE: 45%, RA: 16%) and downward phases (difference OE: 21%, RA: 12%). The breath-holding in exhalation also caused higher activation than the inhalation situation for OI, OE and RA. Comparisons between trunk curls with ongoing breathing showed higher EMG with exhalation than inhalation for OI and OE. No significant differences between situations were seen for TrA.
Discussion: The level of activation of superficial abdominal muscles, OE and RA, can be increased by holding the breath in maximal exhalation during trunk curls. A possible reason for that could be that an extreme exhalation decreases the lever arm for the prime trunk flexor muscles and thus a higher level of activation is needed to carry out the movement. The lack of significant effects of breathing interventions on the deep abdominal muscles, OI and TrA, was unexpected, considering their potential role in control of breathing. Possibly, the generally low activation of the TrA, and a concomitant low intra-abdominal pressure, would be mechanically beneficial for the execution of the trunk curl.

EFFECTS OF ARM POSITION AND TWIST DIRECTION ON ABDOMINAL MUSCLE ACTIVATION DURING TRUNK CURL EXERCISES

UCHIYAMA, S., TINMARK, F., BJERKEFORS, A., NORDLUND EKBLOM, M., WELIN, L., THORSTENSSON, A.
DEPARTMENT OF NEUROSCIENCE, KAROLINSKA INSTITUTET, SWEDEN, THE SWEDISH SCHOOL OF SPORT AND HEALTH SCIENCES (GIH), SWEDEN, AND SCHOOL OF PHYSICAL EDUCATION, TOKAI UNIVERSITY, JAPAN

Introduction: Sit-ups are common exercises in sport and recreational training. A multitude of practical recommendations flourish on how to best perform this type of exercise to reach a specific effect. In recent years, special attention has been paid to training of the innermost abdominal muscle, the Transversus Abdominis (TrA), which has been ascribed a role in trunk stabilization and posture control, but whose mechanical contribution to trunk movements is uncertain. Here, we use fine-wire electromyography to investigate effects of arm position and twist direction on the involvement of all four abdominal muscles during trunk curl exercises.
Methods: Ten healthy habitually active young females performed trunk curls from a supine position with bent knees. The movement speed was set by a metronome and the upward and downward phases each lasted approximately 2 s. Five different variants were carried out: 1) straight trunk curl with straight arms in front of the body, 2) ditto with arms crossed over the chest, 3) ditto with hands behind the neck, 4) trunk curl with left twist, and 5) trunk curl with right twist. Kinematics was obtained with a position transducer. Intramuscular electromyography (EMG) was recorded via fine-wire electrodes placed under the guidance of ultrasound in TrA, Obliquus Internus (OI), Obliquus Externus (OE), and Rectus Abdominis (RA) on the right side. EMG amplitude was calculated for a 1 s interval in the middle of the upward and downward phases and expressed in % of the EMG in an isometric maximal voluntary straight trunk curl in a supine position.
Results: The overall range of relative EMG-levels was 7-70%. The activation of TrA was lower than that of the other muscles (7-36% vs 14-70%). All muscles showed higher activation during the upward than the downward phase (ranges: 14-70% vs 7-52%). Changing the arm position increased the EMG of all muscles in both phases. EMG on the right side was increased in the upward phase with right twist for OI and with left twist for OE. TrA and RA activation was unchanged with twist.
Discussion: As expected, the modification of arm position, and thereby load, caused a general increase in activation of the prime abdominal flexor muscles. Interestingly, there was an increase also in TrA activation, which can be interpreted either as related to a concomitant increase in the need for spine stabilization or to a hitherto undefined mechanical role of TrA in trunk flexion itself. The asymmetric activation of the oblique abdominal muscles is in accordance with their main fibre directions. A tendency towards a similar pattern of activation in TrA and OI is in line with our earlier observations during trunk twisting in a standing position and suggests a mechanical role for TrA in ipsilateral trunk rotation. From a practical viewpoint, the data presented can provide guidelines for specific trunk muscle training and for explaining effects thereof.

REACTION TIME ANALYSIS FOR KENDO STRIKES IN RESPONSE TO LIGHT SIGNALS USING ELECTROMYOGRAPHY AND A TRANSCRANIAL MAGNETIC STIMULATOR

YOTANI, K., TAMAKI, H., SAKASHITA, I., YUKI, A., KIRIMOTO, H., KITADA, K., OGITA, F., TAKEKURA, H.
NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA

PURPOSE: Latency of motor-evoked potentials (MEP) reflects neural conduction time between stimulus location, i.e., cortical or peripheral, and muscle, and can be recorded using a transcranial magnetic stimulator (TMS). Furthermore, visual-motor related time (VMRT), central motor conduction time (CMCT), and peripheral response time (PRT) can be calculated by subtracting MEP latency from pre-motor time (PMT) in simple-reaction time using electromyography (EMG). We assessed time factors of EMG reaction time and MEP latency during kendo strikes.
METHODS: Eight male college students were asked to perform kendo strikes in response to visual stimulation from a flashing light signal. The strikes, Hiki-men (HM) to the frontal region of the head and Hiki-kote (HK) to the right wrist, were performed as quickly as possible with a bamboo sword (shinai) using the upper limbs. EMG signals from bilateral biceps brachii and triceps brachii muscles were recorded together with elbow joint angle and hitting shock. MEP latencies were also recorded from bilateral biceps brachii and triceps brachii muscles using TMS. Total task time (TTT), VMRT (PMT - MEP latency of cortical stimulation), CMCT (MEP latency of cortical stimulation - MEP latency of spinal stimulation), PRT (MEP latency of spinal stimulation), motor time (MT) and action time (AT) were measured for HM and HK tasks.
RESULTS: TTT and AT were significantly shorter in the HM task than in the HK task (TTT, $P<0.01$; AT, $P<0.05$). However, no significant differences were observed for VMRT, CMCT, PRT or MT between tasks. Significant and strong positive correlations were observed between VMRT and TTT for both tasks ($P<0.01$, $r=0.91$-0.92). Multiple regression analysis was used to determine the contribution of each component of the model in TTT. The standardized partial regression coefficient (β) was highest for VMRT (β=0.96-0.82). Individual

time ratios for PMT, MT and AT to TTT were approximately 50%, 20% and 30%, respectively. Furthermore, individual time ratios for VMRT, CMCT and PRT to PMT were approximately 92%, 3% and 5%, respectively.

DISCUSSION/CONCLUSION: We have already demonstrated in previous studies that PMT is the most important component contributing to TTT. The present findings suggest that VMRT is the most important component contributing to TTT in kendo strikes. Differences in TTT and AT were evident in according to different striking tasks, i.e., HM and HK tasks.

REPEATABILITY OF MINIMUM MEAN FREQUENCY OF EMG POWER SPECTRUM DURING EXHAUSTING VOLUNTARY ISOMETRIC CONTRACTIONS OF THE TRICEPS BRACHII MUSCLE AT DIFFERENT INTENSITIES

STIRN, I., JARM, T., STROJNIK, V.

UNIVERSITY OF LJUBLJANA, FACULTY OF SPORT;FACULTY OF ELECTRICAL ENGINEERING

Mean frequency (MNF) of the power spectrum of surface EMG decreases during the sustained voluntary isometric contraction due to progressive development of fatigue as observed by many researchers 1. An exponential decrease of MNF, first reported by Lindstrom et al. (1977), was usually observed. MNF decreased and reached some plateau asymptotic value. However in our study a slightly different pattern of the MNF decrease was observed and was best fitted by a polynomial curve. Minimum instead of plateau values were therefore obtained close to the end of contraction. The aim of our study was to investigate whether the minimum values of MNF differ with respect to the different starting intensity of the contraction. Repeatability of the minimum achievable MNF of long head (TBLoH) and lateral head (TBLaH) of triceps brachii muscle at the end of a sustained isometric contraction was investigated. Twelve volunteers performed isometric elbow extensions at the elbow angle 90° at 60%, 80% and 100% of the maximal voluntary contraction (MVC) until exhaustion on three different days with enough time to recover from previous contraction. Fourier transform was used for estimation of power spectrum of one second non-overlapping segments of the EMG signal. MNF values were calculated for all segments and plotted as a function of time. A 5th order polynomial model was fitted to the results in order to obtain the minimum value of MNF labelled TBLoH and TBLaH for the long and lateral head, respectively. The MNFs for TBLoH were 49.6 ± 6.9, 48.2 ± 7.8 and 49.5 ± 7,8 Hz for 60%, 80% and 100%, respectively and for TBLaH 62.3 ± 11.7, 62.1 ± 11.9 and 62.5 ± 10.7 Hz. Using repeated measures ANOVA, no statistically significant differences in minimum MNF among the contractions performed at different intensities were found. Repeatability was calculated using Intraclass Correlation Coefficient (ICC). ICC (2,1) for TBLoH and TBLaH and were 0.77 and 0.65, respectively. No differences in TBLoH and TBLaH among the contractions of different intensities and relatively high ICC values imply high repeatability of estimate of the minimum MNF value after a long sustained contraction for a wide range of contraction intensity level. TBLoH showed greater repeatability then TBLaH (P=0.02).

THE COORDINATION OF MULTI-JOINT POINTING MOVEMENTS IN 3D-SPACE

STEIN, T., FISCHER, A., SIMONIDIS, C., BAUER, F., SEEMANN, W., SCHWAMEDER, H.

UNIVERSITÄT KARLSRUHE (TH)

Introduction: The ease with which humans point to distant visual targets hides the intrinsic complexity of those movements. Due to the redundancy of the neuro-motor-system, humans are able to perform pointing movements in countless ways. The key issue is how humans select one specific movement out of the plethora of possible movements. In this context one of the main assumptions is that the information about the process of movement coordination in the central nervous system can be deduced from behavioural regularities (Bernstein, 1967). A large number of such regularities have been reported in literature (Goodman & Gottlieb, 1995). Nevertheless, the analysis of multijoint 'daily life' movements in 3D-space is rather rare. Thus, the purpose of this study was to analyse multi-joint pointing movements in 3D-space with respect to the selection of regularities.

Methods: Twenty students performed five standardized pointing gestures to four different targets. Subjects were instructed to perform the gestures similar to daily living. All pointing movements were tracked at 120 Hz using an IR-tracking system. For the calculation of joint angles and generalized actor forces the simulation framework MKD-Tools was developed in Matlab consisting of a recursive multibody algorithm to numerically establish the spatial dynamic equilibrium equations for arbitrary systems (Stelzner, 2008). An implemented nonlinear constrained least-square approach transfers motion capture data to subject-specific anthropomorphic models. The full-body model consisted of 38 dof and the dynamic parameters were taken from the literature. Inverse dynamics was performed in order to calculate the generalized actor forces.

Results: The results show that the shapes of the hand trajectories of all subjects were curvilinear. Although some unsystematic differences concerning the trial-to-trial variability could be observed, these results indicate that the hand movements in space show a topological invariance concerning the shape of the hand path in all investigated pointing tasks. Additionally, the velocity profiles of the hand trajectories are single peaked and almost bell-shaped. Concerning the head-hand coordination all subjects moved their head, first, followed by the hand. However, Desmurget and Grafton (2000) recently showed that this sequential organization does not seem to have a functional foundation but results primarily from inertial factors. These results indicate that in multi-joint movements in 3D-space humans produce movements with certain regularities. In the next step mathematical models have to be constructed in order to detect and reproduce those regularities.

ENDURANCE EVALUATION WITH SURFACE EMG DURING UNILATERAL STATIC BALANCE IN ELITE TAEKWONDO ATHLETES

RAMAZANOGLU, N.

MARMARA UNIVERSITY

Introduction: Proper balance control is mainly based on muscular synergies that minimize displacements of the centre of the gravity while maintaining upright stance, proper orientation and adapt techniques imparted to the sport practised (10,5). Taek-won-do requires a unipedal posture to perform different technical movements (eg. kicking).

Purpose: The aim of this study was to to evaluate the activation patterns of M. Biceps femoris and M. Quadriceps Femoris of elite Taek-won-do athletes during unilateral stance.

Method: Six national male Taek-won-do athletes (age=22.8±2.5 years, sport age=10.6±4.2 years, height=173±5.5 cm, weight=66.5±6.3 kg, BMI=22±0.7) participated in the study. Surface EMG data were recorded from M. Biceps Femoris and M. Vastus Lateralis during the unipedal stance condition on the stabilometer. We asked to maintain right and left unilateral stance positions as long as possible. EMG Ag-AgCl (silver/silver chloride) surface disk electrodes were placed according to the recommendation by SENIAM. The amplifier EMG 100C was equipped with a band pass filter 10-500 Hz; gain was chosen 1000. The EMG signal was sampled at 2000 Hz.

Results: Endurance time for the right leg was longer (429.9 s versus 298.4 s; $p<0.05$). According to EMG measurement, the subjects employed different muscle activation patterns as they became fatigued. M. Biceps Femoris mean EMG frequency was at 100 Hz for all measurements. For both stance conditions, the activation of M.Quadriceps Femoris (root mean square) and mean EMG frequency was higher. Also, alternating activation of the two muscles was also observed. There were no significant differences for Center of Pressure, Forward-Backward Standart Deviation, Medium-Lateral Standart Deviation, Average Forward-Backward Velocity, Average Medium-Lateral Velocity, Perimeter and Ellipse Area between unilateral left foot stance and right foot stance.

Discussion: Elite male Taek-won-do athletes employ similar muscle activation strategies during unilateral stance, but endurance time is different for the right and left leg

RELATIONSHIPS BETWEEN PHYSICAL ACTIVITY, AGE, BODY MASS INDEX AND IGF-1 SERUM CONCENTRATION IN HEALTHY, ELDERLY MEN

SLOWINSKA-LISOWSKA, M., JOZKOW, P., MEDRAS, M., TRZMIEL-BIRA, A., KULICZKOWSKA-PLAKSEJ, J.

UNIVERSITY OF PHYSICAL EDUCATION, MEDICAL UNIVERSITY, WROCLAW, POLAND

Introduction: Insulin–like growth factor (IGF-1) plays a pivotal role in mediating metabolic and especially anabolic responses during altered energy states. IGF-1 has been indicated as an important modulator of muscle strength and muscle function, but studies on relationships between IGF-1 and physical activity have provided conflicting results (Gómez et al 2003 ,Onder et al 2006)

The aim of our study was to investigate associations between the level of physical activity, age, BMI and plasma concentrations of IGF-1 in healthy, elderly men of European origin.

Methods: We randomly selected 900 adult men from one administrative region of Poland (Lower Silesia). From among them 387 (aged 24-72 y) agreed to participate in the study. We used the International Physical Activity Questionnaire (IPAQ, last 7-days recall) for the assessment of the level of physical activity of the studied subjects. IGF-1 serum concentration was measured using RIA kits (BioSource, France).

Results: IGF-1 concentration was significantly lower in men aged >45 y. (B=-4,05) and >55 y. (B=-2,82). IGF-1 was also associated with body weight (B=0,1), height (B=0,084), BMI (B=0,29) and physical activity (B=1,4).

Conclusions: Age, anthropological parameters and physical activity are associated with serum concentrations of IGF-1. A statistically significant correlation between IGF-1 and locomotion is found only in men presenting low and medium, but not high level of physical activity.

This work was supported by the Ministry of Science and Higher Education of Poland (grant code: 2PO5D 0730).

ADRENALINE DOES NOT BLOCK GLYCOGEN SYNTHASE ACTIVATION AFTER EXERCISE.

LIN, F., STUENÆS, J., LAI, Y., JENSEN, J.

NATIONAL INSTITUTE OF OCCUPATIONAL HEALTH

Background: Glycogen is the most important energy substrate during endurance exercise of high intensity and fatigue occurs when the glycogen stores in the active muscles are depleted. After exercise, the glycogen stores are gradually refilled when glucose is available. For glycogen synthesis, glucose has to be transported into the muscle cells and phosphorylated before glycogen synthase incorporates the glucose moieties into the glycogen particles. Exercise activates both glucose transport and glycogen synthase. Insulin also stimulates glucose uptake and activates glycogen synthase. Glycogen synthase activity is regulated by phosphorylation at nine different sites and allosterically activated by glucose 6-phosphate. This complex regulation has made it difficult to get a thorough understanding of the mechanisms for regulation of glycogen synthase.

Purpose: The main purpose of the present study was to investigate the effect of adrenaline on glycogen synthase activity after contraction. Furthermore, the effect of adrenaline on insulin-mediated glycogen synthase activation was investigated.

Methods: Rat epitrochlearis muscles were stimulated electrically in vitro for 30 min; non-contracted muscles served as controls. After contraction, muscles were incubated 15 min with or without adrenaline. Non-contracted muscles were also incubated with insulin in the presence or absence of adrenaline. Muscle glycogen synthase activity was analysed to achieve kinetic data for GS affinity for UDP-glucose and affinity for glucose 6-phosphate (fractional velocity).

Results: Muscle contraction reduced glycogen content from 196.4±10.8 mmol/kg to 93.7±4 mmol/kg dry weight ($p < 0.05$, n=8 in each group). Furthermore, glycogen synthase fractional activity increased from 10.4±0.9 % (basal) to 51.9±1.3 % 15 min after contraction. Adrenaline reduced glycogen synthase fractional activity to 4.1±0.3 % in non-contracted muscles. In contracted muscles, glycogen synthase fractional activity remained elevated (25.5 ±6.0 %) when adrenaline was present. Insulin increased GS fractional activity to 17±1.3 %, and adrenaline completely blocked insulin-stimulated glycogen synthase fractional activity (9.8±1.4 %). Glycogen synthase Km for UDP-glucose decreased from 0.65±0.04 (basal) to 0.15±0.01 mM after contraction. Insulin reduced glycogen synthase Km for UDP-glucose to 0.42 ±0.02 mM. Adrenaline did not significantly influence glycogen synthase Km for UDP-glucose.

Conclusions: Muscle contraction is a much stronger activator of glycogen synthase than insulin, and glycogen synthase fractional activity remains high even when adrenaline is present in contracted muscles. Insulin-mediated glycogen synthase activation, on the other hand, is completely blocked by adrenaline.

THE EFFECTS OF A WATER POLO GAME ON THE BLOOD REDOX STATUS OF MALE WATER POLO PLAYERS.

PETRIDIS, L., JAMURTAS, A.Z., NIKOLAIDIS, M.G., VESKOUKIS, A., KOURETAS, D.

UNIVERSITY OF THESSALY, TRIKALA, 42100, GREECE

The purpose of this study was to examine the effects of a single water polo game on the blood redox status of male water polo players. Twelve male adult athletes (25.8±3.7 yrs) participated in the study and blood samples were taken before and after a water polo game of the Greek national championship. Mean playtime was 42.8 ± 9.4 min, which corresponded to 78.12±17.14% of the total playtime. Blood lactate concentration after the game reached considerably high values (9.16±3.91 mmol/L). Blood volume didn't change after the game. Thiobarbituric acid-reactive substances (TBARS) increased significantly following the game (44%) whereas there was no difference in oxidized glutathione concentration (GSSG), protein carbonyls, catalase activity and total antioxidant capacity. Eventhough the results suggest that an intense exercise, like a water polo game, can induce blood oxidative stress, as it is indicated by the increase of TBARS, the absence of change in the other redox status indices measured in this study, indicate that further studies need to be done in this field to elaborate a possible connection between this type of activity and the redox status of the athletes.

EFFECT OF RUNNING EXERCISE ON THIOL REDOX STATUS AND INFLAMMATORY MEDIATORS IN HEALTHY UNTRAINED MEN

ZEMBRON-LACNY, A., OSTAPIUK-KAROLCZUK, J., NACZK, M., GAJEWSKI, M., SZYSZKA, K.

PHYSICAL CULTURE GORZOW WLKP. UNIVERSITY OF PHYSICAL EDUCATION POZNAN, PUBLIC COUNTY HOSPITAL GORZOW WLKP.

Introduction: Glutathione is the major non-protein thiol and one of the reactive oxygen species (ROS) sensors engaged in cellular control of thiol redox. The ratio of reduced (GSH) to oxidised glutathione (GSSG) plays an essential role in regulating thiol-depend metabolic pathways. Changes in thiol redox affect transcriptional activity via activation or inhibition of transcriptional factors, finally modulating the synthesis of many molecules such as cytokines (Allen and Tresini 2000, Ji et al. 2006). The present study was designed to evaluate the plasma marker of ROS activity and pro- and anti-inflammatory cytokines, and their relationship with thiol redox status in nonathletes exposed to running exercise.

Method: Twelve untrained male subjects performed 90-min run at 60% VO2max. Blood was sampled before, 20 min, 6 h, 24 h and 48 h following exercise to measure blood thiol redox status (GSHt - 2GSSG/ GSSG), plasma concentrations of interleukin IL-beta1, IL-4, IL-6, IL-10, tumour necrosis factor (TNF)-alpha and 8-isoprostane as a marker of ROS activity. The post-exercise values were corrected for changes in plasma volume.

Results: The running exercise caused significant increase in thiol redox status at 6 h, 24 h and 48 h rest. The pro-inflammatory cytokines did not change following exercise whereas anti-inflammatory IL-6 and IL-10 increased 5-fold and 1.76-fold at 20 min rest. Changes in IL-6 and IL-10 levels were independent of thiol redox status but were associated with 8-isoprostane concentration. 8-isoprostane increased at 20 min and 6 h rest and directly correlated with IL-6 ($r = 0.761$) and IL-10 ($r = 0.617$).

Discussion: Our study has shown 1) changes in thiol redox status and anti-inflammatory cytokines in nonathletes performed running exercise and 2) an integration of changes anti-inflammatory cytokines with marker of ROS activity but no relationship with thiol redox status.

THE LEVELS OF PRO- AND ANTI-INFLAMMATORY CYTOKINES AND REACTIVE OXYGEN AND NITROGEN SPECIES IN NON-ATHLETES EXPOSED TO RUNNING EXERCISE

OSTAPIUK-KAROLCZUK, J., ZEMBRON-LACNY, A., NACZK, M., GAJEWSKI, M., SZYSZKA, K.

FACULTY OF PHYSICAL CULTURE GORZOW WLKP., UNIVERSITY OF PHYSICAL EDUCATION POZNAN, PUBLIC COUNTY HOSPITAL GORZOW WLKP. (POLAND)

Introduction: The induction of reactive oxygen and nitrogen species (RONS) by physical exercise is well documented in both animal and human studies. RONS are physiological products of aerobic metabolism, and impact on variety of metabolic processes including gene expression, protein turnover, inflammatory reaction, arachidonic acid immobilisation, cellular differentiation etc. RONS are released from muscle, endothelial, and immune cells to stimulate changes in the immune status related to the cytokine synthesis (Kosmidou et al. 2002, Valko et al. 2007). The aim of the study was to determine the changes in RONS and pro- and anti-inflammatory cytokines levels in response to running exercise.

Method: Twelve untrained male subjects performed 90-min run at 60% VO2max on a treadmill. Blood was sampled before, 20 min, 6 h, 24 h and 48 h following exercise to measure plasma concentrations of hydrogen peroxide (H2O2), nitric oxide (NO), interleukin IL-1beta,

IL-4, IL-6, IL-10, tumour necrosis factor (TNF)-alfa and number of immunological cells. The post-exercise values were corrected for changes in plasma volume.

Results: The running exercise did not caused any changes in levels of pro-inflammatory cytokines IL-1beta, IL-4 and TNF-alfa but significantly elevated anti-inflammatory cytokines IL-6 and IL-10 at 20 min rest. The significant changes in H2O2 and NO took place at 6 h rest. H2O2 concentration increased from 6.26  0.93 to 8.29  1.48 mmol . ml-1 whereas NO increased from 24.92  2.79 to 32.27  3.30 mmol . ml-1. NO remained on high level to 48 h rest. The number of neutrophils increased at 20 min and 6 h rest, and monocytes was elevated to 48 h rest. Neutrophil count directly correlated with concentrations of IL-6 (r = 0.768) and IL-10 (r = 0.442).

Discussion: Our results have shown the 90-min running exercise at submaximal intensity induces changes in RONS and anti-inflammatory cytokines level but has no effect on pro-inflammatory cytokines in nonathletes.

EFFECT OF ACUTE EXERCISE ON HEART TISSUE PROTEINS OF WISTAR RATS

PETRIZ, B., ROCHA, L.A.O., GUIMARÃES, M.E.G., OLIVEIRA, R.J., FRANCO, O.C.

CATHOLIC UNIVERSITY OF BRASILIA - BRAZIL

Physical activity is known as an external agent capable to promote stress response and biological adaptation. This adaptation on cardiac myocit indicates work capacity, resistance to physical stress and cardiovascular system improvement (ROBERGS & ROBERTS., 1997). These exercise-promoted adaptations can be pointed by biological markers, some of them specific proteins as the hsp70 (MELLING et al, 2007). To verify the acute responses of one session of moderate and intense exercise, Wistar rats were submitted to 30 minutes of intense or moderate swimming exercise. 15 male Wistar rats with 8 (+/-1) weeks, were distributed into 3 groups: control (C, n=3), moderate exercise (ME, n=6) and intense exercise (IE, n=6) group. The moderate and intense exercises were performed by 30¨ of swimming with 5 or 10% of overload related to the animal body weight, attached to its chest. After the exercise session all animals were sedated (Chloroform 100%) and sacrificed. The left ventricular fragment of each rat was excised, immediately liquid N2 frozen and stored at -80 oC. The tissues were homogenized according to SHORT et al. (2005) and protein content was obtained by the Bradford method. The samples were analyzed by 12% SDS-PAGE and 2DE, with strips of 3-11 Ip range. The analysis indicated a modification on the proteins pattern between the ME and IE group and between them and the CG. SDS-PAGE indicated that proteins of approximately 70 kDa are over expressed on the MEG compared to the CG. It was verified that one session of moderate and intense exercise is capable to promote proteins modification indicating a possible biological adaptation by the cardiovascular system.

EFFICIENCY OF THE FOOD SUPPLEMENT 'TRIBULUS' USED BY ATHLETES

MILASIUS, K., DADELIENĖ, R.

VILNIUS PEDAGOGICAL UNIVERSITY

Introduction: Tribulus is one of the quite popular food supplements used by a big number of athletes. When investigation of the effect of Tribulus Terrestris had been started more widely, it was found out that this herb had influence on masculine hormone testosterone level in blood, on strengthening immunity, improving endurance, when its effect was started to be analyzed widely (Antonio et al., 2000; Elder et al., 2001; Rogerson et al., 2004). The aim of the research was establishing the influence of food supplement Tribulus on athletes' physical development, physical working ability, aerobic functional capacity, blood circulation and respiratory systems.

Methods: The sample of the research included thirty-two 20-22 year old athletes. The first experimental group consisted of 20 individuals. For 20 days they used 3 capsules of the food supplement Tribulus (produced by the USA Company (OPTIMUM NUTRITION) a day. The control group (n=12) participants did not consume any food supplements.

Results: Their relative AAMP the members of experimental group, having used food supplement Tribulus for 20 days, have increased from 16,3±1,1 to 17,2±1,5 W/kg (F= 5,12, p=0,03). Relative alactate glycolyte working capacity (AGWC), when work duration is 30-s, in 20 days have increased from 8,2±0,8 to 8,7±0,8 W/kg (F=4,34, p=0,04). VO2max at the critical intensity threshold have increased from 50,3 to 55,4 ml/min/kg (F=3,63, p=0,07). During the experimental period still growing erythrocyte sedimentation rate, statistically importantly increased percentage of granulocytes and decreased percentage of leucocytes show negative impact of this food supplement on changes of leucocytes formula in athletes' blood. Accordingly, complete blood counts (CBC) for athletes who consume food supplement Tribulus 25 mg per 1 kg of body mass for the period of 10 days or longer must be carried out.

Creatinkinase concentration in athletes' blood statistically importantly has increased and creatinine amount has had a tendency to decline during 20 days period of consuming food supplement Tribulus. The declining tendency of urea, cholesterol and bilirubin concentrations has appeared. The concentration of blood testosterone increased statistically reliable during the first half (10 days) of the experiment; it did not grow during the next 10 days while consuming Tribulus still.

EFFECT OF CO-INGESTION OF CARBOHYDRATE AND WHEY PROTEIN HYDROLYSATES ON EXERCISE PERFORMANCE AND BLOOD BIOCHEMICAL PARAMETERS OF CARBOHYDRATE METABOLISM IN MALE ATHLETES.

MORIFUJI, M., AOYAMA, T., NAKATA, A., SAMBONGI, C., KOGA, J., KURIHARA, K., KANEGAE, M., SUZUKI, K., HIGUCHI, M.
WASEDA UNIVERSITY

Introduction: It has been reported that co-ingestion of carbohydrate (CHO) and protein induces more effective replenishment of muscle glycogen following exercise than CHO alone. We have also demonstrated that whey protein increased liver and skeletal muscle glycogen content to higher levels in exercise-trained rats than casein (Br J Nutr 2005). Furthermore, we reported recently that BCAA-containing dipeptides, identified in whey protein hydrolysates (WPH), increased glucose uptake in isolated muscles (J Nutr Sci Vitaminol 2009). We therefore hypothesized that ingestion of CHO plus WPH may have beneficial effects on post-exercise glycogen repletion, thereby resulting in increased exercise performance. The aim of this study in male athletes was to compare the effect of co-ingestion of CHO and WPH with CHO alone on 1) blood biochemical parameters of carbohydrate metabolism during the post-exercise phase and 2) exercise performance.
Methods: The study was a double-blind, cross-over design. Eight male athletes exercised continuously for 60 min on two separate occasions using a cycle ergometer at 68% VO2max, interrupted by six 2-min intervals at 88% VO2max. The subjects cycled at 60% VO2max during the last 10 min. Immediately after exercise and 30, 60, 90 and 120 min later, the subjects received a supplement containing either 1) 17.5 g CHO, 2) 3.0 g WPH and 17.5 g CHO (L-WPH), or 3) 8.0 g WPH and 17.5 g CHO (H-WPH). After a 2 hr recovery period an exercise performance test (time trial) was performed. Blood samples were drawn before exercise, at 0, 30, 60, 90 and 120 min after exercise, and also after the exercise performance test.
Results: Data expressed as AUC for the entire 120 min trial showed that the blood glucose response was lower in the H-WPH group compared to the CHO group, while the plasma insulin response was significantly higher in the H-WPH group than in the CHO group. The concentrations of plasma amino acid and dipeptide were also higher in the L-WPH and H-WPH groups compared to the CHO group. In addition, there was a strong positive correlation between the plasma concentrations of insulin and Leu, Ile, Met, Thr, Tyr, Phe, Trp, Ile-Leu and Val-Leu ($P<0.001$, $r>0.650$). Furthermore, the plasma IL-6 and free fatty acid (FFA) levels after the performance test were significantly lower in the H-WPH group than in the CHO group. Although endurance performance was not statistically different between the three groups, 6 of the 8 subjects improved their performance in response to intake of H-WPH.
Discussion: This study demonstrated that co-ingestion of CHO and WPH was more effective than ingestion of CHO alone for stimulating insulin secretion and plasma amino acid and dipeptide availability in exercise-trained athletes. Furthermore, blood parameters of substrate metabolism, such as FAA and IL-6 also changed after co-ingestion of CHO and WPH. These results therefore may suggest that ingestion of CHO with WPH has a beneficial role of increasing post-exercise glycogen repletion rates, resulting in an improvement in exercise performance.

EFFECT OF RHODIOLA ROSEA SUPPLEMENTATION ON PHYSICAL PERFORMANCE FOLLOWING ENDURANCE TRAINING

VIEILLEVOYE, S., COPPOLA, C., POORTMANS, J.R., CARPENTIER, A.
UNIVERSITÉ LIBRE DE BRUXELLES

Introduction: Rhodiola Rosea (RR) is a medicinal plant, known as an ergogenic and adaptogen aid, and supposed to enhance physical and mental performance. Studies showed positive effects on cognitive function and mental fatigue (Olsson et al., 2008; Fintelmann et al., 2007). However, literature pointed out equivocal results on physical performance (Walker et al., 2006). The aim of the present investigation was to evaluate the increase in aerobic performance following RR supplementation combined, or not, with an endurance training programme.
Methods: Thirty-two young male or female subjects (mean 22 y) were divided into three groups; one group received a RR supply and the two other groups received a placebo (PL). The RR group and one PL group performed two sessions of endurance training per week during three months. Before and by the end of training, maximal oxygen uptake was assessed by a triangular exhaustion test on a treadmill. The average speed maintained 20 minutes at a target heart rate (85% of the maximal heart rate) was also recorded on a treadmill, 3 days after the maximal test. Heart rate was recorded during the three minutes following the end of the exercise.
Results: The maximal oxygen uptake increased in the trained RR group (5.5 % ± 3.5) while this parameter decreased in the non-training PL group (4.8 % ± 6.3). Significant difference was showed between the RR group and both PL group (trained and untrained) and between the trained (0.2 % ± 4.5) and the untrained PL group for the maximal oxygen uptake. After training, the maximal aerobic speed increased significantly for the RR group (5.2 % ± 7.5), and tended to increase for the trained PL group (4.3 % ± 6.7). Significant difference for the maximal aerobic speed was obtained between the trained RR and PL groups and the untrained PL group. The average speed at the target heart rate rose for the trained RR group only (6,6 % ± 11.5), the regression in heart rate tended to occur faster in the RR group compared to the PL groups.
Discussion: The present study pointed out an increase in maximal oxygen uptake, maximal aerobic speed and average speed at target heart rate in RR group, showing improved aerobic performance compared with the PL groups. Furthermore, the RR group appears to recover faster after endurance training session.

THE JUSTIFICATION OF DIET SUPPLEMENTATION OF THE POLISH NATIONAL TEAM OF ATHLETES

CZAJA, J., LEBIEDZIŃSKA, A., SZEFER, P.

MEDICAL UNIVERSITY OF GDANSK

Nutrition is an important aspect of an athlete's training program. Every deficiency and excessive intake of nutritive elements may negatively influence sportsman performance especially high class athletes. However, for various reasons, not all athletes are able to consume a diet that meets nutritional needs and thus resort to nutritional supplements with the intention of preventing deficiencies and even enhancing performance (1, 2, 3).

The aim of the study was to examine the justification of the diet supplementation.

The investigation was carried out on a group of 62 athletes, members of Polish national team of middle and long distance runners (24 women aged between 19-31 and 38 men aged between 18-36). General information concerning respondents, their nutrition (food consumed within 24 hours before an interview) and their diet supplementation (frequency and quality) was gathered using the method of questionnaire interview at training camps and sport competitions. Values of energy and nutritive elements contents in athlete's diets were calculated by means of a computer program "Wikt 1.3" based on current tables of food products' nutritional value prepared by the National Food and Nutrition Institute in Warsaw (2001).

In the result of the investigation concerning diets quality some abnormalities has occurred. The examined daily food portions of women (W) and men (M) supplied amount of energy (2892 kcal-W; 3955 kcal-M) sufficient to fulfill daily requirement in case of moderate active people, not high class athletes. The investigated diets provided too low energy from carbohydrates and proteins limited by greater percentage of delivered energy from fat. The quantity of macroelements (Ca, P, Na, K, Mg), microelements (Zn, Cu, Mn) and vitamins (A, D, B group, C) in the analyzed diets was sufficient to fulfill daily requirement of athletes. The examined diets provided insufficient amount of Fe and vitamin E to ensure against potential deficiency.

According to diet supplementation 100% of the examined women and 94,7% of the examined men used dietary supplements. Most of the investigated athletes reached for carbohydrates powder products, vitamin-mineral products, vitamins C and B group, ferrum and magnesium supplements. Moreover, the examined runners also often enriched their diet in BCAA and carnitine.

In the analyzed daily food rations of Polish national team of runners only carbohydrates, ferrum and vitamin E supplementation seems to be justified.

THE EFFECT OF ORAL VANADYL SULPHATE ON MUSCULAR STRENGTH, POWER AND BODY COMPOSITION IN TRAINED AND NON-TRAINED MALES

VLECK, V., ALI, A.

UNIVERSITY OF WESTMINSTER

Background: Athletes use vanadyl sulphate supplementation to promote muscle growth and glycogen synthesis in the muscle and liver, with little scientific basis (Jentjens and Jeukendrup, 2002).

Purpose: To investigate the effects of oral Vanadyl Sulphate (VOSO4)

(30mg/day) supplementation on anthropometrical variables, body composition, and performance within a double blind, placebo-controlled trial of both untrained and trained participants.

Method: Eleven males (mean ± SD age 24 ± 2 yrs, mass 74 ± 11 kg), of whom n=5 were classed as trained and n=6 as untrained (mean ± SD scheduled training hrs/ wk 6 ± 2 and <1 hr, respectively), and allocated to 2 supplementation groups (G1 and G2), participated in a double blind placebo controlled study of 5 weeks total duration. Physiological trials, which were always at the same time of day, and 1 week apart, were conducted in the order T_Familiarisation (Wk 1, all); T_Baseline (B, Wk 2, all); and then either T_VS (vanadyl sulphate supplementation, VS, G1 or T_P (placebo supplementation, P, G2) (wk 3); T_Washout (wk 4, no supplementation, all), and then T_P (placebo supplementation, P, G1) or T_VS (vanadyl sulphate supplementation, G2) (wk 5). During the week prior to each trial, each subject consumed no supplement (Wks 1 and 2), or 10mg of either VS or P, with each of their morning, lunch and evening meals (i.e. a total daily dose of 30mg/day for a total of 7 days) (wks 3 and 5). Muscular strength, anthropometrical variables and 10s Wingate test power variables were assessed, in triplicate, within each physiological trial.

Results: Two way repeated ANOVA revealed no significant effect over baseline of one weeks supplementation of either VS or P, at the p>0.05 level, for bench press one-rep maximum (1RM) (Bas 79 ± 8 kg, VS 84 ± 9 kg, P 80 ± 8 kg), leg extension 1RM (Bas 54 ± 4 kg, VS 60 ± 3 kg, P 58 ± 3kg) vertical jump height (B 0.44 ± 0.03m, VS 0.43 ± 0.02m, P 0.43 ± 0.02m), peak power (B 734 ± 44 W, VS 783 ± 42 W, p 786 ± 44 W), average power (B 663 ± 34 W, VS 723 ± 40 W, B 705 ± 33 W), or fatigue ratio (B 9 ± 2, VS 11 ± 2, P 11 ± 2), biceps girth (B33 ± 1mm, VS 34 ± 1mm, P 33 ± 1mm), or (BODPOD) % body fat (B 13 ± 1, VS 13 ± 2, P 14 ± 1). However, VS values tended to be higher than B or P values (NS); and more so in trained than in untrained subjects (NS), especially for bench press 1RM (trained B 98 ± 33 kg, VS 101 ± 39 kg, P 100 ± 33 kg; untrained B 61 ± 11 kg, VS 65 ± 3 kg, P 67 ± 7 kg).

Conclusions:

The influence of 1 week of oral VS supplementation on muscular strength and anthropometric variables, and the extent to which this is influenced by subjects' training status, requires further investigation using larger sample sizes.

THE EFFECT OF CHRONIC TAURINE SUPPLEMENTATION ON HIGH INTENSITY, SHORT DURATION EXERCISE PERFORMANCE.

VLECK, V., SAUNDERS, D.J.

UNIVERSITY OF WESTMINSTER

Background: Taurine supplementation has been observed to lead to improvements in exercise performance in both rats and mice (Yatabe et al., 2003; Hamilton et al., 2006). Supplementation with (a higher than typical dose of) 6000 mg taurine for 7 days (Zhang et al., 2004) has also been found to result in increases in both cycle time to exhaustion and maximal cycle workload in humans.

Purpose: This study investigated the influence of 7 days of daily oral dosage of 1000 mg taurine on muscular power related variables in untrained humans.

Methods: Seven healthy, untrained, males (age (mean ± SD) 22.9 ± 1.9 yrs, height 1.74 ± 0.08 m, mass 69 ± 6 kg, body mass index 22.9 ± 1.9), randomly allocated to two supplement groups (G1 and G2), took part in a six week, single blind, placebo controlled cross over study. Physiological trials, which were always one week apart and at the same time of day, were conducted for each participant in the order: 1st Familiarisation (week 1, all); 2nd Familiarisation (week 2, all); Baseline (B, week 3, all); Taurine (T, week 4, G1) or Placebo (i.e. cornflour) supplementation (P, week 4, G2);Washout (week 5, all); and then Placebo (P, week 6, G1), or Taurine (T, week 6, G2) supplementation. Muscular power was assessed via Vertical Jump test (Newtest, UK) height (m); and peak power output (PPO), mean uncorrected power (P_av), and fatigue index (FI) within a 30 s Wingate cycle test. Fingertip blood lactate concentration ([BLA]) was determined (using a Lactate Pro) both immediately- and 1 min- post test.

Results: One way repeated measures ANOVA showed no significant difference (for $p>0.05$), on any of the measured variables, between the results at baseline and after either T or P supplementation (for Vertical Jump test B = 0.40 ± 0.08 m, P = 0.41 ± 0.08 m, T = 0.41 ± 0.10 m; for peak power output B = 772.2 ± 203.9 W, P = 849.5 ± 174.5 W, T = 761.1 ± 186.8 W); for uncorrected P_av (B = 588.0 ± 101.1 W, P = 564.9 ± 110.0 W, T = 545.1 ± 115.9 W); for FI B = 35.8 ± 17.4 %, P = 46.4 ± 12.1 %, T = 39.4 ± 18.7 %); for [BLA] immediately post exercise B = 4.9 ± 1.6 mM, P = 5.6 ± 3.0 mM, T = 5.5 ± 2.8 mM; for [BLA] 1 min post exercise B = 8.9 ± 3.1 mM, P = 10.3 ± 3.4 mM, T = 11.1 ± 3.5 mM).

Conclusion: The effect of different dosages of taurine supplements on exercise performance in humans requires further investigation, using larger sample sizes.

DIETARY SUPPLEMENT USE OF ELITE GERMAN ATHLETES AND KNOWLEDGE ABOUT THE CONTAMINATION PROBLEM

BRAUN, H., KOEHLER, K., GEYER, H., THEVIS, M., SCHAENZER, W.

GERMAN SPORT UNIVERSITY COLOGNE

Introduction: Dietary supplement (DS) use is widespread in elite athletes. Mainly described motives for DS use are increasing performance, maintaining health or optimizing regeneration. (Braun et al., 2009) The benefits of most products are still unclear because their effectiveness is often not scientifically proven. In contrast, since 1999 the risk on DS for contaminations and adulterations with doping substances is well described (Geyer et al. 2008). Therefore, the aim of the study was to evaluate DS use in elite athletes and their knowledge about the contamination problem.

Methods: During the preparation period (June-July 2008) for the Olympic Games 2008 in Beijing, we provided to 193 elite German athletes a closed-ended questionnaire to assess the past and present (DS use in the past 4 weeks) use of DS. Additionally, athletes have been asked about the contamination problem, motives of DS use, sources of advice, and supplement sources. The questionnaires were voluntarily returned by 117 (age 26.4 ± 5.8 y, male n = 74, female n = 43) athletes from 16 different sports.

Results: Almost all athletes (97 %) have used DS in their active sports career, while 88 % reported a use (range 1-19) in the present period. For the group of DS users Minerals (74 %), vitamins (65 %), sport beverages (63 %) were most frequently used in the present period. Major motives for using supplements were optimizing regeneration (70 %), immune functions (64 %), health related (61 %) and increasing performance (48 %). Physicians (56 %), coaches (35 %), nutritionists (30 %) and physiotherapists (22 %) mainly recommended DS.

Among all athletes, 63 % classified the contamination problem correctly (CCPC). However compared to the non-CCPC, this did not influence their supplement use according to frequency, motives, sources of advice, and supplement sources. Apart from that, the group of CCPC used more often individual nutrition consulting ($p = 0.002$) and felt better elucidated about usage of DS ($p = 0.002$).

Discussion: The present data confirm the fact that DS use is widespread in elite athletes. Leading sport organizations recommend that: "athletes should be ensure they have a good diet before contemplating supplement use" (Maughan et al., 2007). However, only 54 % of the athletes ever had an individual nutrition consulting.

Almost 2/3 of the athletes reported to be aware of the contamination problem. This is more than we found in young athletes (Braun et al., 2009). Anyway, it still seems necessary to educate athletes about risks and benefits of DS and include physicians, coaches, nutritionists and physiotherapist into this process.

EFFECTS OF CREATINE SUPPLEMENTATION ON 12-WEEK WATER EXERCISE PROGRAM IN OLDER ADULTS

ISHIZAKI, S., KATAMOTO, S., NAITO, H., NOGAWA, H., SAKURABA, K., KAI, F., SEITA, T., KUNII, M., AOKI, J.

OYAMA NATIONAL COLLEGE OF TECHNOLOGY, JUNTENDO UNIVERSITY, CENTRAL SPORTS CO. LTD

Introduction: Water exercise is well-rounded exercise program to improve not only cardiovascular fitness but also muscular strength. And it is getting popular for older people (Takeshima et al. 2002). Recently it is reported that Cr supplementation can apply to older people to improve muscle strength and fat free mass with resistance training (Brose et al. 2003). However, it is not clear whether the effects of

water exercise program can be enhanced with Cr supplementation in older people. The purpose of this study was to investigate the effects of 12-week water exercise program (WEP) with Cr supplementation on health-related fitness in older adults.

Methods: Sixteen elderly men and women (age 68.1±5.1yr), free of cardiorespiratory and nuerological diseases, gave informed consent to participate as volunteers for this study. Subjects were randomly assigned in a double-blind design to either a Cr supplementation group (CRE, n=8) or a placebo group (PLA, n=8). The CRE ingested 3-g doses of Cr monohydrate (Creapure, AlzChem Trostberg GmbH, Germany) per day for 3 months, whereas the PLA ingested the same dosage of lactose. Before (pre-) and after (post-) the supplementation period, the following physical characteristics were measured; chair stand (CS), arm curl (AC), sit-up (SU), up & go (UG), sit & reach (SR), and 6-min walk (6-MW). In addition, body composition was estimated using a bioelectrical impedance method (InBody 3.2, Biospace, Japan). After the first test, all subjects completed 12-week WEP (70min./d, 3times/week, total 36 sessions). This WEP consisted of 20 min. of warm-up and stretching, 30 min. of endurance-type exercise (walking and dancing), 10 min. of resistance exercise, and 10 min. of cooling down exercise. During the WEP, heart rate was monitored continuously for all subjects using a heart rate monitor (S610i, Polar, Finland). In addition, all exercise session was led by trained fitness instructors and semi-supervised by the researchers.

Results: In both groups, body weight, fat, %fat, and fat free mass were not significantly changed after 12-week WEP. On the other hand, improvements were observed in CS, AC, SU, UG, SR, and 6-MW in both groups after 12-week WEP ($P<0.05$). However, % increase of CS and AC in CRE (CS: 23.8±10.0%, $P<0.05$, AC: 24.6±9.0%, $P<0.05$) was significantly higher than PLA (CS: 12.0±5.3%, AC: 13.9±9.2%).

Conclusion: It has been demonstrated that 12-week WEP improves health-related fitness for older adults. Moreover, the additional of Cr supplementation to the water exercise have a beneficial effect on an increase of muscular strength in older adults.

EFFECTS OF CHRONIC RHODIOLA ROSEA SUPPLEMENTATION ON SPORT PERFORMANCE AND ANTIOXIDANT CAPACITY IN TRAINED MALE: PRELIMINARY RESULTS

DURANTI, G., PARISI, A., CIMINELLI, E., CECI, R., CERULLI, C., QUARANTA, F., TRANCHITA, E., BORRIONE, P., SABATINI, S.

UNIVERSITY OF ROME

Rhodiola Rosea (RR), is an adaptogen plant, that belongs to Crassulaceae family, that has been reported to affect several physiological mechanisms, stimulating metabolism, promoting fatty acids utilisation, having an ergogenic function, improving body resistance to physical strenuous efforts [1,2] and showing an antioxidant function [3]. The purpose of this study is to investigate the effects of chronic Rhodiola Rosea supplementation on physical performance parameters, redox status and the capacity of substrate consumption during endurance exercise in a group of competitive athlets.

We selected 14 well trained male athletes, between 20 and 35 years old. After an admission test evaluating the maximal oxygen uptake (VO2 max), the subjects underwent a chronic supplementation with Rodhiola Rosea (170 mg/die) or placebo (P) every morning for 4 weeks in a double blind clinical trial. At the end of supplementation period, the athletes underwent the cardio-pulmonary exhaustion test at 75% of their VO2 max.

Physical performance parameters evaluated show that HR Max (171±10 for P vs 172±8 bpm for RR), the Borg Scale level (all 4-5), VO2 max (49.86±12.75 for P vs 52.61±12.35 ml/kg/min for RR) and duration of the test (19±9 for P vs 19±11 min for RR) are essentially the same after Rhodiola Rosea or placebo intake.

Rhodiola Rosea reduced in a statistically significative manner ($p<0.05$ at acme and $p<0.01$ after 30 minutes recovery) plasma free fatty acids levels in supplemented group (12.86±1.62 for P vs 7.31±1.31 mgFFA/dl plasma for RR at acme and 11.41±0.56 for P vs 7.01±1.16 mgFFA/dl plasma for RR after 30 minutes recovery). No effect on blood glucose was found.

Blood antioxidant status (Haemolysis, Total Antioxidant Status, Manoldialdheyde) and inflammatory (Interleukine-6) parameters results unaffected after RR supplementation.

Blood lactate ($p<0.05$) and plasma creatine kinase (all $p<0.01$) levels decreases in a statistically significative way in Rhodiola Rosea group compared to placebo (37.19±7.29 for P vs 23.50±3.96 U-CK/L plasma for RR at acme and 35.52±4.20 for P vs 25.70±5.24 U-CK/L plasma for RR after 30 minutes recovery).

In conclusion, we demonstrate that a chronic Rhodiola Rosea supplementation can be useful for sports activity, during endurance exercise by decreasing lactate levels, parameters of skeletal muscle damage as creatine kinase and ameliorating fatty acid consumption.

LOCALIZATION OF SEVERAL ANGIOGENIC FACTORS IN THE MOUSE MYOCARDIUM IN RESPONSE TO ENDURANCE TRAINING

BELLAFIORE, M., BATTAGLIA, G., BIANCO, A., PALMA, A., FARINA, F.

UNIVERSITY OF PALERMO

Introduction: Previous studies carried out in our laboratory showed the presence of hypertrophy associated with angiogenesis in the mouse myocardium in response to endurance training (I). Moreover, we analysed the expression of several angiogenic factors as VEGFR-1/Flt-1, VEGFR-2/Flk-1, HIF-1a, iNOS and MMP-9 showing that the exercise differently regulates their expression levels in the angiogenic hearts according to the intensity and length of endurance training (II).

The aim of this study was to examine the localization of VEGFR-1/Flt-1, VEGFR-2/Flk-1, HIF-1a, iNOS and MMP-9 in the same experimental model in order to observe in which cells these proteins are expressed in response to exercise.

Methods: Hearts from sedentary and trained mice were fixed with formalin, embedded with paraffin and cut to obtain 5μm sections that were used to perform the immunohistochemical analyses. Sections were incubated with the monoclonal primary antibodies for VEGFR-1/Flt-1, VEGFR-2/Flk-1, HIF-1a, iNOS and MMP-9 at specific concentrations. Nonimmune mouse serum was substituted for negative controls.

Results: We observed that VEGFR-1/Flt-1 and VEGFR-2/Flk-1 were specifically expressed by vascular endothelial cells of the myocardium. HIF-1 alpha was localized in nucleus of vascular endothelial cells and myocardiocytes. iNOS was expressed in cells of interstitial connective tissue and smooth muscle and MMP-9 localized in interstitium and vascular endothelial cells. We did not find any difference in the localization of these factors between sedentary and trained groups; instead we noted different expression levels between sedentary and trained groups and within the trained group in agreement with our previous data from immunoblotting analyses.

Discussion: Our results suggest that both VEGFR-1/Flt-1 and VEGFR-2/Flk-1 might be involved in the proliferation of capillary endothelial cells in the cardiac angiogenesis induced by exercise. The expression of HIF-1a suggests that brief and transient episodes of hypoxia may occur in the heart during cardiac cycle in response to endurance training. This factor could modulate the gene expression of VEGF to increase the angiogenic response of heart to exercise. The expression of iNOS suggests the production of NO by the cells of interstitial tissue and smooth muscle in order to promote the vascular relaxation fundamental in the early steps of angiogenesis. The localization of MMP-9 in the vascular endothelial cells and interstitium suggests that endurance training can promote the expression and release of pro-enzymatic form of MMP-9; and a possible conversion of pro-MMP-9 in the active form in the interstitium.

ENDURANCE TRAINING RESTORES HEPATIC CARNITINE PALMITOYLTRANSFERASE ACTIVITY IN CACHECTIC TUMOUR-BEARING ANIMALS

GONÇALVES, D., LIRA, F.S., YAMASHITA, A.S., LIMA, W.P., CARNEVALI JR, L.C., ROSA NETO, J.C., CAPERUTO, E.C., COSTA ROSA, L.F.B.P., SEELAENDER, M.C.L.

UNIVERSITY OF SÃO PAULO

Introduction: Cancer cachexia is a syndrome characterized by various metabolic alterations, and liver lipid metabolism is markedly affected, in concommitance to systemic increased pro-inflammatory factor expression Our previous studies show that sub-maximal intensity endurance training is able to increase the capacity for fatty acid oxidation and regulate the inflammatory profile in the cachexia-inducing Walker 256 carcinosarcoma animal model .

Methods: The effect of endurance training on PGE2 levels and on the activity of hepatic carnitine palmitoyltransferase (CPT) system was studied in Walker 256 tumour-bearing rats. Animals were randomly assigned to a sedentary control (SC), sedentary tumour-bearing (ST), or exercise control (EC) and exercise tumour-bearing (ET) group. Trained rats ran on a treadmill (60%VO2max) for 60min/day, 5 days/week, for 8 weeks. The maximal activity of carnitine palmitoyltransferase system (CPT I and CPT II) in the liver was measured by radioassay. Gene expression of hepatic cyclooxygenase type 2 (COX-2) was measured by RT/PCR. PGE2 content in serum, liver and tumour tissue was determined by ELISA.

Results: Maximal activity of CPT I and CPT II were decreased ($p<0.01$) in ST (2.66±0.0 and 0.16±0.10 nmol min-1mg-1protein, respectively) as compared with SC (3.66±0.38 and 1.68±0.16 nmol min-1mg-1protein, respectively). In contrast, mRNA COX-2 in the liver of cachetic animals increased, as well as serum PGE2 (2526±132 pg/mL, $p<0.05$) when compared to SC (1901±259 pg/mL), and in liver (2030 ± 47 pg.ug protein-1, $p<0.05$) as compared to SC (997±36 pg.ug protein-1). High levels of PGE2 were found in tumour tissue (4580±88 pg.ug protein-1). Endurance training restored maximal activity of CPT I and CPT II in tumour-bearing (10.61±1.62 and 9.25± 1.12 nmol min-1mg-1protein, respectively, $p<0.0001$) when compared to ST. Besides, exercise restored PGE2 levels in the liver of cachectic rats (1150±53 pg.ug protein-1, $p<0.05$) and decreased PGE2 levels in tumour tissue (2750±96 pg.ug protein-1, $p<0.01$), as well as decreased hepatic COX-2 gene expression.

Discussion: Endurance training promoted the reestablishment of hepatic carnitine palmitoyltransferase (CPT) system activity that was a key role in lipid oxidation. This alteration was followed by a reduction in PGE2 levels in liver, serum and tumour mass in cachectic animals and a reduced COX-2 gene expression in liver. These changes in inflammatory state can be related with the improvement on lipid metabolism in tumour bearing rats, submitted to a treadmill sub maximal exercise.

ACE ION/DELETION I/D POLYMORPHISM AFFECT ARTERIAL COMPLIANCE IN ENDURANCE ATHLETES

IZZICUPO, P., DI FRANCESCOMARINO, S., SANTARELLI, F., DI MAURO, M.,3, GRANIERI, M., RIPARI, P., DI BALDASSARRE, A., GALLINA, S.

1.2. UNIVERSITY OF CHIETI-PESCARA, 3. UNIVERSITY OF CATANIA

Arterial stiffness is an important determinant of cardiovascular morbidity and mortality. The I/D polymorphism of angiotensin-converting enzyme (ACE) gene is associated with cardiovascular disease. However, the relationship between ACE polymorphism, arterial stiffness, and wave reflections in healthy, low-risk population has not been defined yet.
Objective: This study was aimed to evaluate the role of insertion/deletion (I/D) polymorphism in intron 16 of the ACE gene, in endurance master athletes.
Methods: A group of 41 white healthy male endurance athletes, aged between 36 and 45 years, were enrolled in this study. All of them participated primarily in endurance sports, training for at least >8 h/week, for at least 5 years. All subjects underwent clinical visit, rest electrocardiography and cardiopulmonary test. Maximal oxygen uptake (VO2max) was 46,7±7,6 whit Anaerobic Threshold (AT) at 62%±14,1. The ACE genotype (insertion [I] or deletion [D] alleles) was ascertained by polymerase chain reaction (DD 35, ID 36 and II in 3). Echocardiography analysis was performed using an ultrasound system with 3,7 MHz transducer, to evaluate systolic and diastolic left ventricular function. Arterial distensibility was assessed by augmentation index using the PulsePen tonometer.
Statistical analysis: A dominant model for I allele was assumed (DD vs ID+II). All statistical analyses were performed using the program SPSS 13.0.
Results: No difference was found between the 2 groups concerning subjects characteristics like age, body mass index (BMI), blood pressure (BP), VO2max and plasmatic markers. ACE-DD group showed an higher augmentation Index (AI) (24,9±11,5) by comparison with ACE-ID/II group (7,7±14,7), p=0,004.
Conclusions: Although endurance training is efficacious in increasing arterial compliance, we found that ACE-DD group is associated with a lower arterial compliance and this founding is independent on BP.

EFFECTS OF NAD PH OXIDASE P22PHOX POLYMORPHISM ON CARDIOVASCULAR REMODELING IN ENDURANCE ATHLETES

IZZICUPO, P., DI FRANCESCOMARINO, S., SOCCIO, M., SANTARELLI, F., DI MAURO, M.,3, GRANIERI, M., AMICARELLI, F., PENNELLI, A., RIPARI, P., DI BALDASSARRE, A., GALLINA, S.

1,2. UNIVERSITY OF CHIETI-PESCARA, 3. UNIVERSITY OF CATANIA, 4. UNIVERSITY OF L'AQUILA

Introduction: An acute bout of exercise increases the production of ROS through several mechanisms including (NAD(P)H. Even though regular physical exercise is generally reported to be the most effective non-pharmacological intervention to enhance the endogenous anti-oxidant capability and to alleviate oxidative stress-induced damages, its influence can be strictly affect by genetic aspect. We focused our attention on p22phox, a subunit of the NAD(P)H oxidase, and on its allelic polymorphism C242T, which is known to affect the functional activity of the enzyme. Aim of our study was to investigate whether p22phox C242T gene variants can influence cardiovascular adaptations to physical exercise in middle-aged endurance athletes. Methods: Seventy-three long distance male runners (26-44 years) participated to the study. All subjects underwent clinical visit, rest electrocardiography and cardiopulmonary test. The p22phox C242T polymorphism was determined by polymerase chain reaction-restriction fragment length polymorphism. Echocardiography analysis was performed using an ultrasound system with 3,7 MHz transducer, to evaluate systolic and diastolic left ventricular function. Arterial distensibility was assessed by augmentation index using the PulsePen tonometer. Statistical analysis: All statistical analyses were performed using the program SPSS 13.0. Results: The subjects were divided into two groups (CC and TC+TT) for further evaluation. There was no difference between demographic subject characteristics like age, BMI or biochemical examination. We did not found significant differences in left ventricle remodeling. About vascular function parameters TC+TT subjects showed a significant reduction (p=0,021) of augmentation index (7,7±15,6) by comparison with CC subjects (16,5±11,9). Moreover TT subjects showed a significant (p=0,010) lower DBP (75±5,7) by comparison with CT+TT subjects (79,4±7,9) and a significant lower (p=.,004) MBP (89,3±6,3) as compared whit CT+TT group (94,3±7,4). Conclusion: We found that p22phox polymorphism is associated with differential adaptive responses of cardiovascular system to aerobic exercise training, supporting a different oxidative state. Endurance athletes with TC+TT allele show better vascular compliance, thanks to a reduced susceptibility to the oxidative damage.

THE EFFECTS OF TRAINING AT DIFFERENT INTENSITIES UPON LIPID METABOLISM IN THE LIVER

EDER, R., CARNEVALI JR, L.C., LIMA, W.P., GONÇALVES, D.C., SEELAENDER, M.C.L.

INSTITUTE OF BIOMEDICAL SCIENCES, UNIVERSITY OF SÃO PAULO

Introduction:
Low intensity continuous training (50-70% Vo2 max) is known to improve fatty acid oxidation in the skeletal muscle. However, there are few studies concerning the adaptations of lipid metabolism in response to intermittent exercise training in the liver. Intermittent exercise is characterized by repeated bouts of brief near-maximal or maximal intensity work, interspersed with periods of recovery (rest or low intensity work) (Glaister, 2005). We evaluated the capacity of intermittent exercise training to induce increased lipid metabolism in the liver, considering the important role of this organ during exercise. Many studies show that the adaptations of lipid metabolism in the liver are closely related with modulation of gene expression of the involved proteins.
Methods: Male adult Wistar rats were distributed in 3 groups: Sedentary (S), intermittent (IT) and continuous (CT) exercise trained. The IT rats swam for fifteen bouts (60-second, with a overload equal to 10% of the body weight). The CT rats swam 1 hour per day (overload 5% of the body weight). Both training strategies were performed 5 times a week, during 8 weeks (Lima et al., 2005).
The mRNA expression of fatty-acid transporter (FAT/CD36), apoliprotein B (apoB), microsomal triacylglycerol transfer protein (MTP) and the proliferator-activated- receptor (PPAR were assessed by real time PCR.
Results: No difference among the groups (P>0.05) was found regarding the expression of the studied proteins.

Discussion: Our aim was to compare the interference of the liver upon the systemic lipid metabolism using two different protocols: Intermittent (around 100% of the VO2max) and continuous (60%VO2max) exercise training. Despite the different exercise stimuli, we found no different adaptations between the groups. Therefore, we can speculate that the two protocols induce similar adaptation in regard to liver lipid metabolism (Chilibeck et al., 1998; Chapados et al., 2008).

TGF-β ISOFORMS INHIBIT IN VITRO MIGRATION AND FUSION OF MYOGENIC PROGENITOR CELLS

SCHABORT, E.J., VAN DER MERWE, M., NIESLER, C.U.

EXERCISE SCIENCE AND SPORTS MEDICINE UNIT, UNIVERSITY OF CAPE TOWN

Introduction: Following muscle injury, the damaged tissue and influx of inflammatory cells stimulate the secretion of various growth factors and cytokines into the afflicted area to initiate repair processes. This release of chemotactic signaling factors activates resident myogenic precursor cells (quiescent satellite cells, other local sources of myocytes) and precursors from external fibers to participate in regeneration. These signaling molecules also control cellular responses required to stimulate the mobilization and migration of cells from distant niches to the site of injury, where fusion can occur to form myofibers. Specifically, sports injuries (e.g. muscle contusions) are a primary concern to athletes who cannot afford the time off to recuperate. While treatment options are limited and time-consuming, research has shown administration of autologous conditioned serum, which stimulates the release of growth factors aiding regeneration, to be a promising new approach by reducing recovery time (Wright-Carpenter et al, 2004). The three Transforming Growth Factor-ß (TGF-ß) isoforms and Insulin-like Growth Factor-I (IGF-I) are among the known factors released following muscle damage. We investigated the effect of TGF-ß1, -ß2, -ß3 and IGF-I on muscle progenitor cell migration and the effect of TGF-ß isoforms on myoblast fusion.

Methods: The C2C12 skeletal muscle satellite cell-line was used to determine the effect of recombinant active TGF-ß1, -ß2 and -ß3, IGF-I and TGF-ß isoforms + IGF-I on the migration of myogenic precursor cells. In addition, the effect of 72 hr TGF-ß treatment was analysed on C2C12 fusion.

Results: IGF-I significantly increased migration compared to TGF-ß isoforms which had no effect on the mobilization of C2C12 cells. Although all isoforms decreased IGF-I-induced cell migration, the number of migrated cells was still significantly higher compared to control. Myoblast fusion was significantly reduced in all TGF-ß-treated C2C12 cells.

Discussion: The ability to regulate cellular processes in response to injury could be of important therapeutic value (Smith et al., 2008). We have previously shown that all three TGF-ß isoforms significantly increase C2C12 satellite cell proliferation (Schabort et al., 2009). We have now gone on to show that both myocyte migration and fusion are negatively regulated by all three isoforms. By distinguishing the factors involved in, and the molecular signals required for myoblast recruitment during repair processes, strategies can be developed towards improved cell-mediated therapies for muscle injury. Future research should involve in vivo combined-effects studies using multiple growth factors. These results highlight the importance of understanding the cytokine milieu of progenitor cells when determining viable treatment options.

THE MODULATION OF LIPID METABOLISM-RELATED GENES IN THE LIVER OF TRAINED TUMOUR-BEARING RATS.

CARNEVALI JR, L.C., EDER, R., LIMA, W.P., LIRA, F.S., PAPESCHI, J.C., GONÇALVES, D.C., SEELAENDER, M.C.L.

UNIVERSITY OF SÃO PAULO

Introduction: Lipid metabolism in the liver is clearly altered by the syndrome of cancer cachexia. Previous studies by our group have shown that, in one such model, liver capacity for the oxidation of long chain fatty acids and for ketone body production is decreased (Seelaender et al., 1996). The activity of the CPT (carnitine palmitoyltransferase) enzyme complex, the main step in the control of mitochondrial long chain fatty acid transport, is reduced in cachectic rats, aggravating cachexia Regular moderate exercise is known to contribute for the prevention of cancer, enhancing resistance against tumour growth. (Lira et al., 2008). A previous study by our group showed that moderate exercise training (60% VO2max, 60min per day, 5 day a week, for 8 weeks) may increase hepatic lipid oxidation and augment very low density lipoprotein (VLDL) secretion in the trained tumour-bearing rats (Lira et al., 2008). Changes in lipid metabolism are closely related with associated protein gene expression modification, which is in many cases, mediated by mechanisms dependent on the activation of PPARs. Some studies show that training is able to induce gene expression of proteins such as CPT I, CPT II, PPARalpha, FABP. Hence, we investigated whether 8 weeks of moderate training would promote changes in the liver lipid metabolism in tumour-bearing rats.

Methods: Male adult Wistar rats were distributed in 4 groups: Sedentary control (SC), Sedentary tumour-bearing (ST), exercise-trained control (EC) and exercise trained tumour-bearing (ET). The mRNA expression of fatty-acid binding protein (FABP), apoliprotein B (apoB), microsomal triacylglycerol transfer protein (MTP), Carnitine Palmitoyltransferase I (CPT I), Carnitine Palmitoyltransferase II (CPT II), peroxisome proliferator-activated- receptor alpha (PPAR alpha) were assessed by real time PCR.

Results: Cachexia (tumour vs control group) induced an increased gene expression of PPAR alpha ($P<0.028$), CPT I ($P<0.026$), CPT II ($P<0.009$) and FABP ($P<0.033$). Moreover, MTP and apoB genes were shown to be affected by both cachexia and training ($P< 0.006$ and $P< 0.012$ respectively).

Discussion: Our results indicate a strong modulation of lipid metabolism-related gene expression both by cachexia and training. Previous studies by our group have shown that moderate endurance training was efficient in improving VLDL secretion in the tumour-bearing rats. Our present data confirmed such results and additionally indicated that the tumour presence per se induced a higher gene expression of such proteins in an attempt to restablish the hepatic cell function. We conclude therefore, that the endurance training was efficient to promote a higher modulation of lipid metabolism-related genes in the liver of tumour-bearing rats.

LEPTIN RECEPTOR EXPRESSION IN HUMAN SKELETAL MUSCLE.

OLMEDILLAS, H., SANTANA, A., FUENTES, T., GUADALUPE-GRAU, A., GUERRA, B., CALBET, J.A.L.
1. UNIVERSIDAD DE LAS PALMAS DE GRAN CANARIA, 2. CHILHOOD HOSPITAL-MATERNO INFANTIL DE LAS PALMAS, 3. HOSPITAL DE GRAN CANARIA DR. NEGRÍN

Leptin plays a crucial role in the regulation of appetite, body fat mass and basal metabolic rate. We have recently shown the presence of leptin receptor (OB-R), long and short protein isoforms, in human skeletal muscle. Human obesity is characterised by a high concentration of leptin in plasma associated with leptin resistance. Yi-Wen Chen et al, showed OB-R expression in human muscle fibers from immobilized muscles whereas no positive signals were observed in healthy control muscles using traditional Immunohistochemistry.

Purpose. The aim of this study was to determine the cellular distribution of leptin receptors (OB-R) at the protein level in healthy human skeletal muscle.

Methods. Muscle biopsies were obtained from the musculus vastus lateralis in fourteen, healthy men (age = 33.1 ± 2 yr, height = 175.9 ± 1.7 cm, body mass = 81.2 ± 3.8 kg, body fat = 22.5 ± 1.9%). The expression of OB-R was determined by immunohistochemistry and indirect inmunofluorescence. Serial 5-μm-thick frozen muscle sections were cut from muscle biopsies obtained from the musculus vastus lateralis, and incubated using a polyclonal rabbit anti-human leptin receptor, a polyclonal rabbit anti-perilipin A and the blue-fluorescent DAPI nucleic acid stain. The specificity of the anti-OB-R antibody was confirmed in our laboratory by Western Blot (Guerra et al., 2007).

Results. OB-R protein was localized in the subsarcolemmal regions of the subject's muscle fibers and this pattern was revealed by an antibody specific for the OB-R long isoform (170 KDa), which is not expressed in the adipose tissue. The OB-R staining near the perinuclear region was negative. There was no co-localization between Perilipin A (a protein exclusively expressed in adipocytes) and the OB-R long isoform. No clear fiber-type specific pattern was observed.

Conclusion. The long isoform of the leptin receptor is abundantly expressed in the subsarcolemmal regions of the skeletal muscle fibers of the m. vastus lateralis in healthy humans.

OBESITY AND THE METABOLIC SYNDROME IN GREEK CHILDREN AND ADOLESCENTS

CHRISTODOULOS, A., KAFANTARI, V., GIKA, H., DOUDA, H., TOKMAKIDIS, S.P.
DEMOCRITUS UNIVERSITY OF THRACE

Introduction: The increasing prevalence of the MS and its components in young populations (Steinberger & Daniels, 2003) suggests that the onset of the syndrome in adulthood may has its roots early in life (Katzmarzyk et al., 2001) and underlines the need for early identification of the condition. In Greece, an alarmingly increase in the prevalence rates of childhood obesity has been documented, accompanied by unfavourable blood lipid profiles and high blood pressure values (Angelopoulos et al. 2006; Bouziotas et al. 2001). However, there is a paucity of data examining the clustering of metabolic risk factors in Greek pediatric populations. The aim of the present study was to determine the prevalence of obesity and the MS in Greek children and adolescents.

Methods: The sample consisted of 112 primary (mean age11.4±0.4 years) and 279 high school students (mean age13.6±0.9 years) living in Central Greece. Data was obtained on children anthropometry, blood pressure, fasting glucose and fasting lipids. The body mass index cut-off points adopted by the International Obesity Task Force (Cole et al. 2000) were utilized for the assessment of overweight and obesity. MS was defined using criteria analogous to the Adult Treatment Panel III definition (De Ferranti et al. 2004) Chi-square tests were used for statistical analyses. The level of significance was set at $p<.05$.

Results: Using the International Obesity Task Force's (IOTF) BMI cut-off points, the prevalence of overweight and obesity was estimated to be 29.5% and 10.7% among primary school and 26.2% and 11.1% among high school students, respectively. 7.2% of the participants were diagnosed with MS, without differences between education levels (primary education: 5.4%, secondary education: 7.9%, $p>0.05$). The prevalence of the syndrome increased directly with the degree of obesity (normal weight: 5.0%, overweight: 7.6%, obese: 18.6%, $p<0.006$).

Discussion/Conclusion

In the present cohort of Greek children obesity and MS prevalence were alarmingly high. MS prevalence was extremely high in obese schoolchildren. Given that obesity and other cardiovascular risk factors track from childhood into adult life, these data suggest that the prevalence of MS among Greek adults will increase, unless effective prevention efforts will be implemented early in life.

THE ASSESSMENT OF LEAD OCCURRENCE FREQUENCY IN THE BLOOD OF CHILDREN FROM THE INDUSTRIAL REGION

IGNASIAK, Z., SLAWINSKA, T.
UNIVERSITY SCHOOL OF PHYSICAL EDUCATION

Introduction: Lead is one of these elements whose occurrence in the environment causes its degradation. In recent years our knowledge about toxic effects of lead on human organism increased significantly (Andrzejak, Smolik, 1996). Children and youth are the most sensitive to the toxic influence of lead, therefore they constitute a higher risk group than adults. Negative health effects caused by lead are observed in almost every systems and organs, however the most significant changes appear in the nervous system, kidneys and the hematopoietic system. The toxic effects of lead include lowering one's intelligence, weakening neurobehavioural development and general impairment of development (Ignasiak et al. 2006, 2007). In Poland several measures were taken in the 1990s to limit lead emissions to the environment, especially in ecologically threatened regions.
The aim of our work is to estimate lead concentration in the blood of rural children and youth living in ecologically threatened areas in 1995 and 2007.
Methods
Since 1995 we have been conducting research regarding health and development of children and youth from the industrial region of Lower Silesia (Legnica-Głogow Copper District). To meet the objectives of the presented work we concentrated on the amount of lead in the blood of children aged 7 – 15 examined in 1995 and 2007. A blood sample was drawn by venipuncture and tested for lead level by atomic absorption spectrometry in a graphite furnace. 1591 people were tested, 899 in 1995 and 692 in 2007.
Results: Comparing the concentration of lead in the blood of girls and boys, a significant decrease is observed in the 2007 research. The highest percentage of children tested in 1995 indicated the concentration of lead in the range 5 – 10 μg/dl, while in 2007 the largest group of the tested children had their concentration in the range 0 – 5 μg/dl.
The apparent decrease of lead concentration in the blood of children and youth in 2007 may be connected to the significant limitation of lead emissions by the copper industry.

CROSS-SECTIONAL ANALYSIS OF OBESITY IN CHILDREN BETWEEN 3 AND 12 YEARS IN RURAL POPULATION

LARA SÁNCHEZ, A.J., MARTINEZ LÓPEZ, E.J., HERRADOR COLMENERO, M., HUERTAS HERRADOR, J.A.
UNIVERSITY OF JAÉN

Introduction: This study examines the state of obesity between boys and girls of primary school education in a rural area, aged between 3 and 12 years. To conduct this analysis, we have updated references to studies of subjects with similar characteristics. The aim of this study was to identify the characteristics of the sample of rural community and compare it with the national average.
Methods: In this work involved 519 subjects of both sexes, belonging to rural villages. Were organized into age groups: G1 (3, 4, 5 years), G2 (6, 7 years), G3 (8, 9 years), G4 (10, 11 years), G5 (12 years). It has weight and height measurements and from these data have been obtained for BMI (Body Mass Index). We have used the statistical program Statistica (for Windows, v 7.0).
Results: Looking to the average values obtained in relation to height, weight and BMI, we see that all are above average, compared to data obtained by the "Research Institute Growth and Development". Only one case was found near the risk BMI (G1 male). Furthermore no significant differences were found between boys and girls in any of the three variables studied. By gender, comparing one group with the following significant differences were observed in all cases, except in weight between the G4 and G5 male in height between G4 and G5 both female and male, and all in between BMI.
Discussion: As can be seen in the data obtained, the averages of all the subjects are above the national reference, which may indicate that they have healthy levels but above the average. Furthermore, analyzing the relationships in BMI there was no significance in the references made, there are no differences. Finally, both the weight and height, there is an important significance, obtained by a general $p < 0.001$, so if there are differences.

SEDENTARY BEHAVIOUR AND INTENSITY-LEVELS OF PHYSICAL ACTIVITY VARIATION DURING ADOLESCENCE YEARS IN BOYS

MACHADO RODRIGUES, A., CARVALHO, H.M., COELHO E SILVA, M.J., MOTA, J.
UNIVERSITY OF COIMBRA

Introduction: Active lifestyles are a topic of current scientific discussion, especially in terms of health promotion and disease prevention. On the other hand, sedentary habits are indicated as a major risk factor for morbidity in adults, and also are increased among children and adolescents. However, most studies have not measured sedentary behaviour or differentiated it from light activity (Pate et al., 2008). The present study examines the age-variation of sedentary habits and physical activity [PA] in its different intensities portions among a sample of male adolescents.
Methods: The sample comprised 173 boys [13-14 years, n=108; 15-16 years, n=65]. Somatic characteristics included body weight, height, sum of six skinfolds and umbilical circumference. PA was estimated using an uniaxial accelerometer (Actigraph,7164) on five consecutive

days assuming a minimum amount of 10h of valid data per day (criterion of inclusion). Freedson et al (1997) and Puyau et al. (2002) cut-points were used to data analysis of PA intensities-levels and sedentary behavior, respectively. Age effect was tested on intensity-levels of physical activity and sedentary habits.

Results: Compared with younger group, older boys are taller [13-14yr: 159.9±9.3 cm; 15-16yr: 170.6±5.9 cm; t=-7.898; p<0.001] and heavier [13-14yr: 50.3±10.9 kg; 15-16yr: 62.6±10.1 kg; t=-7.430, p<0.001]. No significant differences were found for BMI [13-14 yrs: 19.51±3.09 kg/m2; 15-16 yrs: 21.51±3.37 kg/m2]. Both 13-14 and 15-16 years-old groups were less sedentary on week-end than during week days, and no significant differences were found throughout week between groups. Younger boys were significant more active on high intensity level of PA than their counterparts in both week [13-14yr: 108±39 min; 15-16yr: 74±31 min; t=6.004, p<0.001] and week-end days [13-14yr: 66±40 min; 15-16yr: 49±32 min; t=2.783, p<0.01]. Moderate to very vigorous PA had a substantial decrease from week days to week-end on two compared groups.

Conclusion: The present study showed that older adolescents were less active than younger boys, especially on moderate to very vigorous PA. In addition, it was found a decrease of high PA intensity-levels and also in the sedentary habits at the week-end. Then, physical activity and sedentary behaviour could not be two sides of the same coin, and it requires the need to track sedentary activities across the second decade of life by longitudinal design studies.

LOSS OF LEAN BODY MASS DURING AN 8-WEEK INPATIENT PROGRAM DOES NOT REDUCE VO2PEAK IN OBESE ADOLESCENTS

NAEF, N., JUNG, A., BOUTELLIER, U., ROCHAT, M., KNÖPFLI, B.

1. ETH ZURICH, SWITZERLAND, 2. EHSM, MAGGLINGEN, SWITZERLAND, 3. AKD,DAVOS, SWITZERLAND, 4. MUNICH UNIVERSITY, GERMANY

Introduction: Loss of muscle mass is a frequent observation in inpatient weight reduction programs. The aim of this study was to evaluate if rapid reduction of lean body mass (LBM) was associated with a change of peak oxygen consumption (VO2peak) in severely obese adolescents. The investigation was undertaken during a multidisciplinary inpatient weight reduction program consisting of daily physical activity, a balanced nutrition regimen, and behavioural modifications (Knöpfli et al., 2008).

Methods: 90 severely obese adolescents (33 girls and 57 boys) with a median (25th, 75th percentile) age of 14.3 years (12.3, 15.8) and a median BMI of 33.5 kg/m2 (30.6, 37.3) were analyzed. LBM and VO2peak were measured before and after an 8-week intervention. Patients were randomized to receive either daily supervised exercise training including whole body vibration (WBV; Powerplate®) 3 times per week or exercise training and educational sessions without WBV. The correlation between the changes in LBM and VO2peak was analysed and the influence of WBV training was investigated. Pre-post treatment differences were analyzed with the Wilcoxon signed rank test. Linear uni- and multivariat regression models were used to analyze correlations between primary outcome parameters.

Results and Discussion: The intervention significantly improved VO2peak by 8.7ml/min/kg (6.0, 11.9; p<0.001) in all subjects despite an average loss of LBM of 0.8kg (0.2, 2.0; p<0.001). No correlation could be found between changes in VO2peak and LBM for the total population (r2<0.001; p=0.925). We assume that individuals experiencing a rapid weight loss may not need all muscles any longer to the same extent for their daily activities resulting in a LBM decrease. For subjects receiving WBV training, a positive correlation between changes of VO2peak and LBM could be observed (r2=0.114; p=0.023) resulting in a stronger improvement of VO2peak in subjects with increasing LBM, which was not the case in the control group.

Conclusion

In a multidisciplinary inpatient weight reduction program in severely obese adolescents, the improvement of VO2peak is independent of a possible loss of LBM and can additionally be increased by WBV training.

GROWTH OF CHILDREN FROM RIO MAIOR, PORTUGAL. COMPARISION WITH LISBON REFERENCES AND THE WORLD HEALTH ORGANISATION <WHO> STANDARDS

SEABRA, P., FRAGOSO, I., VARELA-SILVA, M.I.

SPORT SCIENCE SCHOOL OF RIO MAIOR-PORTUGAL, FACULTY OF HUMAN KINETICS-PORTUGAL, LOUGHBOROUGH UNIVERSITY-UK

Introduction: Physical growth of a population is an indicator of the quality of life, reflecting both social, economic and political conditions of the environment. Better conditions lead to improved physical growth, namely in height (Bogin, 1999). Therefore, the aims of this study were to document the physical growth of children from Rio Maior-Portugal (2007) and to compare these data with references from Lisbon (2001) (Fragoso & Vieira, in press) and the WHO standards, using anthropometry.

Methods: We assessed 823 children (421 boys), 3 to 9 years old, from the Rio Maior county's public and semi-public school network. Informed consent and assent were obtained. Height, weight, subscapular and triceps skinfolds were measured according to the International Society for the Advancement of Kinanthropometry (Marfell-Jones et al., 2006). Descriptive statistics and one sample t-test were used to compare results between samples. The alpha value was set at less than 0.05.

Results: From 3 to 9 years old, the values of the anthropometric measures follow the expected tendency (increase with age). Compared with Lisbon, Rio Maior children's generally had higher mean values in weight and height. Statistical significant differences were found in boys at 9 years (height and weight) and in girls at 4, 5 and 7 years for weight and at 4 years, for height. Although the higher weight found in Rio Maior, skinfolds were not higher than in Lisbon. Looking at WHO standards for height and weight, the same tendency was found. Statistical significant differences were found in boys at all ages except at 3 years (height and weight) and, in girls, at all ages except at 3 years for weight and from 6 to 9 years in height.

Discussion: Concerning to physical growth, we infer that children from Rio Maior live in better environmental conditions than those from Lisbon. Considering the differences found in weight and the values of the skinfolds, we presume that Rio Maior children's are heavier, but not due to fat mass. However, we must keep in mind the difference in data collection year between Rio Maior and Lisbon. Regarding

WHO standards Rio Maior children's generally present higher mean values either in height and weight. Life conditions should be studied to better understand these differences.

METHODS FOR DETECTING AND MONITORING CHANGES IN BODY COMPOSITION AND FUNCTIONAL CONDITION LIKE ADOPTED METHOD BY YOUNG POPULATION

HRÁSKÝ, P., MALÝ, T., ZAHÁLKA, F.

FACULTY OF PHYSICAL EDUCATION AND SPORT, CHARLES UNIVERSITY IN PRAGUE

Introduction: Specific playtime or sport locomotion induced load of young population will be manifested in the functional status in their body composition (BC) and by the condition of the locomotive system's executive structures. The monitoring and determination of changes in BC, in particular the body water volume and the body fat percentage and fat free mass has become a standard procedure of detecting the current state of health and appropriate training activity. BC and its changes during the ontogenetic development is a significant parameter of an individual's ontogenetic development (Bunc and Dlouhá, 1998). It may help us to diagnose overtraining (Roche et al. 1996) or incomplete player's adaptation to training load. Observing of contracted muscle tissue were based on method Functional muscle test by Janda (1995) and dynamic range of joints.

Methods: Bioelectric impedance methods represent modern non-invasive methods for the determination of BC, both in laboratory and field conditions (Fidanza, 1991; Lukaski, 1987).

The condition of the locomotive system will be determined by means of an examination detecting shortened muscles. We used 3 rank scale for testing from unshortened to much contracted muscles (Janda, 1995). For dynamic range we used angular measuring.

Results: The results of the BC have shown asymmetries in the distribution of body liquids between the lower extremities, upper extremities and the trunk. Kinesiological testing of probands diagnosed the occurrence of numerous muscular shortenings in muscular groups specifically participating in moving. The most prominent muscular shortenings are found in the area of the dominant lower extremity and in the area of the dominant upper extremity.

Discussion and conclusions

Based on this study, we should decide, that these methods are useful for detecting of changes in motional apparatus of body. We presume that the dominant and therefore the more loaded body segments, or muscular groups of population, contain more body liquid as a result of morphological changes in the muscular tissue. Another potential field of the used methodology implementation includes diagnostics of sport induced injuries of the locomotive apparatus, or the convalescence period (using changes in the volumes of liquid in the respective segment). We, therefore, assume that the occurrence of muscular shortenings and dynamic range of joints are caused by the unilaterality of the locomotive activity during moving and by insufficient and inadequately targeted compensation mechanisms.

PHYSICAL ACTIVITY AND MOTOR FUNCTION IN PRIMARY SCHOOL STUDENTS OF RURAL AND URBAN ENVIRONMENTS

BRANDES, M., NEMETSCHEK, W., PAUL, H.

UNIVERSITY BREMEN

Physical activity (PA) is considered as an important factor for public health. In contrast to its impact, PA decreases in most western civilizations. It is stated that changes in transportation, media access as well as activity-toxic environments are the main reasons for the drift towards a less active population. In addition to health factors, it is assumed that subjects with low PA also show deficits in motor function (MF, e. g. acceleration, physical endurance, coordination). Following the argumentation that urban environments are crucial for lower PA, this study compared PA and MF of children living in an urban and in a rural area in the north of Germany.

To reflect urban situations, 58 children (30 girls, 9.8 ± 0.7 years, 139.8 ± 5.8 cm, 33.4 ± 6 kg, BMI 17.0 ± 2.3) of a primary school in Bremen were recruited. As rural equivalents, 58 children (31 girls, 10.1 ± 0.7 years, 144.3 ± 7.4 cm, 34.7 ± 6.2 kg, BMI 16.5 ± 2) were included from three primary schools in the region "Wendland" (district Lüchow-Dannenberg).

PA was assessed with the Step-Activity-Monitor (OrthoCare Innovations, USA) storing the number of gait cycles for 7 consecutive days. Motor skills were evaluated by the AST 6-11 [1] during physical education in school. All procedures were carried out within four weeks to avoid seasonal effects. The data was tested for normal distribution and significant differences by t-tests or Wilcoxon signed-rank tests.

In PA, children of the urban and the rural area showed high significant differences ($p<0.01$) by accumulating 7569 ± 1559 and 9724 ± 2206 gait cycles per day on average, respectively. An area-related significant difference is also found when separating in weekdays vs. weekend ($p<0.01$) and by gender ($p<0.01$). The mean score as well as all subcategories except of 'steeplechase' of the AST 6-11 revealed significant differences ($p<0.01$) between the children from rural and urban area. Significant area-related differences ($p<0.01$) were found when distinguishing between by gender as well as between skills reflecting coordination or physical condition. Moderate correlations were found between number of daily steps and AST 6-11 ($r=0.3$, $p<0.05$).

In MF, the children of the urban area achieved comparable results to the reference of BÖS [1]. However, children of the rural area exceeded the values by far. PA of children in the urban area was lower, activity of children from the rural area was higher than values

obtained from a smaller city in Germany [2]. Due to the similarities of the subjects, the rural environment can be considered as the determining factor for more PA and enhanced motor skills. The link between daily PA and motor skills might increase in adults due to the lapse of the institutionally organized school day.

PEDOMETER-DETERMINED PHYSICAL ACTIVITY LEVELS OF PORTUGUESE ADOLESCENTS. DIFFERENCES BY GENDER, BODY MASS INDEX AND TIME OF WEEK

SEABRA, A.C., MAIA, J., FONSECA, A., SEABRA, A.

FACULTY OF SPORTS

Introduction: The increasing prevalence of overweight and obesity in adolescents is a major public health problem. A sedentary lifestyle is implicated in the development of these conditions (Bouchard et al., 2006). Therefore it is essential to develop interventions that will increase the physical activity levels (PAL) in adolescents. The aims of this study were: (1) to examine current levels of pedometer-determined PAL in Portuguese adolescents and (2) to investigate the variation in PAL among weekday and weekend step counts, gender and body mass index (BMI).

Methods: A cross-sectional study was carried out in the city of Matosinhos, northern Portugal, in 2008. A total of 345 adolescents of both gender (girls-n=179; boys-n=166; mean age:13.6±1.2) attending basic schooling was surveyed. PAL was assessed using an electronic pedometer (OMRON HJ-113-E) to measure mean steps counts for 5 consecutive days (2weekend/3weekdays). Adolescents were classified as normal-weight, overweight, or obese using international BMI cut-off points suggested by Cole et al. (2000). Differences in adolescents PAL between gender, BMI and time of week were assessed by ANOVA models. Data were analyzed using SPSS version 16.0.

Results: (1) Mean step counts for this sample were 9871.7±3364.9 (girls) and 13159.1±4142.5 (boys) on weekdays, and 5081.5±3037.9 (girls) and 6396.8±3696.5 (boys) on weekends. (2) Significant differences in step counts were observed between weekdays and weekends ($P<0.001$) and among gender ($p=0.004$). (3) Twenty-five percent of adolescents were overweight (girls=23.9%; boys=26.0%) and 7.6% were obese (girls=11.3%; boys=4.1%). (4) No significant differences in PAL were found between normal-weight, overweight and obese adolescents ($p=0.345$). (5) No significant interaction between gender and BMI was found ($p=0.523$).

Discussion: The results showed that pedometer-determined PAL dropped significantly on weekends when compared with all other days of the week and boys were more active than girls. Similar results have been found previously in other reports (Van der Horst, 2007; Duncan et al., 2006). Like other studies no evidence of a link between PAL and BMI in adolescents was found (Van der Horst, 2007). In summary the findings of this study emphasize the importance to develop programmes of PAL that would specially focus on girls and during the weekend.

INFLUENCE OF DEMOGRAPHIC AND SOCIAL-CULTURAL CORRELATES IN PHYSICAL ACTIVITY. A STUDY IN PORTUGUESE ADOLESCENTS FROM 12 TO 16 YEARS

SEABRA, A.C., MAIA, J., FONSECA, A., SEABRA, A.

FACULTY OF SPORTS

Introduction: It is absolutely certain that physical activity (PA) is very important to promote an healthy lifestyle, not only in early childhood and adolescence, but also during adulthood (Kristensen et al., 2008). This behaviour which seems to be determined by an interaction between someone's genetical inheritance and its family and schooling influence, plays, nowadays, a very important role in preventing disease and premature death, with clear benefits to adolescence and adulthood (Rowland, 2006). It is, therefore, extremely important to identify the correlates of participating in PA, that is, the personal characteristics and the participating factors, which have an influence upon the usual PA patterns (Van der Horst et al., 2007). The purpose of this study was to determine the association between adolescents PA and demographic (age, gender and body mass index (BMI)) and social-cultural correlates (family PA and peers influences). Methods: A cross-sectional study was carried out in the city of Matosinhos, northern Portugal, in 2008. A total of 345 adolescents of both gender (girls-n=179; boys-n=166; mean age:13.6±1.2) attending basic schooling was surveyed. PA was assessed using an electronic pedometer (OMRON HJ-113-E) to measure mean steps counts for 5 consecutive days (2weekend/3weekdays). Factors associated with adolescents PA were investigated using multiple regression. Data were analyzed using SPSS version 16.0. Results: (1) age and BMI were not related to adolescents PA; (2) boys were more involved in PA than girls; (3) siblings PA had a positive and significant influence in the adolescents' PA; (4) no significant influence of father, mother and peers were found. Discussion: Demographic and social-cultural correlates - in particular gender and siblings PA - were significantly associated with adolescents' PA. Portuguese boys were more physically active than girls, which is consistent with other studies (Van der Horst et al., 2007). It is generally accepted that socio-cultural support, namely family and peers influence, is important and critical for child and adolescent development, interest and involvement in PA. However, in this study only siblings seem to exert a positive influence upon the habits of PA. In summary these results suggest that intervention programmes should focus on girls who face a higher risk of inactivity and need to include siblings because they positively influence adolescents' PA. ADOLESCENTS TRYING TO LOSE WEIGHT: PREVALENCE, PHYSICAL ACTIVITY, AND WEIGHT LOSS STRATEGIES IN 13 TO 15 YR OLD NORWEGIANS

STANGELAND, I., LOHNE-SEILER, H., SEILER, S.

UNIVERSITY OF AGDER

Purpose

The purpose of this study was to quantify the prevalence of weight loss behaviour in Norwegian teenagers from age 13 to 15 and compare weight loss behaviour with anthropometrics, body image, and physical activity characteristics.

Methods

Norwegian adolescents from 12 public schools (n= 1059), initially 13.4±0.4 years (8th grade) were tested during the fall of their 8th, 9th and 10th grade years. Height, weight and BMI were recorded. Physical activity (PA), body image and body change strategies were measured by questionnaire. Current and desired body shapes were quantified using a 9-silhouette scale. A normally distributed physical activity index was derived from 6 different questions related to sports activity, transport to school, school physical education participation, and frequency of intense PA.

Results: Physical activity index (0-25 pt scale) decreased modestly in both genders from 8th to 10th grade (F: 10.9±3.5 to 10.1±4.1; M: 13.1±4.2 to 12.2±4.6, $p<0.05$). Males were more physically active than females at all 3 time points ($p<0.05$). Cole et al standards based overweight prevalence was 11.4% and 13.2% in females and 13.4% and 13.5% in males at age 13 and 15 respectively. Females reported a significant discordance between present and desired body shape that increased from age 13 to 15 (13 yrs: 4.7±1.3 vs. 4.2±0.9; 15 yrs: 5.1±1.2 vs. 4.3±1.0, $p<0.05$), and more females than males were trying to lose weight (13 yrs: F: 24%, M: 10%; 15 yrs: F: 35%, M: 10%, $p<0.05$). Males reported no discordance between present and desired body shapes. By age 15, males more frequently reported trying to gain weight (13yrs: F: 7 %, M: 9%; 10th: F: 5%, M: 17%, $p<0.05$). 15 yr olds trying to lose weight had significantly higher mean BMI values but also greater variation in BMI (F: 24.0± 3.6, M: 25.2±4.5), and 15 yr olds trying to gain weight had significantly lower BMI values (F: 18.0±1.8, M: 18.4±1.7) compared to those not trying to change their weight (F: 20.7±2.4, M: 20.0±2.0) or stay the same weight (F: 21.3±2.2, M: 21.4±2.4) ($p<0.05$). However, PA index was not significantly different among the 4 weight strategy groups. Among the 35% of 15 yr old females in the sample who reported trying to lose weight, 84 % reported using exercise, and 72% reported trying to reduce caloric/fat intake.

Conclusions

Norwegian female adolescents report discordance between desired and present body shape and a prevalence of weight reduction behavior clearly exceeding the prevalence of objectively identified overweight. In contrast, male adolescents show no body shape discordance and report marked lower prevalence of weight reduction efforts despite similar objectively measured overweight prevalence.

EFFECTS OF A TWO-YEAR ADDITIONAL PHYSICAL EDUCATION PROGRAM ON PHYSICAL PERFORMANCE AND SELF-PERCEPTION IN OVERWEIGHT GIRLS

MORANO, M., COLELLA, D., CAPRANICA, L.

1. UNIVERSITY OF FOGGIA, 2. UNIVERSITY OF ROME FORO ITALICO

Introduction: A relatively small number of longitudinal studies have been designed to evaluate the impact of physical activity (PA) on physical performance and self-perception in overweight children. Data suggest that the rising prevalence of obesity has occurred simultaneously with changes in PA patterns (Wareham, 2007), and that an age-related decline have occured in both physical education (PE) participation and out of school PA in the last years, with decrease more marked for girls than boys (Nader et al., 2008).This study investigated the effects of two-year additional PE lessons program (2 times.week-1) on motor abilities, phisical self-efficacy, and body image in primary school children.

Methods: Participants were 30 overweight and 30 obese girls (8.3±0.5 yrs) equally (n=15), randomly assigned to either an experimental group (EG) or a control group (CG). Weight status was classified using body mass index (BMI) cut-off points (Cole et al., 2000). The Perceived Physical Ability Scale for Children (PPAS_C; Colella et al., 2008), Collins' Child Figure Drawings (1991), and fitness tests of standing long jump (SLJ), 20m sprint, basketball throw and agility (4x10m) were administered to each participant at baseline, mid- and post-test. A 2 (weight status) × 2 (group) × 3 (test) univariate analysis of variance with repeated measures on the last factor and Scheffé post-hoc were performed for each variable.

Results: Significant group × test interaction effects were found, with EG reporting better performances on 20m sprint ($p<.02$) and agility tests ($p<.001$), higher self-efficacy mean scores ($p<.001$), and lower body dissatisfaction ($p<.005$) at mid- and post-test. Differences emerged for weight status, with obese participants showing poorer SLJ performances ($p<.005$), lower scores in the PPAS_C ($p<.01$), and a greater body discrepancy ($p<.004$) than overweight peers. Weight status × test interaction effects were obtained, with obese girls at baseline reporting higher sprint time ($p<.04$) and body dissatisfaction ($p<.01$), and a lower self-efficacy score ($p<.03$) than the other groups.

Conclusions

The study revealed positive effects on weight-bearing tasks and physical self-perception of overweight girls after a two-year additional PE program. These improvements were not due to changes in BMI. Findings suggest that physical self-efficacy and body image are potential targets for PA intervention programs involving overweight children. Long term follow-up studies are essential to assess whether changes in overall volume of PA provide psychosocial benefits, and wheter improvements in psychosocial functioning lead to increase PA levels, or both.

CORRELATES OF CHILDREN'S COMPUTER USE ON WEEKENDS: BASELINE RESULTS FROM HEIA, A TWO-YEAR MULTI-COMPONENT SCHOOL BASED INTERVENTION PROGRAM

BERGH, I.H., GRYDELAND, M., BJELLAND, M., LIEN, N., KLEPP, K.I., ANDERSSEN, S.A., OMMUNDSEN, Y.
NORWEGIAN SCHOOL OF SPORT SCIENCES, UNIVERSITY OF OSLO, NORWAY

Introduction: In order to regulate children's weight it is important to increase physical activity (PA) and reduce sedentary activities (van Sluijs et al, 2008). As part of sedentary activities, children's computer use has increased substantially. Hence, determinants of children's computer use seem important to identify.

Purpose

To examine the associations of gender, BMI and social-environmental influences with children's computer use on weekends.

Methods

Eleven year olds 6th graders from the eastern part of Norway and their parents (n=1209) taking part in the HEIA project, a school based intervention to promote healthy weight development, participated at the baseline data collection (September 2007). The dependent variable consisted of child's self-reported time spent on computer use on weekends. Independents were gender and BMI and parental (mother) data on a) mother's computer use on weekends, regulation of child's computer use and support of child's PA, and b) perceived screen use as an indoor limitation to PA.

Results: Entered in step 1 gender (beta = .23, $p < .001$) and BMI (beta = .09, $p < .01$) related significantly to child's computer use on weekends; altogether accounting for 6% of the variance in computer use. Entered in step 2, mother's time spent on computer use on weekends (beta = .11, $p < .01$); parental regulation of child's computer use (beta = -.07, $p < .05$) and parental social support for child's PA (beta = -.08, $p < .05$); altogether accounting for 2% additional explained variance in child's computer use. By entering screen use as a perceived limitations to PA (beta = .15, $p < .001$) this added 2% additional variance in child's computer use. The total predictor set accounted for 10% of the total variance in child's computer use. When entering screen use as a perceived limitation to PA in step 3, the relative influence of parental support for child's PA and parental regulation of child's computer use no longer were significant. In contrast, the role of mothers computer use on weekends for child's computer use was upheld.

Discussion:

Current findings suggest that boys more strongly than girls use computers on weekends and that parents to some extent may be in the position to reduce child's computer use by reducing their own computer use, by being more supportive of child's PA, and by strengthening their regulation of child's computer use. Interestingly, when parents report screen use to be a limitation to child's PA child's computer use is increased.

APPLICABILITY OF SEGMENTAL BIO-ELECTRICAL IMPEDANCE FOR ESTIMATING SKELETAL MUSCLE VOLUME IN CHILDREN AGED 6-12 YEARS.

OHTA, M., MIDORIKAWA, T., HKIHARA, Y., MASUO, Y., SAKAMOTO, S., KAWAKAMI, Y., KANEHISA, H., FUKUNAGA, T.
KANAZAWA SEIRYO UNIVERSITY

Background: The skeletal muscle volume is closely related to physical functions, and it increases rapidly during growth age. There is increasing interest in the use of bio-electrical impedance analysis to estimate segmental skeletal muscle volume (Miyatani et al. 2000, Ishiguro et al. 2006). However, available information on the applicability of bio-electrical impedance method for predicting the fat free mass for children is limited (Fuller et al, 2002). No study has attempted to examine whether bio-electrical impedance analysis can be used to estimate segmental skeletal muscle volume in children.

Objective: To investigate whether segmental bio-electrical impedance analysis is useful for estimating segmental skeletal muscle volumes in children.

Methods: Fifty boys and 15 girls aged 6 to 12 yrs (mean age 10.0yr) volunteered under permission of their parents to participate in this study. Contiguous MRI images with a 1-cm slice thickness were obtained from the first cervical vertebra to the lateral malleoli. The volume of skeletal muscle was calculated from the summation of digitized cross-sectional area for every body segment, i.e., arm, trunk, thigh and lower leg, with the separation between segments based on anatomical landmarks visible in the scanned images. The electrical impedance of 6 segments (right and left side of arm, thigh and lower leg, and trunk) was measured by a bio-electrical impedance apparatus (500μA, 50kHz). An impedance index (BI index: L2/Z) for each segment was calculated as the ratio of the segment length squared (L2) to the impedance (Z).

Results and discussion: The MRI-measured total volume of skeletal muscle was 10496 +/- 2654 cm^3 for boys and 8234 +/- 1990 cm^3 for girls. For each segment, the volume of skeletal muscle was significantly correlated with BI index with the correlation coefficients of 0.78 to 0.94 ($P < 0.001$). This result indicates that bio-electrical impedance analysis is useful for assessing segmental skeletal muscle volumes of adolescents below the age of 12. The difference of correlation coefficients between segments was caused by error of measurement due to the electrode position. A small difference of the electrode position has substantial influence on measured values. Thus the electrode position becomes important to raise the accuracy of estimation.

RELATIONSHIP BETWEEN IMPROVEMENTS OF EATING HABITS AND PHYSICAL FITNESS BASED ON A 3-YEAR LONGITUDINAL STUDY OF JAPANESE CHILDREN

SUZUKI, K., NISHIJIMA, T.

TOHOKU GAKUIN UNIVERSITY

Introduction: The Ministry of Education, Culture, Sports, Science and Technology (MEXT) in Japan (2006) reported that endurance performance in groups of children who ate breakfast everyday was higher than the other groups (sometimes or never). However, there is a need for longitudinal studies, since the previous study was based on a cross-sectional survey which provided only limited information about the changes in eating habits and the physical fitness of children. The purpose of this study was to examine the effects of a change in eating habits on a change in physical fitness in Japanese children using 3-year longitudinal data. Methods: The participants were 456 Japanese children aged 6-9 (230 boys, and 226 girls). Data were collected on 3 occasions over a one year period. Survey items included eating habits (3-point ordinal scale: eating breakfast every day; 3, sometimes; 2, never; 1), physical fitness (Japan Fitness Test: Grip Strength, Sit-ups, Sit & Reach, Side Steps, 20m Shuttle Running, 50m Dash, Standing Long Jump, and Handball Throwing). Physical fitness in participants was graded into five categories according to norm-referenced criteria. A latent growth modeling (LGM) was used to examine the influence of the change in a eating habit score to a change in a physical fitness score. The LGM allow researchers to examine the change at both individual and group levels. In the LGM, the intercept term provides the initial level of scores and the slope describes how much a score was changed from initial value over time (Park and Schutz, 2005). In addition to an analysis using all data, for examining LGMs of each physical fitness level, the data were split into two groups (lower level group: lower two categories, higher level group: higher three categories) according to norm-referenced criteria. The LGM was conducted with Amos 7.0 (SmallWaters Corp., Chicago, IL) using maximum likelihood estimation. Statistical significant was set at .05. Results: There were no significant differences in physical characteristics between participants and Japanese standard values of each age. Results for LGMs using all data and data of the lower level group indicated good fits to the data (e.g., CFI = .997, and 1.000, RMSEA = .030, .000, respectively). With the physical fitness change factor, there was statistically significant and a positive direct effect from the change in eating habits (slope) (beta = .66) only in the lower level group, and the initial levels of the eating habits in all data (beta = .31) and the lower level group (beta = .55). CONCLUSION: These findings, with limited samples and a statistical method, might suggest that an improvement of eating habits (specifically, eating breakfast) has an effect on improvement of physical fitness in a lower level group of physical fitness, and an initial level of eating breakfast also affects improvement of physical fitness. Because eating breakfast is part of a lifestyle, future research should investigate relationships between comprehensive lifestyle and physical fitness.

COMPARISON OF THE LIPID PROFILE BETWEEN ADOLESCENT ATHLETES AND NON-ATHLETES

STADNIK, A., MASCARENHAS, L., BOGUSZEWSKI, M., ULBRICHT, L., PETROSKI, C.

UNIVERSIDADE TECNOLÓGICA FEDERAL DO PARANÁ; UNIVERSIDADE FEDERAL DO PARANÁ

Introduction: Data have shown an increase in the number of adolescents with an unfavorable lipid profile to health. The practice or not of physical activity may be related to the lipid profile of adolescents, so the purpose of this study was to compare the lipid profile of adolescent athletes and non-athletes.

Methods

Were evaluated 137 children with mean age of 14.39 ± 1.81, with 33% of basketball players and 67% did not practiced any competitive activity, all from city of Curitiba, Paraná, Brazil. For the estimation of cholesterol (CT), high-density lipoprotein (HDL-c) and triglycerides (TG), we used the automated colorimetric-enzymatic method (Abbott Spectrum, model CCX). The LDL-c was calculated by Friedewald formula (LDL-c = CT - HDL-c – TG / 5).

Results: It was observed that the basketball players were significantly higher and heavier than the peers not practicing, but the BMI showed no significant difference. Regarding lipid profile, individuals who practice basketball training had lipid values of CT (t =- 3.8 p <0001), HDL-c (t =- 5.5 p <0001), LDL-c (t =- 2.6 and p <0001) and TG (t =- 4.6 p <0,001) significantly lower than non-practitioners.

Discussion: Consistent with the findings of this study, Durstine and Haskell (1994) found that physically active individuals and involved in programs of aerobic training have lower levels of total cholesterol and triglycerides when compared to their sedentary peers. This is physiological characteristics of the exercise, which improves the ability of muscle to hold the oxidation of fatty acids, in addition, stimulates the activity of the enzyme lipase in the muscle, thereby contributing to the decrease in plasma lipids and lipoproteins, including young individuals (Wood et al., 1990; Durstine et al., 1994).

PHYSICAL ACTIVITY, HEALTH, BMI AND BODY COMPLAINTS IN HIGH SCHOOL STUDENTS

ALRICSSON, M., LANDSTAD, B.J., GUNDERSEN, K.T.

SWEDISH WINTER SPORT RESEARCH CENTRE

Background

Children and adolescents in the industrial world are becoming less physically active and are adopting a sedentary life-style in front of computers and television screens. Aim: The aim of the present investigation was to determine self-related health, physical activity, prevalence of overweight and body complaints in high school students in Norway. Based on these aspects another aim was to compare students in academic programs with those in vocational programs.

Methods: 702 high school students aged 16-19 years participated in the study. A questionnaire was completed at three high schools and included questions about weight and height, health, physical activity, type of physical activity/sport, intensity, possible injuries or complaints, during the last three months.

Results: Twenty three percent of the students suffers from overweight/obesity or are at risk of being overweight. Males reported better health than females (p<0.02). Sixty-six percent of the study group reported body complaints during the last three months, a higher number of females than males (p=0.0001). Students in vocational programs reported poorer self-related health than those in academic programs and the males reported better self-related health generally than females. Furthermore, there were a higher level of prevalence of overweight students in vocational programs than academic programs (p=0.039).

Conclusions

It is important to make it easy for school children and adolescents to perform physical activity at school and during leisure-time in order to prevent overweight and obesity as well as chronic diseases later in life.

CHANGES IN PHYSICAL FITNESS AND BMI DURING EARLY ADOLESCENCE IN A NORWEGIAN SAMPLE

HAUGEN, T., MØLL, Ø., SEILER, S.

UNIVERSITY OF AGDER

Purpose: Given the potential connections among PA, overweight, and future risk of disease, considerable attention has been given to increasing physical activity to improve cardiovascular fitness and reduce or maintain a healthy body composition. Current data quantifying different components of fitness in Norwegian children are scarce, making longitudinal assessment in the adolescent population difficult. The purposes of this study were; 1) to provide normative data quantifying the current physical fitness level of 13-to 15 year old Norwegian youth using a multi-component fitness assessment, 2) to quantify longitudinal changes in fitness in adolescents during this period of rapid physical growth, and 3) to compare the fitness of Norwegian teenagers with available European and International fitness data.

Methods: 1059 adolescents (529 male, 530 females) from 12 public schools were invited to testing at age 13, 14, and 15. Test participation was 75-80%. The participants performed the following tests in October-November each year: Physical fitness: Standard or modified Push-ups (PU) to failure, standing broad jump (SBJ), Sit & Reach (SAR), Flamingo balance test (FLB), side to side hop (SS), Endurance Shuttle Run (ESR), and anthropometric measures: height, weight and BMI.

Results: At 13 yrs, there was no significant gender difference in bodyweight (females 51.5 + 9 kg, males 51 + 10 kg) or height (females 162 + 7 cm, males 163 + 8 cm). By 15 yrs males were both significantly heavier (females 59 + 9 kg, males 65 + 11 kg, p<0.001) and taller (females 167 + 6 cm, males 176 + 8 cm, p< 0.001). Females increased their performances in all fitness-tests (PU: from 22 – 31 reps; SBJ: from 160 – 172 cm; SS: from 76 – 90 reps; FLB: from 10 – 8 errors; SAR: from 19 – 23 cm), except ESR, from age 13 to 15. Males improved in PU (from 18 – 30 reps), SBJ (from 176 – 204 cm), and SS (from 75 – 92 reps). There were also improvements in ESR, SAR, and FLB, but only from age 13 to 14. When FLB, SBJ, and SAR, results were compared with age-matched data from 23 other European countries, and the ESR test with age-matched data from 37 countries globally our Norwegian sample was on average at the 72nd percentile for ESR, 71st for FLB, 58th for SBJ, but only the 29th percentile for SAR.

Conclusion: As expected, gender differences in fitness expand during puberty. Strength and power relative to bodyweight increases more in males than females. Aerobic capacity increases in males while remaining stable or tending to decline in females. However, balance and coordination improve identically in males and females from age 13 to 15 yrs. Correlations among fitness components were modest (Pearson's r = 0.2-0.5), supporting the need for a multi-component index of fitness. Summation of test results as a combined Z score, with equal test weighting, yields a normal distribution for fitness index in both males and females.

OBJECTIVELY ASSESSED SLEEP DURATION AND EFFICIENCY IN OVERWEIGHT AND NORMAL-WEIGHT 11-YEAR OLD CHILDREN

SORIC, M., MISIGOJ-DURAKOVIC, M.

FACULTY OF KINESIOLOGY

BACKGROUND AND AIMS: The growing epidemic of obesity is becoming more and more pronounced, even among children. Inverse associations between sleep duration and the risk to develop childhood obesity were consistently reported (Cappuccio et al., 2008). However, studies that evaluated sleep with objective measures are scarce. Therefore, the aim of the current study was to objectively evaluate sleep duration and efficiency in overweight and normal-weight 11-year old children in Croatia.

SUBJECTS: Fifty seven 5th grade students (35 girls and 22 boys, mean age 11,3 [0,2] years) from five different elementary schools in Zagreb (Croatia) were selected to participate in the study.

METHODS: Height and weight were measured and body mass index (BMI) was calculated. Ten girls and nine boys were considered overweight or obese according to IOTF BMI cut off points for age and gender (Cole et al., 2000). Sleep patterns were assessed using a multi-sensor body monitor (SenseWear Pro2 Armband, BodyMedia, Pittsburgh, USA). SenseWear armband has recently been validated as a sleep detection device (Germain et al., 2006). The device was worn for four consecutive nights including 2 weekdays and 2 weekend days. Sleep duration and time spent lying down were estimated and times of going to and out of bed were detected. Sleep efficiency index (SEFI) was calculated as sleep duration divided by time spent lying down. Group differences were tested using Student's t-test for independent samples. All values are presented as mean [SD].

RESULTS: No significant differences between overweight and normal-weight children were found regarding either sleep duration (434 [36] min/day vs. 425 [40] min/day, respectively p=0,40) or time spent lying down (548 [45] min/day vs. 531 [39] min/day, respectively p=0,15). The average time children went to bed did not differ between overweight (22:33 [00:49]) and normal-weight children (22:47 [00:42]), (p=0,30). The same was found for the time children got out of the bed (07:50 [00:55] and 07:44 [00:45], in overweight and normal-weight children, respectively, p=0,65). No significant difference between groups was found for SEFI (0,80 [0,07] vs. 0,80 [0,07], p=0,73).

CONCLUSION: Results from this study do not support the hypothesis that overweight children have shorter sleep duration or lower sleep efficiency than their normal-weight counterparts.

EFFECT OF OBESITY ON AEROBIC FITNESS OF CHILDREN AND ADOLESCENTS

LESKOSEK, B., KOVAC, M., STARC, G., STREL, J.

UNIVERSITY OF LJUBLJANA

A large sample of schoolchildren and adolescents from primary and secondary schools of Slovenia (n=5012, 2658 boys, 2354 girls), 7 to 19 years of age participated in 2003/4 in a large national repeated cross-sectional study, leaded by Janko Strel.

Body mass index (BMI) and % body fat, estimated by bio-electrical impedance method using Maltron BF–906 instrument were used to diagnose excessive weight and categorize children into normal, overweight and obese category. Aerobic fitness was evaluated by 600-metre run and shuttle run test. According to IOTF norms 17.5% boys and 15.5% of girls in the sample were found overweight, whereas 4.4% of boys and 4.5% of girls were obese. Patterns of changes of aerobic fitness with gender and age mostly coincided with those found in other European countries (Armstrong, 2007), as though some differences existed, especially in boys in early puberty, where mean/median values in both 600-metre and shuttle run were almost unchanged in the period of 12–14 years of age.

The effect of excess weight on aerobic fitness was evaluated by multi-factor ANOVA separately for each measure of excess weight (BMI, % body fat) and each measure of fitness (600-metre run, shuttle run). After controlling only for gender and age, BMI category explained 7.3% of variance in 600-metre run and 6% of variance in shuttle run. The effect of body fat % was even higher, explaining 10.8% variance of 600-metre run and 7.1% of variance in shuttle run. Obese boys and girls achieved worse results in both aerobic fitness tests and the highest differences in comparison to their leaner peers were found in the period of early puberty (10 to 12 years of age).

In order to establish the influence of body fat on differences between different weight categories, % body fat was partialed out of 600-metre and shuttle run. After partialization differences between weight categories almost disappeared with BMI category explaining only 1.4% and 1% variance of 600-metre run and shuttle run, respectively. At some ages overweight boys and girls achieved even better results then their non-overweight peers. This result is not surprising, as it was found in this same sample that amount of physical (sport) activity of obese and non-obese pupils is similar. The results also coincide with the results of several other studies (review by Armstrong, 2007) where little or no influence of habitual physical activity on peak VO2 existed. On the other hand, these results are reassuring for obese boys and girls because they indicate that if obese children loose their weight even after puberty they can expect to be equally successful in aerobic activities as their non-obese peers.

URMEL-ICE (ULM RESEARCH ON METABOLISM, EXERCISE AND LIFESTYLE INTERVENTION IN CHILDREN) EFFECTS ON SPORT MOTOR ABILITY IN OVERWEIGHT AND NON-OVERWEIGHT SECOND GRADE SCHOOL CHILDREN IN GERMANY

STEINER, R., BRANDSTETTER, S., KLENK, J., PROKOPCHUK, D., WARTHA, O., PETER, R., GALM, C., BERG, S., WABITSCH, M., STEINACKER, J.

SPORT AND REHABILITATION MEDICINE

Sedentary lifestyle and obesity are risk factors for various diseases. In the last decades motor ability declined while overweight rate rose even in children. Therefore prevention should start in early childhood. URMEL-ICE (Ulm Research on Metabolism, Exercise and Lifestyle Intervention in Children) is a school based intervention program targeting physical activity, reduction of sugar-sweetened beverage and reduction of media consumption. The intervention is integrated in normal school classes, without consuming additional teaching time. It included two daily movement exercises each 5 to 7 min and 29 teaching units on health behavior. Aim of the intervention was to educate and motivate children for a healthier lifestyle. Purpose: The effect of this intervention on sport motor ability, in overweight and non-overweight second grade children in Germany is examined. Methods: 1119 children (average age: 7.6 +/-0.4 yrs) in 64 classes, in south Germany were included in the URMEL-ICE program. After school-wise randomization the intervention was done with 579 children (32 classes), 540 children (32 classes) were controls. Children were measured for overweight according to Kromeyer-Hauschild percentiles and participated in 8 sport motor ability tests, both at the beginning and after one year of intervention. Regression analysis for each of the 8 sport motor ability tests with intervention as independent variable, controlled for baseline results and sex, was calculated with and without grouping in overweight and non-overweight children. Results: In control group prevalence of overweight at baseline was 10.5 %, at follow-up 13.5 %, in intervention group at baseline 14.5 %, at follow-up 15.1 %. In the intervention group children covered more distance in 6 min endurance run (B = 18.251 m, p = 0.017, N = 919) and were by tend faster in 20 m sprinting (B = 0.04 s, p = 0.091, N = 949). The split in overweight and non-overweight children showed a similar effect of the intervention on sport motor ability for both groups. Non-overweight children in the intervention group again covered more distance in 6 min endurance run (B = 16.93 m, p = 0.038, N = 774) and where faster in 20 m sprinting (B = 0.05 s, p = 0.032, N = 799) than non-overweight children in control. Overweight children in the intervention group covered by tend more distance in 6 min endurance run (B = 32.81 m, p = 0.110, N = 113) and scored higher in ball aiming (B = 1.07 points, p = 0.087, N = 116) than overweight children in control. Conclusion: These findings suggest an effect of intervention on endurance performance and sprinting. Children being overweight at baseline do not benefit in sprinting, but seem to benefit in ball aiming through intervention. It is especially remarkable to get an effect on sport motor ability without systematic sportive training and consuming additional teaching time.

PHYSICAL ACTIVITY, GENDER AND PHYSICALITY IN ELDERLY WOMEN

SILVA, P., BOTELHO-GOMES, P., SANTOS, M.P., NOVAIS, C., CARVALHO, J.

FACULTY OF SPORT

Regular physical activity has been described as a co-adjuvant for the prevention of many physical, psychological and social aspects related to the ageing process. Although the majority of the elderly subjects recognize the importance of regular physical activity for the functionality and well-being, older people are inactive, being this type of behaviour associated with social impositions and with poor self-perception of physical fitness and physicality. As a formative construction, physicality, in its broadest sense, explores how the body physically engages life, and how it can be understood as the physical expression of agency (McDermott,2000). Maintaining functionality and physicality is currently considered a crucial element for the quality of life and socialization of older people.

Accordingly and considering that bodily experiences lived by elderly women were submitted to a clear regime of discipline and standardisation of the body that was perceived as a "natural gift" (i.e.grace, frailty), it is extremely important to understand the impact of regular physical activity on physicality and "body empowerment" of elderly women.

Within this context, the main purpose of this study is to identify and analyze the multicomponent physical activity program to the notion of physicality.

Methods: This research consisted in a longitudinal evaluation of elderly women (n= 19; mean age=69.5±5.3 years old) living in the area of Porto, submitted to a multicomponent exercise program of 2 sessions/week, for 10 months.

To understand how elderly women experience their bodies and the gender influence, it was applied semi-structured interviews, focus groups and depth interviews in different moments of the exercise program: baseline - conduct prior the beginning of training (1st/2nd week of September), during (after 5 months - 1st/2nd week of February) and at the end of training program (1st/2nd week of July). In order to inspect the interviews results, content analysis technique and interpretation was applied, after data being processed by the program QSRNVivo7.

Results: Qualitative analysis before the beginning of exercise program allowed to access physical identity perceptions that reveal a concern with the body image and with physical limitations.

After training, older women speeches reflect: (i) a better capacity to cope with chronic disease and counter with advancing age; (ii) a physical repositioning of identities that result in feelings of self-confidence conferred by a more active, agile, balanced and flexible body; (iii) a clear perception of femininity as socially constructed category.

Conclusion

The results suggest that, a generalized physical activity program can be considered as an important tool for body empowerment and physicality, witch, in turn, highlights the significance of social body in the commitment to an active life style of elderly women.

Granted by FCT/PTDC/DES/70261/2006.

EFFECTS OF A FEASIBLE AEROBIC TRAINING ON OLDER WOMEN'S BODY COMPOSITION, BLOOD PRESSURE, PHYSICAL FITNESS, AND HEALTH-RELATED QUALITY OF LIFE.

WANDERLEY, F., CARVALHO, J.

UNIVERSIDADE DO PORTO

INTRODUCTION: Several models have been suggested to explain the interaction between active lifestyles and prevalence of chronic diseases and their impact on physical fitness, quality of life and morbidity of older adults. According to Jette et al. [1] and Rikli & Jones [2], all these factors interact each one another. The clinical manifestation of a chronic disease leads to physical fitness decline, which, in turn, represents enhanced functional limitation that, most of the times, is linked to a tendency on reducing physical activity, functional capacity and therefore, worsening disease [3]. In this way, it seems important to identify the impact of different types of physical activity in functional fitness and cardiovascular risk factors in older people. Identifying the type, quantity and intensity of exercise to promote general and specific benefits to health can lead to better and accurate recommendations for those who begin training program aiming the improvements on cardiovascular health and on functional ability.

PURPOSE: To evaluate the effects of a moderate walking program, as one of the most accessible and feasible ways of aerobic training for older adults, on older women's body composition, blood pressure (BP), physical fitness and perceived health-related quality of life (HRQOL).

METHODS: Twenty-two older women (71,4±5,9 yrs; BMI= 27,7±2,6) without habitual exercise practice but physically independent were evaluated in 3 distinct moments, at baseline (M1), after 4 months with no exercise (M2- control period) and, finally, after participated in a 4 months walking program (M3). Subjects walked 3 times/week at progressive duration (15-30 min.) and intensity (50-70% of HRreserve; 4-5 of CR10 scale). BP, body composition (Dual-energy X-ray Absorptiometry), physical fitness (Senior Fitness Test) and, perceived HRQOL (Medical Outcomes Study Short-Form-36) were assessed at each moment. One-way ANOVA for repeated measures was used.

RESULTS: Data demonstrate that: i) to the exception of diastolic BP and upper limb strength, no significant changes occurred in the control period; ii) After walking training (M3) it was observed: a reduction on systolic (-12,0mmHg, p=0,04) and diastolic (-5,0mmHg, p=0,015) BP, improvements on emotional role limitation (+29,6, p=0,019) and lower limb strength (+4 reps, p=0,001).

CONCLUSION: These findings suggest that a walking program with progressive duration and intensity is able to reduce older women BP, improve muscle function and emotional dimensions of quality of life. Granted by FCT (PTDC/DES/70261/2006; SFRH/BD/33124/2007).

EFFECTS OF PHYSICAL TRAINING ON BONE STATUS AND MENTAL HEALTH IN YOUNG AND OLDER WOMEN

KIMURA, Y., HISATOMI, M., OHKI, K., EZAKI, T., SATO, T.

SAGA UNIVERSITY

Benefits of regular exercise on bone mass accretion are greatest during childhood and adolescence when peak bone mass can increase to the greatest extent. These benefits often accrue into the seventh and even eighth decades of life. The portion of bone mass

variation attributable to diet may actually reflect how diet interacts with genetic factors, physical activity patterns, body weight, and diet or medication use. Despite these interactive effects, adequate calcium intake throughout life remains the prime defense against bone loss with age. PURPOSE: To determine the effects of habitual physical exercise on bone status and mental health in college female athletes; judo, long distance running, volleyball, swimming (n=32, aged 20.9 yrs.) and older women; walking/jogging, tennis, gate ball, aqua exercise/swimming (n=49, aged 62.6 yrs.). METHODS: The Calcaneus was measured twice at interval of 9 to 12 months by the ultrasound method (AOS-100NW, ALOKA), and sound of speed (SOS), % young age matched (YAM) and % age matched were calculated. A questionnaire survey examined mental health status, such as subjective happiness and geriatric depression score. Daily intake of milk also reported. RESULTS: % YAM and % age matched of college swimmers was significantly lower compared with those of judo and volleyball players. There were no significant differences between college long distance runners and age-matched non-exercise controls. % YAM and % age matched of college volleyball players was significantly higher than that in long distance runners. % YAM and % age matched in older swimmers (swimming time 28.6 hrs/month, milk intake 188 ml/day) decreased significantly during 9.8 months. Tennis players (playing time 21.3 hrs/month, milk intake 290 ml/day) increased SOS, % age matched and % YAM during 10 months. Significant improvements in exercise groups were seen in regard to subjective health degree, everyday feeling, human relation and life satisfaction degree. RESULTS: The judo and volleyball were good effects on bone health status increase in the young period, and it is important for older women to do mild physical exercise, take in calcium in milk. Habitual physical activities improve in psychological items.

THE CHANGES OF AUTONOMIC AND PSYCHOLOGICAL INDICATORS IN A LONG-TERM LIGHT EXERCISE PROGRAM FOR ELDERLY PEOPLE

SASAKI, H., TAKAHASHI, M.

1. HOKUSHO UNIVERSITY, 2. HOKKAIDO UNIVERSITY

Introduction: The QOL for elderly people has two aspects; physical health and mental health WHO (2000). Exercise maintains and promotes physical and mental function. Exercise is also one of the main stated factors that influence the improvement of QOL. Furthermore, some studies suggest that a sedentary lifestyle result in negative mood symptoms, especially feeling of fatigue and depressive symptoms (Blumenthal et al., 2005; Weinstein et al., 2007).

Objective

The purpose of this study was to make a clear that the changes of the heart rate variability and psychological parameters for long-term light exercise in elderly people and to assess the program's effect on QOL.

Subject & Method: Subjects in this study were 23 elderly people with a mean age of 64.1±6.0. They participated in a senior fitness class once a week for about 17 months. Physical and psychological measurements were taken once every about four months. The physical measurements were anthropometric indexes, fitness tests and autonomic nervous system activity. Anthropometric indexes were height, body weight, body fat, systolic and diastolic blood pressure, chest girth, abdominal girth, hip girth, left and right thigh girth, left and right lower leg girth. Fitness tests were grip strength, sit-ups, sitting trunk flexion, foot-balance opening with eyes opened, 10 m walking crossing over obstacles, up and down step test. Heart rate variability (HRV) was measured as autonomic nervous system activity. The psychological measurement used a 30-item General Health Questionnaire (GHQ30) and QOL was measured at the same time by WHO/QOL26. And activity checks including number of steps, sleeping hours, and daily activity hours were taken for 7 days every once a month.

Results: In the physical measurements, left and right thigh girth and grip strength significantly improved. Systolic blood pressure, sit-ups, sitting trunk flexion, and step test had a tendency to improve. GHQ30 and QOL26 did not significantly changed. In each factor on the GHQ30, the ratio of the person with a high score (3-5point) of insomnia was about 30 percent. It was higher than in the other factors. HRV and activity checks had seasonal changes.

Discussion: From these results, it was suggested that the physical indices changed clearer than the psychological index in a long-term light exercise program for elderly people. And it was also supposed that activity of the autonomic nervous system changed seasonally. The psychological index did not significantly change, but from the ratio of the persons with the highest scores in the factor of the GHQ30, it was suggested that one in three or four persons experienced a sleeping disorder. Continuous measurement is necessary to assess the change of psychological index.

AEROBIC TRAINING EFFECTS ON SALIVARY IGA AND PLASMA IGA, IGG AND IGM ON OLDER WOMEN AND MEN

MARTINS, R., VERISSIMO, M.T., TEIXEIRA, A.M.

UNIVERSITY OF COIMBRA, FACULTY OF SPORT SCIENCES AND PHYSICA

Introduction: As people age, they experience a decline in immune responses. Unusually heavy acute or chronic exercise could increase the URTI risk, while regular moderate physical activity may reduce URTI symptomatology. The purpose of the present study is to analyze how an aerobic exercising program is able to promote chronic adaptations in plasma IgA, IgG and IgM, and salivary IgA, in both elderly women and men.

Methods: Forty three independently living older men (n=16) and women (n=27) voluntary for the study. The age varied between 65 and 96 years-old. Participants were randomly separated into an aerobic exercising and a control group. They all passed a complete medical examination and received permission from their doctors to be included. Each participant was submitted to three evaluations (pre, post exercise and follow up) separated by a period of 16 weeks. Factorial 2x2 ANOVA with repeated measures, and multiple comparisons based on the Bonferroni were performed.

Results: Control group shows a salivary IgA decrease between post-evaluation and follow up-evaluation (p≤0.05), and an increase in the plasma IgG between pre-evaluation and post-evaluation (p≤0.01) followed by a decrease in the follow up-evaluation (p≤0.05). The plasma IgA did not show any significant changes [F(1, 14)=1.08, p=0.32], and the salivary IgA secretion rate shows a tendency for decreasing [F(2, 15)=3.27, p=0.07] between pre-evaluation and follow up-evaluation.

Aerobic exercising group increased plasma IgA concentration from 1.08g/L±0.50g/L to 2.29g/L±0.93g/L while salivary IgA concentration was unchanged. The IgG and the IgM plasma concentrations increased in both aerobic and control groups. However, exercising group maintained raised values in the third evaluation which did not happen in control group.

Discussion: The results have shown an improvement in the plasmatic IgA during the exercise period that is in accordance with others [1,2,3], and maintenance in the salivary IgA concentration and secretion rates, in both women and men. Aerobic exercise seems to have been effective in promoting IgA immunity and in protecting against the deterioration in the sIgA values that occurred in control group. Regarding the plasma IgG and the IgM concentration results, a positive effect due to the moderate intensity aerobic exercise protocol used could not be confirmed because positive changes also occurred in the control group. Finally, one would emphasize that women and men, submitted to the same physical exercising programs, have a similar chronic immune response for the four variables analyzed.

IS STRENGTH TRAINING AS EFFECTIVE AS AEROBIC TRAINING ON THE CONDITIONING AND DECONDITIONING OF FUNCTIONAL FITNESS IN OLDER ADULTS?

MARTINS, R., VERISSIMO, M.T., TEIXEIRA, A.M.

UNIVERSITY OF COIMBRA, FACULTY OF SPORT SCIENCES AND PHYSICA

Introduction: Environmental factors play an essential role in the aging process, which confers importance to the physical exercise training. The aim of the current study is to determine if a strength exercise program is as effective as a cardiovascular exercise program to promote chronic outcomes in the functional fitness including upper and lower strength, upper and lower flexibility, aerobic endurance, and velocity, agility and dynamic balance. Additionally, the effects of the detraining are also studied.

Methods: Seventy two women (76.72±8.38 years old) and forty six men (74.61±6.43 years old), aged at least 65 years-old, were randomly separated into control, strength and aerobic group and were evaluated three times. They all passed a medical examination and received permission from their physicians to be included in the study. Between evaluations a sixteen-week period elapsed. The Senior Fitness Test battery [1, 2] was used to evaluate the functional fitness. The intensity of the cardiovascular training varied between moderate and vigorous, with a frequency of 3 times per week, during a 16-weeks period. The moderate strength training was based on eight exercises for the major muscular groups, with 1 set of 8 repetitions increasing progressively to 3 sets of 15 reps. Factorial ANCOVA and a MANOVA, with post hoc test of Bonferroni were used.

Results: On the 6-minute walk test, 100% of the participants in the three groups were below the percentile 50 of the published norms. This lower performance on the tests suggests that participants were unfit. After the exercise period, control group did not show any improvement in any one of the six functional fitness parameters. Contrarily, strength exercising group improved all functional fitness variables during exercise the same occurring on aerobic exercising group, with exception for the upper flexibility, in both sexes, and the lower flexibility, in women. After the detraining period, aerobic group only maintains gains in the lower strength and upper flexibility, while strength group maintains gains in the lower flexibility.

Discussion: The key findings are that both specific aerobic and strength exercising programs are able to improve the various components of the functional fitness of older women and men, and the positive effects remain beyond the end of the training period in some functional fitness parameters.

Presented data sustain the idea that strength exercise alone is as effective as cardiovascular training in developing the physical parameters that support the functional mobility in later years. Moreover, even considering that after a detraining period some functional fitness parameters still raised, negative effects of interrupting exercise programs are visible.

RELATIONSHIP BETWEEN ONE-LEG STANDING TIME WITH EYES OPEN AND PHYSICAL FUNCTION AMONG COMMUNITY-DWELLING ELDERLY FEMALES

MURATA, S.

NISHIKYUSHU UNIVERSITY

PURPOSE : One-leg standing ability and its related factors have been studied in elderly subjects. In past studies on muscular strength in the upper and lower limbs, only part of the muscles were examined. To examine factors involved in one-leg standing, it is necessary to measure and evaluate total body function. In this study, we measured the muscular strength of the lower limbs, foot grip, and plantar sensibility, which were considered to affect one-leg standing, and evaluated the relationship between these parameters and one-leg standing time with eyes open. SUBJECTS : The subjects were 56 community-dwelling elderly women with an average age of 74.8 ± 6.3 years. METHODS : The isometric contraction was measured as the muscular strength of the lower limbs using Hand-held dynamometer, and the foot grip was measured using a foot grip meter. The plantar sensibility was evaluated using Semmes-Weinstein monofilaments. The attention function was using Trail making test - Part A. These measurements were performed in the dominant leg. ANALYSIS : The relationships between one-leg standing time and other body measurement values were examined using Pearson's correlation coefficient. Multiple regression analysis (stepwise method) was performed using body sway on one-leg standing as the objective variable, and factors affecting one-leg standing time were extracted. RESULTS : One-leg standing time with eyes open was significantly correlated with foot grip (0.61), attention function (-0.45) , femoral quadriceps muscle strength (0.38), and grip strength (0.27). Factors involved in body sway in the one-leg standing position extracted by stepwise regression analysis were the foot grip (0.49) and attention function (-0.35). Standing balance was stabilized as the foot-gripping force and attention function increased. CONCLUSIONS : These results suggested that foot functions, such as foot grip, affected body sway in the one-leg standing position rather than the strength of major muscles in the lower limbs, such as femoral quadriceps muscles. Further, the attention function of elderly women may be directly involved in duration of standing on one leg.

DAILY PHYSICAL ACTIVITY RELATED TO AEROBIC FITNESS IN YOUNG CHILDREN: THE COPENHAGEN SCHOOL CHILD INTERVENTION STUDY

DENCKER, M., BUGGE, A., HERMANSEN, B., ANDERSEN., L.B.

UNIVERSITY HOSPITAL MAS

Background: Aerobic fitness (VO2PEAK) is a strong, independent risk factor for cardiovascular disease and mortality in adults. It is therefore of interest to investigate how VO2PEAK is related to daily physical activity, both volume and intensity, already in childhood. The purpose of this study was to investigate the cross-sectional relationship between accelerometer measured physical activity and VO2PEAK (ml/min/kg), by direct measurement in a population-based cohort of young children, since such data are scarce.

Methods: Cross-sectional study of 475 (248 boys and 227 girls) children aged 6.8±0.4 yrs (range 5.7-8.2 yrs), recruited from a population-based cohort. VO2PEAK was measured by indirect calorimetry during a maximal treadmill exercise test. Physical activity was assessed by accelerometers during four consecutive days. From accelerometer data number of minutes of light activity (LPA), moderate activity (MPA), moderate-to-vigorous (MVPA), and vigorous activity (VPA) per day were calculated. Mean count per valid minute of recording (counts/min) was considered to reflect general physical activity (GPA).

Results: All children were Tanner stage 1. Boys were more physically active than girls, with the exception of LPA that did not differ. Boys vs. Girls for GPA, LPA, MPA, MVPA, and VPA; 769 vs. 703; 634 vs. 638; 84 vs. 73; 95 vs. 83; 12 vs. 10 ($P<0.01$ for all, except LPA $P=0.05$, NS). Boys had higher VO2PEAK level than girls 49 vs. 45, $P<0.01$. Pearson correlation coefficients indicated a low-moderate relationship between daily physical activity variables and VO2PEAK in boys, with the exception of LPA that was not related to VO2PEAK. None of the daily physical activity variables were related to VO2PEAK in girls. Summary of Pearson correlation between VO2PEAK and physical activity variables (GPA, LPA, MPA, MVPA, and VPA) for boys; 0.16, -0.02 NS, 0.21, 0.21, 0.16 ($P<0.05$), and for girls; 0.05, -0.06, 0.08, 0.09, 0.08, all NS.

Conclusion: In this population-based cohort most daily activity variables were positively related to aerobic fitness in boys, but no such relationships could be detected in girls.

ASSOCIATED PHYSICAL PERFORMANCE OF SARCOPENIA IN NON-OVERWEIGHT ELDERLY JAPANESE MEN AND WOMEN

MACHIDA, S., YOSHIOKA, N.

TOKAI UNIVERSITY

Background:

Sarcopenia is a term utilized to define the loss of muscle mass and strength that occurs with aging. Sarcopenia is believed to play a major role in impaired physical performance that occurs with old age in Western populations. Little is known about sarcopenia among Asian elderly populations.

Objectives:

Our aim was to determine whether skeletal muscle mass was associated with physical performance in non-overweight elderly Japanese population with sarcopenia.

Subjects and Methods: Thirty-one men and 19 women aged 65-82 years were recruited from the community of Tatebayashi-City, Gunma Prefecture, Japan. All 50 subjects were screened at the time of enrollment with clinical history, physical exam and a number of laboratory tests to ensure their eligibility, such as non-overweight and/or non-obese (body mass index < 25 kg/m2) and sarcopenia. Sarcopenia was defined according to previously established criteria based on appendicular skeletal muscle mass (ASM) /height2 (kg/m2) by dual energy X-ray absorptiometry (DEXA). Physical performance was determined using a battery of physical performance tests (8 item) approved by the Ministry of Education, Culture, Sports, Science and Technology in Japan.

Results: Mean ASM was 6.82 and 5.77 kg/m2 in men and women respectively. In men, ASM was significantly associated with muscle strength [hand grip ($r = 0.560$, $p<0.001$) and sit-up ($r = 0.524$, $p<0.01$)]. However, there were no significant correlations between ASM and sit-to-stand movement from a chair, static balance [timed up and go, and one-leg standing with opened eyes], dynamic balance [functional reach and body flexibility [sit-and-reach], and agility [stick response]. On the other hand, in women, ASM was associated with sit-up ($r = 0.719$, $p<0.001$), timed up and go ($r = -0.645$, $p<0.01$), and sit-to-stand movement from a chair ($r = -0.626$, $p<0.01$), while hand grip, functional reach, sit-and-reach, one-leg standing with opened eyes, and stick response were not related to ASM.

Conclusions: Our hypothesis was that lower skeletal muscle mass in sarcopenic population was associated with impaired muscle performance. Hand grip, sit-up and sit-to-stand movement from a chair tests were assessed muscle performance in this study. ASM was strongly associated with sit-up in both sexes. However, the sex-related differences in correlation between muscle mass and hand grip and sit-to-stand movement from a chair tests were found in non-overweight elderly Japanese population with sarcopenia. These results suggest that sit-up may be a good indicator of physical performance in sarcopenic population. Further studies with large numbers of subjects are needed.

STABLE BMI BUT INCREASED WEIGHT LOSS BEHAVIOUR IN NORWEGIAN ADOLESCENTS BETWEEN 1996 AND 2008

MØLL, Ø., HOIGAARD, R., LOHNE-SEILER, H., SEILER, S.

UNIVERSITY OF AGDER

Purpose

This study was performed to investigate changes in BMI, prevalence of overweight, obesity, and weight loss behaviour in Norwegian adolescents over the last 12 yrs.

Methods: Data from three different assessments performed in public schools in Kristiansand, Norway over a 12 year period were collected and compared. These data, based on measurements in 1996 (246 males, 287 females), 2005 (332 females, 387 males) and 2008 (259 females, 284 males), were all performed in the fall semester on 14 yr olds (median age 14.5 yrs for all three samples). Participation rates were similar for all 3 samples (~75%). Prevalence of overweight and obesity was estimated based on age and gender specific internationally derived cut-offs from Cole et al (2000)*.

Results: Mean BMI was stable in both boys and girls between 1996 and 2008 (Females: 95% CIs 20.3 to 20.9, 20.0-20.7; Males: 19.9 to 20.5; 19.9 to 20.7). Overweight prevalence in the female sample was 11% in 1996 and 12% in 2008. In males overweight prevalence was 15% in 1996 and 16% in 2008. The prevalence of obesity in the 1996 male and female samples was <1%, but had increased to 1.5% in females and 2.5% in males by 2008. Corresponding data from 2005 was essentially identical to the other two measurement time points. We observed no statistically significant changes in overweight or obesity prevalence. In contrast to quite stable BMI data over the 3 time points, self-reported weight loss efforts increased significantly. In 1996, 18% of 14 yr old females reported having tried to lose weight. In 2005 and 2008, 32 and 34% respectively, reported weight loss efforts. Among males, only 3% reported trying to lose weight in 1996, compared to 10 and 13% in 2005 and 2008 respectively.

Conclusions: These data, based on similar samples taken in 1996, 2005, and 2008 suggest that mean BMI has remain relatively stable over the last decade in southern Norway. We see no evidence of a generalized increase in BMI in Kristiansand teenagers. Slight trends towards an increase in the proportion of overweight and/or obese teenagers were not statistically significant in these samples of only a few hundred children, but the data suggest that the small proportion of children with obesity is increasing. There does appear to be a marked increase in the proportion of both males and females who report trying to lose weight from 1996 to today. Currently, the proportion of females reporting weight loss efforts greatly exceeds the proportion with objectively measured overweight.

PREDICTORS OF WALKING SPEED IN NURSING HOME RESIDENTS

STROJNIK, V., PREVC, P., JEREB, B., DOLENEC, A., RUGELJ, D., PALMA, P., ULAGA, M.

UNIVERSITY OF LJUBLJANA

Walking is a simple and natural form of movement that can be recognized as a good indicator of independence and mobility of the elderly. Many studies have confirmed significant association between strength and functional performance [1, 2, 3]. Also maintaining balance (postural sway) has previously been identified as one of the significant independent determinants of self selected walking speed [1].The aim of the present study was to determine the influence of strength and balance on sex-meter walking test in nursing home residents that represent lower part of elderly population regarding mobility.

We measured 105 elderly people (31 men and 74 women), aged 80 ± 7 years, who voluntarily participated in the study. The maximum torque (adjusted for body mass) of plantar and dorsiflexors, knee extensors as well as trunk flexors, extensors and lateral flexors was measured during isometric MVC. Static balance on force platform (area of path of force application point) was measured in two conditions: opened and closed eyes. Berg balance test was administered as well – only total score used for analysis. For walking, time to cover 6-m distance in self-paced speed was used. Relationship between strength, balance and the walking time was explored using linear regression. Relationships between the tests were determined with Pearson's correlation coefficient.

The subjects needed on average 8,0 ± 6,1 s to cover the 6 m distance, that accounts for average gait speed of 0,75 m/s, which is in accordance with previous reports for elderly population [4]. All nine relative strength and balance tests showed significant correlations with time to complete the 6 m walking task (r= 0,19 to -0.76; $p<0.025$). Stepwise linear regression revealed that the strength measures and balance test explained 59% ($p<0.000$) of the variance in walking time, where the Berg balance test had the highest and the only significant beta weight (-0.85; $p<0.000$).

As the Berg balance scale was the only significant predictor of 6 meters walking time, it seems that the static balance and strength are of less relevance for walking in this population. On the other hand, the relative strength of leg and trunk muscles was highly correlated with walking ability. Therefore it seems that their variance was incorporated into Berg balance scale and didn't provide any unique variance relevant to walking. For that reason dynamic balance seems to be the best predictor of walking ability in nursing home residents.

LOW-LOAD SLOW RESISTANCE TRAINING CAUSES MUSCLE HYPERTROPHY AND STRENGTH GAIN, BUT DOES NOT IMPROVE MOTILITY FUNCTION IN ELDERLY PEOPLE.

TANIMOTO, M., WATANABE, Y., OHGANE, A., ISHII, N., MIYACHI, M.

NATIONAL INSTITUTE OF HEALTH AND NUTRITION

BACKGROUND It has been reported that resistance training at intensities lower than 65% of one repetition maximum (65%1RM) is virtually ineffective for increasing muscle size and strength. However, the concept of enhancing exercise movement variation was not explored in these studies. When exercise movement is designed to place muscles under continuous tension throughout the exercise movement, resistance training, even with low-intensity loads of less than 65% 1RM, promotes muscle hypertrophy and increases strength. We previously reported that relatively low-load (50% 1RM) resistance training with slow movement and tonic force generation (named LST) caused as significant an increase in muscular size and strength as high-load (80% 1RM) resistance training with normal speed in young men. However, that study targeted a limited age group. PURPOSE The present study was performed to examine whether LST is effective for muscle hypertrophy and strength gain in elderly people as well. METHODS Thirty-two healthy elderly men and women were assigned into two groups and performed resistance training regimens comprised of knee-extension and knee flexion by the following methods: low-load (50% 1RM) with slow movement and tonic force generation (3 s for eccentric and concentric actions, and no relaxing phase; LST); low-load (same load as for LST) with normal speed (1 s for concentric and eccentric actions, 1 s for relaxing; LN). Each exercise session consisting of 8 repetitions and 3 sets was performed 2 times a week for 12 weeks. The load of LST (50%1RM) was about 8RM load with LST movement. In LN, both load and amount of work were matched with those in LST. Muscle mass, strength, and motility function were measured before and after the training intervention period. RESULTS LST training caused significant increases in muscle thickness in thigh (+9.7±3.3% in men, +4.1±5.4% in women), and significant increases in knee extension and flexion torques, whereas LN training did not cause increase in muscle thickness in thigh. However, LST training did not improve motility functions such as walk speed and sit-to-stand times. CONCLUSION The results suggest that LST resistance training is effective for improving basic ability of muscles through muscular hypertrophy, but does not improve motility functions such as coordination ability in daily life activities. When LST is adopted to improve muscle strength and motility functions, it should be combined with exercises that improve motility functions, such as plyometric training.

THE EFFECT OF 6-MONTHS EXERCISE INTERVENTION ON THE BRAIN FUNCTION, QUALITY OF LIFE, AND PHYSICAL FITNESS IN THE MIDDLE-AGED AND ELDERLY JAPANESE

MINAMI, S., KASAOKA, S., KONISHI, Y., INOUE, T., TANIGUCHI, Y.

PHYSICAL EDUCATION AND MEDICINE RESEARCH CENTER UNNAN AND INTERNATIONAL BUDO UNIVERSITY

Introduction: It was reported that six months aerobic training (Kramer, A. F., et al., 1999) or resistance exercise (Cassilhas, R. C., et al., 2007) intervention improved cognitive function of the elderly. However there are few studies about the effect on the brain function by the overall fitness program in which many people popularly participate for improving their physical fitness. We investigated whether the brain function in middle-aged and elderly people were affected by the participation in 6-months exercise program which included aerobic and anaerobic exercise and whether the change of brain function and quality of life (QOL) were related to the change of physical fitness.

Methods: Eight men and six women (mean age 62.9 ± 6.2 years old) participated in a 6-months exercise program. All the subjects gave their informed consent for participation in the study. One hour exercise class, including aerobic exercise, strength exercise and stretching, was held once a week. Before and after the 6-months exercise program, the brain function, health-related QOL, and physical fitness of subjects were evaluated. In present study, brain function was evaluated by the revised version of Hasegawa's Dementia Scale (HDS-R) and a modified Stroop task. QOL was scored by the Short Form-36 (SF-36) (Ware, J. and Scherboume, C., 1992). Grip strength, sit-and-reach, whole-body reaction time, static balance test, sit-up, estimated maximal oxygen uptake and leg extension power were measured as physical fitness. A one-factor analysis of variance with two times (before and after) was introduced into the analysis for the brain function, QOL, and physical fitness.

Results and Discussion: Grip strength (pre 34.9 ± 7.7 kg, post 33.5 ± 7.5 kg, $P<0.05$) and whole-body reaction time (pre 387 ± 56 msec, post 363 ± 65 msec, $P<0.05$) were significantly decreased, sit-up (pre 14 ± 8 times, post 18 ± 6 times, $P<0.001$) and the score of social functioning in SF-36 (pre 89.2 points, post 97.5 points, $P<0.05$) were significantly increased by the exercise intervention. The time of a modified Stroop task was significantly shortened after the exercise intervention (Word test: pre 12.4 ± 0.6 sec, post 10.8 ± 0.5 sec, $P<0.01$, Color test: pre 16.6 ± 0.9 sec, post 14.5 ± 0.6 sec, $P<0.01$, Color Word test: pre 23.5 ± 0.9 sec, post 21.9 ± 0.8 sec, $P<0.01$,). No other significant change was observed. It was concluded that the exercise intervention designed for improving physical fitness could improve QOL and higher brain function in the middle-aged and elderly Japanese.

ASSESSMENT OF PHYSICAL ACTIVITY PATTERNS AND LEVELS BY ACCELEROMETRY IN ADULTS AND ACROSS AGES – SISTEMATIC REVIEW OF STUDIES

BENTO, T., MOTA, M.P., LEITÃO, J.C., SANTOS-ROCHA, R.

ESCOLA SUPERIOR DE DESPORTO DE RIO MAIOR

Background: Age has been shown to be inversely associated with PA in children, adolescents and adults, when evaluated by self-report and objective measures of PA. However, few studies have shown this considering in an adult or older population using objective measures.

Methods: Investigations with the aim of measuring physical activity, physical activity levels and patterns, in adult or older population, using accelerometry technology, were searched and reviewed.

Results: Data from studies indicate that mean counts decline with age, and males appear to be more physically active than females. The majority of older adults failed to accumulate minimum recommendations of 30 min of moderate to vigorous physical activity on 5 or more days of the week. In terms of pattern of PA throughout the week, participants were less active on weekends than weekdays.

Conclusions: More longitudinal studies using objective measures in combination with self-report methods are needed to better understand PA levels and patterns in young and older adults, in order to better prescribe intervention programs in these populations. Also, is advisable to consider more than one cutoff point for adults and older adults, in order to account for the decline in exercise capacity with age, and also to standardize them.

USING THE TIMED UP-AND-GO TEST TO HEALTHY OLDER PERSONS

SAKAI, T., ISHIHARA, K.

DOSHISHA UNIVERSITY

Introduction: The Timed Up-and-Go test was recommended for older persons with a high risk of falls 1). On the other hand, there were a few reports about the Timed Up-and-Go test for healthy older persons. If the Timed Up-and-Go test would be applied to healthy older persons, then it was possible to evaluate age-related decline in physical fitness. The purpose of this study was determined to whether the Timed Up-and-Go test was applied to healthy older persons.

Methods: The subjects were 42 young persons (young group, 20 male and 22 female, 19.3 ± 0.82 yr) and 34 healthy old persons who were frequently participated exercise classes or/and community meetings (old group, 15 male and 19 female, 65.2 ± 6.75 yr). All subjects were measured the Timed Up-and-Go test twice and the better score of two trials was recorded using a stopwatch (seconds). Additionally, it was videotaped while performing the Timed Up-and-Go test and five components of the Timed Up-and-Go test, standing up from a chair, walking 3 m, turning around, walking back to chair, and sitting down, were elevated their scores.

Results: The test scores were significantly differences between young and old groups (4.99 ± 0.51 sec vs. 5.35 ± 0.53 sec, $P < 0.05$). The stopwatch-measured scores were significantly faster than the videotape-measured score in both groups (young group: 4.99 ± 0.51 sec vs. 5.53 ± 0.53 sec, old group: 5.35 ± 0.53 sec vs. 5.70 ± 0.55 sec, $P < 0.05$, respectively). With respect to each component, the test scores of standing up from a chair, walking 3 m, turning around, and walking back to chair were significantly differences between two groups (standing up from a chair; 0.72 ± 0.12 sec vs. 0.84 ± 0.13 sec, walking 3 m; 1.08 ± 0.18 sec vs. 1.25 ± 0.19 sec, turning around; 0.80 ± 0.12 sec vs. 0.91 ± 0.14 sec, walking back to chair; 1.66 ± 0.21 sec vs. 1.86 ± 0.21 sec, $P < 0.05$, respectively). However, surprisingly, no significant differences existed for sitting down (0.82 ± 0.18 sec vs. 0.85 ± 0.14 sec, $P < 0.55$). As a result, we were suggested that the movement of sitting down was easier and simpler than the movements of other components.

Conclusion

We concluded that the Timed Up-and-Go test would be applied widely to not only frail older persons with a risk of falls but also healthy older persons and it would be possible to evaluate age-related decline in physical fitness.

FUNCTIONAL FITNESS, PHYSICAL ACTIVITY AND NUTRITIONAL INTAKE IN AZOREAN OLDER ADULTS

MARQUES, E., SANTOS, R., MOREIRA, P., CARVALHO, J., MOTA, J.

1. FACULTY OF SPORT, UNIVERSITY OF PORTO, 2. FACULTY OF NUTRITION AND FOOD SCIENCES

Introduction: Considering that Portugal is one of the ten most aged countries of Europe, the maintenance of functional independence is a major public health goal. Physical performance tests can provide valuable information to establish a diagnosis and to plan the related preventive or counteractive strategies.

Methods: A total of 271 community-dwelling older adults (190 women and 81 men) aged between 65 and 90 years who participated in the Azorean Physical Health Study II. The Functional Fitness Test battery was performed to assess the physical parameters associated with independent functioning in older adults. Dietary intake was assessed with self-administered semi quantitative food frequency questionnaire, previously validated for Portuguese population [1]. Daily physical activity (PA) was assessed with the Modified Baecke Questionnaire for Older Adults and with a pedometer during 7 days.

Results: The prevalence of overweight in the whole sample was 94.6%. Sixty-one percent reported no leisure physical activity and only 9.9% reported being engaged in sports. A total of 8.1(±9.3) min/day of moderate-to-vigorous PA was achieved. Older women had lower performance (below the norm) than older men in the 6-min walk test, chair stand 30s, up and go and arm curl tests ($p<0.05$). On the other hand, older women had better upper and lower flexibility than older men ($p<0.05$). Based on the Dietary Reference Intakes from WHO/FAO [2], 39.5% of the elders met the adequate intake for carbohydrates and 14.1% met the adequate intake for proteins.

Discussion: The results suggest that Azorean older adults do not meet the recommended PA level and dietary intake. Moreover, the performance in the endurance and mobility/agility tests, on both genders, were, highly below the suggested norm values, previously established by Rikli and Jones [3]. In fact, poor functional performance may endanger a successful aging by limiting independence, functional capacity to perform various activities of daily living and quality of life. Urgent strategies aimed at increasing levels of PA of older adults are necessary in Azores.

Supported by FCT-MCTES Grants (BD/22587/2005 and BD/36319/2007) and by the Azorean Government.

MULTICOMPONENT EXERCISE IN OLDER ADULTS: EFFECTS ON FUNCTIONAL FITNESS AND ANAEROBIC THRESHOLD

MARQUES, E., SANTOS, P., MOTA, J., CARVALHO, J.
FACULTY OF SPORT, UNIVERSITY OF PORTO

Introduction: Multicomponent exercise (ME) has been used as an interesting training alternative to endurance or resistance training programs for older adults, given the known positive effect on functional fitness (FF). As ME comprises a large variety of exercises, including aerobic, an increase in muscle ability to perform prolonged activities may be expected. However, no data have yet been provided regarding the effects of ME on aerobic capacity evaluated through anaerobic threshold (AT), an accurate physiological parameter sensitive to muscle metabolic adaptation beneficial for endurance activities. The blood lactate concentrations (BLC) corresponding to 4 mM has been set as the most accurate criteria for AT cross determination. Therefore, the purpose of this study was to analyze the effect of ME on AT and FF end-points in older adults.

Methods: Twenty-two healthy community-dwelling older adults (age 60-73 yr) were engaged in 8 months of ME (two times/ week for 60 min). Protocol included aerobic exercises, muscular endurance exercises and activities targeting to balance and flexibility improvement. Before- and after-training, FF was assessed using the 30-s chair stand (30-sCS), 8-foot up and go (8-fUG) and 6-min walk test (6-mWT). An incremental step test was used to determine the workload (V4) corresponding to AT as 4mM of BLC. During the test capillary blood was taken from the ear lobe 30s after the end of each step and immediately analyzed using an enzymatic blood analyzer (YSI 1500L-Sport). In addition, body composition was determined by bio-electrical impedance and habitual physical activity levels by Modified Baecke questionnaire for older adults.

Results: Following 8-months of ME significant increases in 30-sCS (27.74%, p=0.001) and in 6-MWT (10.09%, p=0.001) were observed, whereas V4 significantly decrease (-3.33%, p=0.006). No significant changes were observed in 8-fUG, physical activity levels and body fat mass after exercise intervention. No correlations were found between all the considered variables.

Discussion: Unexpectedly, the data suggested that 8 months (2 times/week) of ME was insufficient to positively alter AT, despite favorable changes in 6-mWT and 30-sCS performance. Taking into account the results of AT, it seems that it is possible that changes in 6-MWT may not represent a true alteration in aerobic capacity. Based upon these findings, it is possible that different factors may be involved in the modification of 6-MWT performance and AT after moderate intensity exercise in older population. Finally, future research evaluating the physiological variables determining AT changes with exercise training in older population is warranted.

Supported by FCT-MCTES Grants (PTDC/DES/70261/2006 and SFRH/BD/36319/2007).

INTERMITTENT CLAUDICATION AND PHYSICAL EXERCISE: EFFECTIVENESS OF A HOME-BASED PROGRAM

TOMÁS, M., ENCARNAÇÃO, A., QUINTANS, D., GONÇALVES, L., CAROLINO, E., COUTINHO, I., MEDEIROS, D.
LISBON HIGHER SCHOOL OF HEALTH TECHNOLOGY, POLYTECHNIC INSTITUTE OF LISBON; S. FRANCISCO XAVIER HOSPITAL; HEALTH CARE UNIT – LISBON AIRPORT ; PRIVATE PRACTICE; EGAS MONIZ HOSPITAL

Peripheral arterial disease (PAD) as a high incidence in general population and 12% to 20% of population with more than 60 years has already clinical symptoms, such as intermittent claudication (IC), pain, loss of strength and functional incapacity. There are already some studies who refer the possible positive effects of physical exercise in functional consequences of PAD. The purpose of this study was to verify the results of a home-based (HB) weekly supervised physical exercise program in patients with IC in consequence of PAD in lower limbs, and observe the medium number of diary steps walked by the subjects of our study.

Fourteen subjects (11 males and 3 female; 72.4±6.7 years; BMI 27.1±2.8 kg/m2) with IC participated in our study.

Through the 6 minutes walk test (6MWT) we have assessed the distance until claudication (DC) (distance walked until pain), maximal distance walked (MDW) (distance walked until maximal pain) and functional capacity (FC) (total number of meters walked in 6MWT). We assessed also the rate of perceived exertion (RPE) with CR10 of Borg and the highest number of repetitions of elevation of heel (EH). We have applied a HB program during 8 weeks. This program included daily execution of elevations of heels for leg muscles and a walk.

Results show elevation in DC (178.8±75.5 vs 259.6±116.7; p=0.01), MDW(255.7±104.4 vs 326.5±137.9; p=0.008), FC (299.1±115.1 vs 389.6±102.1; p=0.000) and EH (42.1±14.7 vs 59.9±21.6; p=0.002), respectively before and after HB program. The RPE has also decreased (3.1±1.1 vs 2.6±0.6) but not significantly. With a pedometer we have also observed that subjects of our study walked 4990±1872 steps a day.

Conclusions: A weekly supervised HB program with walk and strength training of leg muscles shows effectiveness with these patients in the relief of symptoms of IC. Nevertheless it is necessary not only to verify these results in a group with more subjects but also to give and spread orientations about the importance of physical exercise programs with these populations.

ELECTROMECHANICAL DELAY IN BALLISTIC MOVEMENT OF SUPERIOR LIMB: COMPARISON BETWEEN MALE AND FEMALE ATHLETES

RODRIGUESFERREIRA, M., VENCESBRITO, A.

SPORTS SCIENCES SCHOOL OF RIO MAIOR

Introduction: The aim of the present study was to analyse the electromechanical delay (EMD) between male and female karate athletes when they performed a ballistic movement of superior limb on a makiwara (karate training instrument).

Methods: Ten male and eight female karate athletes performed 10 repetitions of a motor skill which consist in upper arm flexion and elbow extension (choku-zuki punch) to the makiwara. Surface EMG activity of the anterior (AD) and posterior deltoid (PD), pectoralis major (PM), latissimus dorsi (LD), triceps brachii (TB) and biceps brachii (BB) of these subjects were recorded, using bipolar electrodes connected to a Biovision System.

Time of movement, beginning and stopping instant, were recorded using electromagnetic tracking device, Flock of Birds System. It was used a set-up of two sensors located on arm and forearm. A third sensor was mounted on the makiwara.

The EMD was defined as the difference between the onset of the EMG and the initiation of movement. Motor skill movement time offset was defined when the subjects reach the target.

The motor skill means from each group were used for analysis. Aiming to verify if there were significant differences we used analysis of variance with One-Way Anova ($p<0.05$), using the statistical programme SPSS version 16.0.

Results: Results revealed that male athletes had smaller EMD (0.003 s ± 0.001) between the onset of AD muscle activation and the beginning of upper arm flexion than female athletes (0.061 s ± 0.046). The difference between groups is significant ($p=0.011$).

Significant differences were found to in agonists/antagonists relation of upper arm flexion, specifically in PM/PD ($p=0.005$) and in AD/LD ($p=0.047$), showing that male athletes had higher EMD in this relation.

No significant differences were found in upper arm flexion antagonists, in elbow extension agonist and antagonist muscles neither in elbow extension agonist/antagonist relation in the EMD.

Conclusion

We concluded that only in upper arm flexion movement was verified a gender influence reflected in EMD, namely in agonist muscular activity and in agonists/antagonists relation. Smaller EMD presented by male athletes in AD muscle reveals a larger effectiveness in the transfer of the contractile force to the beginning of movement and in its duration, but it leads to an antagonist activation instant adjustment, retarding the beginning of agonist/antagonist cocontraction. The differences in EMD between male and female athletes could represent a different strategy of control the neuromuscular coordination in those groups.

COMPARISON OF STRATEGIES FOR MODULATING RAPID GRIPPING BETWEEN THE LEFT AND RIGHT HANDS OF RACKET-SPORT ATHLETES

KIMURA, M.

TOKYO POLYTECHNIC UNIVERSITY

Introduction: When exerting rapid isometric force, the peak of force trajectory closely correlates to the peak of its second derivative. This high degree of correlation is seen within a certain range of force, and there are individual differences in the upper limit of force (critical force level) (S. Ono et al., 1997). However, to the best of our knowledge, no studies have measured the critical force level of the left and right hands in individuals with large differences in grip strength between the two hands. The objective of the present study was to ascertain strategies for modulating left and right hand grip strength during rapid gripping in racket-sport athletes with large asymmetry in grip strength.

Methods: Subjects were five tennis players and one badminton player. All were right-handed, and the grip strength of the right hand was 15.2-30.8% greater than that of the left hand. Each subject was instructed to grip voluntarily and isometrically at different exertion levels (10-90% MVC) 40-50 times each for the left and right hands. The subjects were asked to grip as rapidly as possible. Surface electromyography (EMG) was measured at the flexor digitorum superficialis (FDS). The following parameters were measured: peak of force trajectory (PF), peak of its second derivative (P-d2F/dt2), and onset-integrated EMG relating to P-d2F/dt2 (onset-I.EMG).

Results: The critical force level at which a positive linear relationship was maintained between P-d2F/dt2 and PF differed between the left and right hands in all subjects. For example, the left and right critical force levels for subject NE (woman, grip strength: 23 kg for the left hand and 33.8 kg for the right hand) were 57 and 35% MVC, respectively. Furthermore, the left and right critical force levels for subject UN (man, grip strength: 40.8 kg for the left hand and 48.1 kg for the right hand) were 61 and 83% MVC, respectively. In this manner, no relationship existed between grip strength and critical force level for the left and right hands. However, when calculating %Max P-d2F/dt2 (P-d2F/dt2 relative to the maximum value of P-d2F/dt2 obtained by rapid gripping with maximum effort), the critical force level as indicated by the relationship between %Max P-d2F/dt2 and PF (%MVC) was the same for the left and right hands. Moreover, except for the right hand of one subject, high correlation coefficients (r=0.667-0.930) were seen between onset-I.EMG and P-d2F/dt2.

Discussion: In racket-sports athletes with a large difference in left and right grip strengths, the critical force level [the relationship between %Max P-d2F/dt2 and PF(%MVC)] was the same for the left and right hands. In other words, strategies for modulating force levels over a broad range during rapid gripping are not based on an absolute scale of muscle force, but on a relative scale of muscle force and speed.

SUCCESSION OF NEUROMUSCULAR ACTIVATION DURING DIFFERENT TECHNIQUES FOR GIANT SWINGS IN GYMNASTICS

VON LAßBERG, C., RAPP, W., KRUG, J.

UNIVERSITY OF LEIPZIG

Introduction: The aim of the study was to analyse the chronological succession of the neuromuscular activation in high performance gymnasts during different techniques for giant swings on the horizontal bar, measured using a telemetric electromyography system (EMG). It should be examined how to optimize current teaching methods to the special demands of neuromuscular activation patterns during long hang swings.

Methods: The sample consisted of three high level gymnasts (male, age: 16-17 years, 28-30 hrs. of training /week). They first had to demonstrate giant swings backward in "conventional technique" (conv.GS, n=11), and then using the high accelerating "power technique" (pow. GS, n=5) (1). The EMG was captured with 1500 Hz (Telemyo 2400T, Noraxon, USA). The following muscles were plotted: Pectoralis major (Pect.), rectus abdominis (RAbd.), rectus femoris (RFem) as essential parts of the anterior muscle chain, and deltoideus, pars posterior (Delt.), erector spinae (ESpin), biceps femoris (BFem) as antagonists (posterior muscle chain). The kinematic data of the elements were captured using video kinemetric analysis with 50 Hz ("2D-Mess" of IAT, Leipzig). For synchronization, the systems were triggered by an analogue signal.

Results: During the leg acceleration phase, in all participants and in all elements, the results showed a succession of muscular activation of the anterior chain from "Punctum fixum" (PF) to "Punctum mobile" (PM). Pect. and RAbd. were coactivated nearly simultaneously. RFem. was always activated last, with no exception. During the upswing phase in conv.GS either a simultaneous or even a recurrent succession from PM to PF was found. In contrast to this, the muscle activation and deactivation patterns (anterior and posterior) during all phases of pow.GS ran through the body from PF to PM.

Discussion: The results support the thesis that for an effective segmental acceleration of PM the activation has to run from PF to PM, generally. To cause an impulse transmission of PM, however, an inverted pattern seems to be necessary. Thus, the succession of neuromuscular activation does not always correlate with the kinematic succession of segmental body movements (1). With regard to the fact, that training methodology is commonly based on kinematic models this could lead to ineffective patterns of neuromuscular activation and cause a prolonged learning process for developing high level swinging techniques. The findings should be verified in larger samples of high performance gymnasts. If these results are affirmed, then these aspects should be accounted for in training methodology for better differentiation and faster learning of correct muscular activation patterns with regard to long hang swings.

FORCE VARIABILITY DURING ISOMETRIC WRIST FLEXION IN HIGHLY-SKILLED AND SEDENTARY INDIVIDUALS

AMIRIDIS, I., SALONIKIDIS, K., OXYZOGLOU, N., SAEZ SAEZ DE VILLARREAL, E., ZAFEIRIDIS, A., KELLIS, E.

LAB OF NEUROMECHANICS

The association of expertness in specific motor activities with a higher ability to sustain a constant application of force, regardless of muscle length, has been hypothesized. Ten Highly-Skilled (HS group) young tennis and handball athletes and ten Sedentary (S group) individuals performed maximal and submaximal (5, 10, 20, 50 and 75% of the MVC) isometric wrist flexions on an isokinetic dynamometer (Kin-Com, Chattanooga). The wrist joint was fixed at 5 different angles (230, 210, 180, 150 and 1300). For each position the percentages of the maximal isometric force were calculated and participants were asked to maintain the respective force level for 5 sec. Electromyographic (EMG) activation of the Flexor Carpi Ulnaris and Extensor Digitorum muscles was recorded using bipolar surface electrodes. Power spectral analysis of the EMG signal was performed to calculate the Median Frequency (MF) on 512-point by fast Fourier Transform technique (FFT). No significant differences were observed in maximal isometric strength between HS and S groups. Participants of HS group showed significantly ($p < 0.05$) smaller force Coefficient of Variability (CV) and SD values at all submaximal levels of MVC at all wrist angles. The CV and SD values remained unaltered regardless of wrist angle. No difference in normalised agonist and antagonist EMG activity was observed between the two groups. However, FFT analysis revealed a greater MF for the HS in comparison to the S group ($p < 0.05$). It is concluded that the greater force steadiness observed in experts was solely accompanied by higher MF of the agonist EMG.

STATIC BALANCE CONTROL AND LOWER LIMB STRENGTH IN BLIND AND SIGHTED WOMEN

AMIRIDIS, I., GIAGAZOGLOU, P., ZAFEIRIDIS, A., THIMARA, M., KELLIS, E.

LAB OF NEUROMECHANICS

The purpose of this study was to examine static balance control and its possible relationship with the lower limb strength in blind women. Eleven blind (BL group) and eleven (SE group) seeing women performed 3 different tasks of increasing difficulty: Normal Quiet Stance (NQS, 1min), Romberg Stance (RS, 20sec) and One Leg Stance (OLS, 20sec). Participants stood barefoot on two adjacent force platforms and the Center of Pressure (CoP) variations [peak-to-peak amplitude (CoPmax) and SD of the CoP displacement (CoPsd)] were analyzed. Seeing participants performed the tests in Eyes Open (EO) and Eyes Closed (EC) conditions. Moment/angular velocity and moment/angular position relationships were also established using a Cybex dynamometer for knee extensors and flexors as well as for ankle plantar and dorsiflexors. The analysis showed that, in comparison to the SE group, the postural sway of the BL group was greater ($p < 0,01$) in A/P direction for all balance tasks, whereas in M/L direction was greater ($p < 0,01$) only for the OLS. When sighted participants performed the postural tasks in the absence of vision, CoP displacement in M/L direction was ($p < 0,05$) greater than in SE group for all tasks. Postural sway in A/P direction was greater only for the OLS. No significant differences were observed between the two groups concerning concentric and isometric tests for both knee and ankle muscles. The eccentric strength of the knee extensors was found to be greater ($p < 0,05$) in the sighted participants in comparison to visually impaired. It is concluded that great differences in static balance control between visually impaired and sighted humans mainly concern the A/P direction. When the sighted participants performed the tasks in the absence of vision, their differences tend to disappear. Strength of both knee and ankle muscles does seem to influence their static balance performances.

LATERAL SPECIFICITY OF BILATERAL TRAINING IN THE MOTOR CORTICAL ACTIVITY AND REACTION TIME DURING THE SIMULTANEOUS REACTION TIME AND STRENGTH TASK

TANIGUCHI, Y.

INTERNATIONAL BUDO UNIVERSITY

Introduction: The lateral specificity in the effect of bilateral and unilateral training is present in the resistance exercise (Taniguchi, 1997, 1998) but not in the reaction time (RT) task (Taniguchi, 1999). These mechanisms in the training have not yet been clarified. In many sports, quickness and strength are required simultaneously. The purpose of this study was to investigate 1) whether the lateral specificity in the effect of training in the simultaneous RT and strength task is present and 2) whether the cortical activity would be changed with the effect of bilateral and unilateral training.

Methods: Before and after the training session, fourteen right-handed subjects were measured simple RT tasks with isometric abduction of the index finger under three conditions; with the right hand, left hand, and both hands. Each response condition consisted of 2 blocks of 20 trials. The order of the blocks was randomized. Electroencephalogram (EEG) activity was recorded on 21 locations using the 10 - 20 system. During the preparatory period, EEG was averaged, time-locked to the preparatory signal, under the three task conditions. Electromyographs (EMGs) were recorded with surface electrodes on the right and left first dorsal interosseous muscles. Isometric abduction forces were recorded by force transducers. EMG-RTs were measured from the response signal to the onset of EMG. Movement times were measured from the response signal to the rise of force. Subjects were assigned to three groups; bilateral training group (BT), unilateral training group (UT), and control group(C). BT and UT continued the 2 blocks of 10 trials of each RT task, 3days a week for 3 weeks. C did not train.

Results and Discussion: A two-factor analysis of variance, with two times (before and after) x two sides (right and left) demonstrated that significant reduce in movement times were found in UT subjects regardless of condition. Movement time of unilateral condition tended to increase in BT. No change was found in RT of C. The amplitude of contingent negative variation (CNV) on motor cortical area (C3 and C4) just before the response signal, as an index of motor preparation, tended to increase for BT in bilateral condition. It was concluded that lateral specificity in the effect of training in the simultaneous RT and strength task was observed only for BT, but not for UT. More studies are needed to clarify whether motor cortical activity during the simultaneous RT and strength task would be changed with the effect of bilateral and unilateral training.

TEMPORAL STABILITY IN DUAL RHYTHMIC MOTOR TASK

SERBETAR, I., MEDVED, V.

FACULTY OF TEACHER EDUCATION, FACULTY OF KINESIOLOGY

INTRODUCTION: Most of the everyday human motor behavior belongs to the category of repetitive movements (e.g. cyclical locomotor behavior). Such oscillatory movements can be well described through periodicity, or in other words - regularity of timing. Research paradigm of interlimb coordination drawn from coordination dynamics and build on famous Haken Kelso Bunz model (HKB; Haken et al., 1985) is most concerned with temporal and spatial organization of movement. HKB model, which basically capture the level of stability of the coordination pattern, anticipates two stable coordination modes, so called in-phase (PH; limbs moves paralell) and anti-phase (APH; limbs move opposite one from another).

METHODS: Ten right-handed adults (aged 19 - 28) voluntarily participated in the experiment. Participants seated behind the desk where the board with two copper contacts plates was placed, another board with same contacts was set on the floor under the subjects feet. Subjects wore copper made contacts on their hands and feet connected to computer via data acquisition card. Contact of two plates provided closing of electrical circuit, thus, exact time and duration of touch was assessed. Participants produced tapping movement (1 Hz) with their hands and feet simultaneously under two initial conditions, in first hands were constrained to PH coordinative mode while feet were in APH, in second condition feet moves in PH while hands were in APH. Sixty seconds of performance were recorded. Customized software provided measures of phasing of homolateral and ipsilateral pairs of limbs. Relative phase was calculated as usual (Donker et al., 2001), standard deviations of relative phase as measures of variability were further analyzed.

RESULTS AND DISCUSSION: Most of the studies in dynamical approach belongs to bimanual coordination while just minority of them are oriented to quadripedal-like patterns. In a present study authors wanted to test the coupling and the stability of coordination patterns when all four limbs were involved. Surprisingly, there were no statistically significant differences in variability between the limbs of two girdles among the coordination modes. The only statistically significant difference acquired by univariate ANOVA was noticed in ipsilateral limbs on the left side (df=1, 17; F=5,10; p=.037). Even more interesting was the fact that the ipsilateral coupling was more stable then the homolateral. Overal variability of two patterns was high which is caused by novelty of joined motion patterns. Most of the trials were heavily saturated with switching to another mode - inside one or both girdle, or patterns simply did broke down. Findings proves known fact that the coalition of constraints most strongly influences stability of rhythmic coordination task.

GENDER AND LEARNING THE BUTTERFLY STROKE TECHNIQUE

MICHIELON, G., SCURATI, R., LONGO, S., INVERNIZZI, P.L.

FACULTY OF ECERCISE SCIENCES - UNIVERSITY OF MILAN

INTRODUCTION: Swimming performance is surely related to gender, as well as spatial and temporal actions of the stroke. However, a discrepancy about gender and learning the swimming techniques seems to occur: in children no differences have been found in learning the front crawl, whereas in young beginners relationships between gender and learning have been shown as a result of different teach-

ing Methods: This study aimed to evaluate and compare the learning of the butterfly stroke technique under gender in young male and female beginners.

METHODS: Eighteen 16 to 21 years old subjects (10 females, F and 8 males, M) composed the sample. In order to proceed with the study, since anthropometric data differed as expected (F vs. M: height 166±5 vs. 177±5 cm, p<.001; weight 52.1±7.3 vs. 68.3±11.2 kg, p<.001; BMI 18.96±2.25 vs. 21.73±2.72, p<.05; arms span 164±6 vs. 177±5 cm, p<.001) aquatic skills were set as criteria of homogeneity: technical level, hydrodynamics, performance in 50m breaststroke. Subjects attended a 10-class program (50 min each class) and were taught the butterfly stroke by a mixed analytic-global method: analytic in the first half of the class and global in the second half.

Evaluation and analysis of the stroke learning process were carried out by a final 25m butterfly stroke. A qualitative analysis of stroke elements such as balance, arm to legs coordination, stroke rhythm, kick, underwater arm stroke phase, arm recovery, head control was carried out. Performance in a 25m butterfly stroke, stroke length (SL) and stroke rate (SR) were collected for a quantitative analysis. Swimming mean velocity (v) and Swimming Index (SI=v2/SR) were calculated.

RESULTS: M seemed to better perform arm to leg coordination and underwater arm stroke. They kept the hip lower underwater and the shoulders higher during recovery. F showed better rhythm and arm recovery, staying higher on the water and better performing the anticipation of the head movement.

Significant differences were found in the 25m performance (F vs. M, 26.5±2.2 vs. 22.5±4.3 s, p<.05) in SL (0.57±0.1 vs. 0.78±0.2 m/cycles, p<.05), SR (0.54±0.1 vs. 0.88±0.2 cycles/s, p<.001) and v (0.94±0.1 vs. 1.14±0.2 m/s, p<.05) but not in the SI (1.72±0.5 vs. 1.56±0.6, p>.05).

CONCLUSION

As expected, there were significant differences between female and male subjects due to physiological features gender related. Differences in force (very important in butterfly stroke) and anthropometric data fully explain better male performances. Anyway, qualitative analysis and SI results (i.e. index of swimmer's technical efficacy) induce to state that no gender differences can be observed in learning the butterfly stroke.

NO EFFECT OF USING FLOTATION SUITS IN GLIDING AND FLOATING ABILITIES OF ADVANCED BEGINNERS IN SWIMMING TEACHING

KJENDLIE, P.L.

NORWEGIAN SCHOOL OF SPORT SCIENCE

Introduction: Flotation suits are proposed as a means to enhance the effect of swimming teaching in children, however there are few empirical data on this effect. Wearing the suit would mean a safer child, more able to do exercises on their own, independently of the teacher, and possibly increasing the activity level. Disadvantages of using flotation aids in general are that children become dependent on the aid, not learning to float free and independently, and that self confidence of learning to swim unaided is not developed.

Purpose: The purpose of this study was to investigate the effect of wearing a flotation suit on the floating and gliding abilities of children in a learn-to-swim program.

Methods: 110 children, with previous swimming school experience, but not yet able to swim, were taught how to swim once a week for ten weeks. Each group were randomised to use flotation aids (FL, n=50, mean age 7.7±1.3 years, height 125±26 cm) in the form of a flotation vest, or non use of the vest (CON, n=60, mean age 7.4±1.0 years, height 121±29 cm). The reported previous swimming teaching experience was 3 or 4, 10 hour courses for the CON or FL respectively (p<0.03). The vest group did also exercises at the end of each lesson without the aid to enhance abilities of real floating. Their skills after 10 lessons were observed through video recordings, measured with a modified Aquatic readiness assessment test (Langendorfer and Bruya 1995) using tagging of events in the Dartfish software. Floating scores were given for each subject, and assisted, supported or free floating was taken into consideration, as well as the duration of the floating. For gliding scores, head up or down as well as the gliding distance were considered.

Results: The mean scores of floating abilities on front (prone position) were 7.6±1.7 and 7.9±2.1 for FL and CON respectively, and for floating on back (supine position) 6.9±2.2 and 7.4±2.3 respectively. The gliding test score for the FL group were 2.3±1.0 and or CON 2.6±1.1. There were no statistical differences between the groups either for floating or gliding abilities. However, looking at all subjects, front floating abilities scored higher than back floating (p<0.01). There were no differences in floating and gliding abilities between genders.

Discussion and Conclusions: There were no differences for floating or gliding abilities in advanced beginners after 10 one hour lessons using flotation suits compared to a control group. If the flotation suit is used wisely, and teaching is also done sometimes without the vest, teaching with a flotation suit does not slow the development of floating and gliding abilities - prerequisites for learning how to swim. Further research is needed to look at the effects on arm stroking, leg kicking and whole swimming abilities.

ATTENTIONAL FOCUSING INSTRUCTIONS INFLUENCE FORCE CHARACTERISTICS DURING KNEE EXTENSION EXERCISE

MARCHANT, D., GRIEG, M., SCOTT, C.

EDGE HILL UNIVERSITY

Introduction: Attentional focusing instructions (either internally or externally focused) can have a significant influence on the muscular activity during exercise type movements (e.g., (Vance, et al., 2004; Marchant, et al., 2008). Specifically, externally focused instructions (direct attention towards the movements being carried out and the object through which force is being exerted) result in lower EMG values when compared to internally focused instructions (directing attention to the movements of the limb involved in the movement). Recently (Marchant, et al., in press), externally focused instructions resulted in increased force production during elbow flexions when compared to internally focused instructions. The present research further addresses the nature of these force production characteristics during instructed exercise movements.

Methods: 15 healthy participants completed 10 isokinetic knee extension repetitions on a Biodex System 3 dynamometer under two counterbalanced conditions: production of maximal force using verbal internally (focusing attention onto the movements of the leg) and externally (focusing attention onto exerting force through the leg pad) focused instructions. Measures were the integral of the torque-time

curve (iT), force variability (fV – SD in iT) and a fatigue index (FI - % decline in iT). A 2 (Attentional Focus Type) X 8 (Repetition) Repeated Measures ANOVA analysed differences in iT. Paired samples t-tests were used to assess differences in fV and FI.

Results: iT was significantly ($p < 0.05$) greater when external focus was adopted (126.88, SE = 8.59 N m) compared to an internal focus (119.20, SE = 9.67 N m). An external focus was also associated with significantly ($p < 0.05$) greater fV (10.17 N m) compared to an internal focus (8.00 N m), but there were no differences in observed fatigue over the course of repetitions in either internal (88.72%) or external (85.55%) focus condition.

Discussion/Conclusion: Supporting recent previous research, an external focus of attention increased force production in an exercise task when compared to an internal focus. Attentional focus did not influence fatigue characteristics effects over the course of this exercise, but requires further research. These findings have significant implications for the instruction of exercise and rehabilitation exercises.

EFFECT OF MODERATE RESISTIVE TRAINING ON IMMUNE FUNCTION IN ELDERLY PEOPLE

SHIMIZU, K., AIZAWA, K., SUZUKI, N., IMAI, T., NANBA, H., AKIMOTO, T., KUNO, S., MESAKI, N., AKAMA, T., KONO, I.

WASEDA UNIVERSITY

The purpose of this study was to examine the effect of resistive training on age-related impairment of immune parameters in elderly individuals. Twenty-four elderly subjects were assigned to an exercise training group (EXC: 3 males, 9 females; aged 61–76) or a non-exercise control group (CON: 4 males, 8 females; aged 62–79). Subjects in EXC participated in exercise sessions 2-days a week for 12 weeks. Meanwhile, subjects in CON maintained their normal physical activity levels during the study period. Blood samples were collected before and after the training period. Samples were measured for the number of leukocytes, lymphocytes and monocytes, as well as for CD3+, CD4+, CD8+, CD28+CD4+, CD28+CD8+, TRL-4+CD14+, CD80+CD14+ cells. The number of leukocytes, lymphocytes, monocytes, CD3+ CD4+ and CD8+ cells did not change after 12 weeks in both EXC and CON. The number of CD28+CD8+ cells significantly increased after the training in EXC ($P < 0.05$), while CON did not show significant changes. In the EXC group, CD80+CD14+ cell numbers were significantly higher following the training ($P < 0.05$), but the number of TLR-4+CD14+ cells was not changed. In the CON group, there were no significant alterations in TLR-4+CD14+ and CD80+CD14+ cell numbers. In conclusion, moderate resistance training in the elderly is associated with improvement of expressions of CD28 on Tc cells and CD80 on monocytes. Therefore, moderate resistive training could up-regulate T-cell activation in elderly people.

THE EFFECT OF LONG-DISTANCE TRANSPORTATION BY AIRPLANE ON SALIVARY SIGA AND CONDITION IN ELITE JUNIOR SPEED SKATERS

KON, M., MAEGAWA, T., SUZUKI, N., IIZUKA, T., TANISYO, K., YUDA, J., AOYANAGI, T., TAKAAHSHI, H.

JAPAN INSTITUTE OF SPORTS SCIENCES

Introduction: Elite athletes often use airplane when they participate in an international competition. It has been reported that a long-distance transportation decreased mucosal immune function (salivary secretory immunoglobulin A: SIgA) in healthy men and women (Terasawa et al., 2008). However, the effect of long distance transportation by airplane on salivary SIgA and condition in athlete has never been studied so far. The purpose of this study was to investigate the effect of long-distance transportation by airplane on salivary SIgA and condition in elite junior speed skaters.

Methods: The subjects were 7 elite junior speed skaters who participated in the North America (Calgary) expedition in 2008. Saliva samples were collected before and after the transportation, and saliva flow rate, salivary SIgA concentration, and salivary SIgA secretion rate were measured. A survey of upper respiratory tract infection symptoms was also conducted before the transportation, 1 day, 2 days, 3days, and 4 days after the transportation.

Results: The saliva flow rate (-21.4 %), SIgA concentration (-33.3 %) and SIgA secretion rate (-52.0 %) significantly decreased after the transportation ($p < 0.05$). One of 7 subjects exhibited upper respiratory tract infection (URTI) symptoms after the transportation. In addition, the decreasing rate of SIgA levels in the subject exhibited URTI symptoms was the highest of all the subjects.

Discussion: These results suggest that the transportation decrease salivary SIgA levels in elite junior speed skaters. In addition, our data might suggest that incidence of URTI symptoms is related to the SIgA level of each subject. There is a possibility that the long-distance transportation by airplane induces a decrease in SIgA levels of elite athletes and leads to a decrease in their condition. Because saliva collection is easy and non-invasive, it is easy to enlist a cooperation of elite athletes. If it becomes possible to measure salivary SIgA more easily, the monitoring of SIgA levels may be useful for the conditioning of elite athletes with an aim to prevent the incidence of URTI during long-distance transportation.

3D SCAPULOTHORACIC AND ISOKINETIC SHOULDER EVALUATION DURING INTERNAL/EXTERNAL ROTATION AT 90° ABDUCTION IN ELITE VOLLEYBAL ATHLETES WITH AND WITHOUT NERVUS SUPRASCAPULARIS LESION

BAEYENS, J.P., VIROUX, P., CABRI, J., MEEUSEN, R.

VRIJE UNIVERSITEIT BRUSSEL

Introduction: The incidence of a n.suprascapularis lesion (NSL) in elite volleybal athletes is about 20% with a predilection at the spinoglenoid notch (Ferretti et al. 1998). Clinically presenting with a hypotrophy of the infraspinatus, these volleybal players do not complain of functional impairment nor pain.

Compared to asymptomatic elite volleybal athletes, the dominant as well as the non dominant shoulder of elite volleybal athletes with NSL present increased passive external rotation in 90° abduction, and no differences for internal rotation at 90° abduction (Witvrouw et al. 2000). In elite volleybal players with NSL, isokinetic concentric mean peak torque at 60° and 180°/sec was different from the asymptomatic volleybal athletes for internal rotation in both the dominant and non dominant shoulder, but only different for external rotation in the non dominant shoulder (Witvrouw et al. 2000).

No study combined isokinetic strength measurement with registration of dynamic scapulothoracic motion.

Methods: In this study, scapulothoracic motion and isokinetic concentric strength was evaluated for external rotation/internal rotation at 90° of abduction in 6 elite volleyball athletes with NSL and 8 without (age-matched groups, 24,2+2.1yrs). Concentric isokinetic testing of 5 at 60° and 240°/sec was evaluated with the Biodex System 3 Pro, simultaneously following the 3D scapulothoracic arthrokinematics by means of electromagnetic tracking (extended Flock of Birds, Ascension Technology) which is validly applicable up to 120° of elevation. Statistic testing was done non parametrically. Parameters evaluated with Biodex included average peak torque, internal and external rotation range of motion, agonist/atagonist ratio.

Results: No significant differences (.05 level) in isokinetic strenght were found in the dominant and non dominant shoulders between the NSL group and the asymptomatic group. Furthermore, in both groups, no differences in isokinetic strenght were found in between the dominant and non dominant shoulder. For the scapulothoracic motion behaviour, no significant differences were found in the scapulothoracic Euler angles between the asymptomatic control group and NSL group.

Conclusion: Examining isokinetic strength and scapulothoracic motion during internal/external rotation at 90° abduction, our data show no differences in isokinetic strength and scapulothoracic motion behaviour. As such, our data differ with Witvrouw et al.'s findings (2000) This may be due to differences in patient group and measurement procedure. Anyhow, our data apply more to the reality that elite volleyball players with NSL do not complain of functional impairment.

THE EFFECTS OF REHYDRATE DRINKS ON THE EXERCISE PERFORMANCE TEST.

IMAI, T., SHINDO, Y., UTSUGI, K., IIDA, K., WATANABE, K., MUKAI, N., MIYAKAWA, S., MEDA, A., KITAGAWA, Y., KISO, Y., YABUKI, H., HARADA, H.

UNIVERSITY OF TSUKUBA, SUNTORY LIMITED, SUNTORY LIMITED

Introduction:When sports player perform in prolong exercise in warm condition, they sweat a lot and lose their body mass. Current recommendations encourage athletes to drink sufficient amount to avoid excessive change in body mass. Adequate fluid intake during exercise is known to prevent cardiovascular strain, which could reduce performance capacity in prolonged exercise. However, how the effect on performance will change by drinking different type of drinks during exercise is not clear.

Purpose: The aim of this study is to investigate the effects of rehydration with drinks on the exercise performance test.

Methods: Ten university football players participated in this study (age 22.1 ± 1.1yr, Vo2max 50.5 ± 3.5ml/kg/min). Each subjects completed the four experimental trials, randomized and administered in a crossover manner, separated by at least 7 days. They exercised on a bicycle ergometer for 90min at 65% of Vo2max then performance test was conducted using the bicycle. In this exercise performance test the workload increased 2W every 5sec from 100W and stopped the bicycle in a state equal to or less than 50 rounds per minute. In experiment 1 lost sweat volume was measured without any fluid intake. Sweat loss during each period of exercise was determined through changes in body mass. In experiment 2.3.4 subjects exercised with drink intake (Gatorade® or Sports drink A or Placebo drink) during the experimental trials. The drink volume consumed was equal to 80% of sweat lost during exercise, provided in three equal bottles at 20 min intervals (drink time 20,40,60 min).

Results: Time of exercise continuance and workload was Sweat test 355±91(s) 242.4±37.5(W),Gatorade® 459.9±86.4(s), 277.6±30.5(W). Sports drink A 403.8±88.5(s) 260.0±36.3 (W), Placebo 394.5±99.4(s), 256.4±40.3 (W). Time of exercise continuance and workload with Gatorade® was significantly greater than those without any drink in Sweat test. There were no significant differences on exercise performance test time or workload among three drinks. However, Gatorade® showed the greatest time in total and 70% of subjects indicated the best time than other drinks.

Conclusions: We suggested that exercise performance was affected by rehydrate drink.

BIKE TRANSALP 2008: THE LIQUID INTAKE AND ITS EFFECT ON BODY'S FLUID HOMEOSTASIS IN THE COURSE OF A MULTI-STAGE MTB CROSS-COUNTRY MARATHON RACE IN THE CENTRAL ALPS

SCHENK, K.

UNIVERSITY OF VERONA

Introduction: Despite the increasing number of bikers who practice off road cycling as recreational or competitive sport, scientific interest in mountain biking is still modest. The lack of sport-specific guidelines in training and competition often seduces athletes to orientate themselves to schemes and standards of related sports, risking a slump in terms of performance and health.

Therefore, the aim of this study was to analyse the drinking behaviour in a multi-stage MTB cross-country marathon race. Conclusions should be drawn about influencing factors and limits of an appropriate fluid intake during the race and about the reliability of body mass change monitoring to self-control body fluid homeostasis in course of the Bike Transalp competition 2008.

Methods

Body weight and complex impedance measurements (using BIA 2000-M, Data Input GmbH) for the estimation of body fat mass, body lean mass and body water compartments were performed at start and after completion of every race. At arrival of stage 5 and 6, blood samples were drawn from the finger pad to analyse for serum Na+, haemoglobin content and haematocrit. Participants were instructed to keep a careful mental note of liquids consumed during the race and to fill in a diary.

Results: Mean (± SEM) hourly fluid intake during the race correlated with air temperature and ranged between 494±191 and 754±254 mL/hour. In absence of exercise induced hyponatremia (EAH, Na+ <135 mmol/L) cases, we report 5 and 4 cases of asymptomatic post-race hypernatremia (Na+ >145 mmol/L), on day 5 and 6 respectively. While post-race serum sodium concentrations correlated with the liquid intake, normalized for race time and body mass (stage 5: r=-0.46, p=0.023; stage 6: r=-0.59, p=0.003), no correlation was found with the change in body mass from pre- to post-race.

Discussion: We hypothesise that the high exercise intensity, the riding on difficult terrain, the impracticality of drafting and the less recreative character of descents, which distinguish MTB sports from road cycling, may reduce the tolerance for drinking in MTB cross-country competition. Further, granted weight penalty by carrying along unnecessary load and the low number of provision stands may reduce the motivation for and the amount of fluid intake during the race. Even though the mean hourly liquid consumption during the race stages was found to lie within the limits of 400-800 mL, recommended for most forms of recreational or competitive exercise (Noakes TD, 2003), it was, however, associated with a high prevalence of dehydration in the studied group.

Organisers and mountain-bikers should be aware not to interchange lastly emphasised risks of overdrinking with the consequences of dehydration by restricted fluid intake. Particular attention should be paid to adjust fluid provision and drinking to air temperature. In this setting, body mass monitoring was not an accurate instrument to control body fluid homeostasis.

INJURY SURVEILLANCE DURING A NATIONAL FEMALE YOUTH FOOTBALL TOURNAMENT IN KENYA. A PILOT STUDY

LISLEVAND, M., JUNGE, A., STEFFEN, K., DVORAK, J., ANDERSEN, T.E.

NORWEGIAN SCHOOL OF SPORTS SCIENCE,

Objective: To analyze the incidence, circumstance and characteristics of injuries during a two-days national female youth football tournament in Kenya.

Study design: Prospective cohort study.

Subjects: Girls under the age of 13 (U13), 16 (U16) and over 16 (O16).

Observation Technique: Specially trained Kenyan injury reporters registered on a standardised injury report form. They were supported by four physiotherapist and two doctors. Injuries were defined as all injuries, painful conditions or physical complaints that occurred during the match, even if the player could continue to play.

Outcome measurement: Injury incidence and characteristics in Kenyan female youth football players.

Results: 229 new injuries were reported from 105 matches, equivalent to an incidence of 174.7 injuries/1000 player hours (95% CI 152.1-197.3). Most injuries allowed the players to continue to play (n=188;82%). Regarding medical attention injuries, U13 players had higher injury rates (160.4 injuries/1000 h, CI 122.3 to 198.5) than O16 players (109.5 injuries/1000h, CI 80.0 to 139.0; RR=1.4, CI 1.0 to 4.0; P=.03). A total of 12 injuries (5%;9.2 injuries/1000h, CI 4.0 to 14.3) were expected to result in absence from play for at least 1-7 days. Risk of sustaining a time loss injury was 5-8 times higher in U13 compared to U16 and O16. Most injuries (57%) were caused by contact with another player, 26% were caused by other contact and in 17% of the injuries there were no contact with another player. The injuries most commonly involved the lower extremity (n= 185;81%) and 5% (n= 12) of the injuries involved the head or neck. The most frequent injury type was contusions (n= 154;67%), followed by superficial skin lesions (n= 47;21%) and sprains (n=19;8%), while a contusion to the knee (n=28;12%) and ankle (n=26;11%) was the most common injury diagnosis.

Conclusion: The incidence of injuries among female youth football players in a national tournament in Kenya was high. However, most of the injured players could continue to play. U13-players had the highest injury risk. Contusions to the knee and ankle were the most common diagnosis.

Acknowledgements: This study was supported by grants from the FIFA Medical Assessment and Research Centre and grants from Norwegian medical society for sports medicine (NIMF) and Norwegian sports physiotherapy society (FFI). The Oslo Sports Trauma Research Centre has been established at the Norwegian School of Sport Sciences through grants from the Royal Norwegian Ministry of Culture and Church Affairs, the South-Eastern Norway Regional Health Authority, the Norwegian Olympic Committee and Confederation of Sport, and NorskTipping AS.

INJURY PROFILE OF COLLEGIATE RUGBY UNION IN JAPAN: TRAINING INJURIES.

NAGAI, S., TAKEMURA, M., FURUKAWA, T., MIYAKAWA, S.

TSUKUBA INTERNATIONAL UNIVERSITY

Introduction: A consensus statement on injury definitions and data collection procedures for studies of injuries in rugby union has recently been published from International Rugby Board (IRB). However, researches followed by the consensus statement have been limited among professional and international competition. The purpose of this study was to document the incidence, severity, nature, and causes of injuries in Japanese collegiate rugby union.

Methods: A prospective design for three consecutive playing-seasons was used to describe training injuries associated with 198 players from a collegiate rugby union team in Japan. The survey was performed according to the IRB consensus procedures. Team medical staffs reported all training injuries, and provided details of the location, diagnosis, mechanism of each injury and the date of return to play. Exposures of individual players in training were recorded on a daily basis. The main outcome measures were incidence (number of injuries/1000 player-hours), severity (days absence), location, type, phase and mechanism of injuries in training.

Results: The incidence of training injuries was 3.3/1000 player-hours (forwards 3.6; backs 3.1). The average severity of injuries was 38.9 days, and moderate (8~28 days absence) and severe (> 29 days absence) injuries were greater than minimal (2~3 days absence) and mild (4~7 days absence) injuries. While ankle, knee, and shoulder were the main injury locations, shoulder and ankle had high recurrence rate. The most common injury type was sprain/ligament. Running was the predominant of phase of injuries; also attempt to tackle and being tackled indicated the greater incidence. The most frequent injury mechanisms were contacting other players.

Conclusion: This study documented injury profile at collegiate amateur level in accordance with the IRB consensus statement. The incidence and severity of training injuries in collegiate level were higher than those in professional level. Ankle and shoulder were more vulnerable locations. Although this study showed the injury profile of collegiate rugby union, we need further studies to confirm the relationship training injury and other injury risk factors, such as training volumes and programs.

PP-RE02 Rehabilitation 2

INFLUENCE OF THREE DIFFERENT BALANCE SHOES ON EMG-ACTIVITY DURING ONE-LEG STANDING

LOHRER, H., TURBANSKI, S., NAUCK, T., SCHMIDTBLEICHER, D.

1. INSTITUTE OF SPORTS MEDICINE, FRANKFURT/MAIN, GERMANY, 2. INSTITUTE OF SPORT SCIENCES, UNIVERSITY OF FRANKFURT/MAIN, GERMANY

Introduction: Injury prevention and rehabilitation is aimed by sensorimotor training on balance boards and on unstable surfaces. Different exercises in one-leg stance are commonly used in appropriate training devices. Recently, manufacturers advertise specific shoes featured by unstable sole constructions to induce appropriate stimuli. Therefore, the purpose of this study was to compare muscle activity during one-leg standing using three different balance shoes.

Methods

Ten healthy subjects, four men and six women, participated in this study (age: 35.1+/-13.3 years; height: 172+/- 0.1cm; weight: 74.1 +/- 21.2kg). Muscle activity of the lower leg was analysed during one-leg standing using surface EMG. Subjects' performance in postural control was assessed using a force plate recording displacements of centre of pressure. First, each person performed three standardised unshod trials lasting 20 seconds (control condition). Then, MBT® shoe (MBT), Finnamic-Rollenschuh® (FIN), and Reflex Control® shoe (RC) were applied and tested identical to control condition in a randomized order. EMG-activity was recorded of the following muscles: m. tibialis anterior (TIB), m. gastrocnemius medialis (GAS), and m. peroneus longus (PER). We calculated iEMG and postural sway for each trial whereas mean values were used for statistical analyses. The four testing conditions (barefoot and three therapy shoes) were compared by ANOVA for repeated measures. Furthermore, subjects answered a standardised questionnaire concerning subjective impression and expected training stimuli of the balance shoes.

Results: In comparison to control condition (barefoot - BF) we found no significant differences in EMG-activity in conditions MBT and FIN, whether in TIB, nor in GAS and PER (p=0,051-1,000). When subjects wore the RC-shoe EMG-activity increased in all tested muscles clearly.

The level of significance (p≤0.05) was not reached in GAS for comparison between RC and BF (p=0,110). But EMG-activity was significantly enhanced in TIB and PER in comparison to testing conditions BF, MBT, and FIN (p= 0,000-0,001).

Moreover, the RC led to significantly higher postural sway (p=0,000-0,072), while MBT, FIN, and control condition (BF) were not statistically different (p=0,818–1,000) in sway of centre of pressure. In questionnaire the RC was graded to be a training device and the FIN was considered to be a comfortable shoe.

Discussion: Our data indicate that the different therapy shoes apply varying demands during one-leg stance leading to different results in EMG-activity and performance in postural control. This study confirms that during upright one-leg stance the RC-shoe is a means for neuromuscular training. It evokes increasing demands in postural control and enhances EMG-activity, while MBT and FIN simulate barefoot stance. Further studies are demanded to assess the influence of the RC-shoe on injury prevention and rehabilitation in athletes and in elderly people.

ANALYSIS OF CHANGE OF 1RM, BODY COMPOSITION AND PHYSICAL FITNESS ACCORDING TO INTENSITY OF EXERCISE IN 12-WEEKS MUSCULAR RESISTANCE TRAINING PROGRAM FOR ELDERLY WOMEN WITH OBESITY

GI DUCK, P., KYUNG-RYUL, CH., SA-YUP, K., CHUNHO, CH.

NAMSEOUL UNIVERSITY, KOREA INSTITUTE OF INDUSTRIAL TECHNOLOGY

The purpose of this research is to provide important basic information for muscular resistance training program by investigating effect of 12-weeks muscular resistance training program for elderly women with obesity on body composition and 1RM which is recognized as a standard of measuring muscular strength. In this research, an analysis was made on change of 1RM and body composition according to intensity of exercise in 12-weeks muscular resistance training program for elderly women with obesity. For that purpose, 39 elderly women with obesity were put into 3 groups for 3 different types of muscular resistance training -high strength, mid strength, low strength- and their body composition and 1RM were checked after 6 weeks and 12 weeks respectively. The result was as follows. As for change of body composition, there was no meaningful difference between groups in terms of strength of exercise, but it is to be noted that since 6th week, body fat and percent body fat started to reduce and muscle mass started to increase. As for change of 1RM, there was meaningful difference between groups according to period of exercise, and especially in 12th week, higher increase of 1RM occurred in the high-strength and mid-strength groups than in the low-strength group. Each group has statistically meaningful differences between period analysis on the 30-Second Chair Stand, Arm Curl, Chair Sit-and-Reach, 244cm Up-and-Go, Functional Reach, but there were no differences on the 6-Minute Walk, Grip Strength(Right). Back Stretch(Right) has statistically meaningful difference in each group, but there was no difference between period analysis, and vice versa on the Grip Strength(Right). There were no differences in between-group at any measurement factor in the senior fitness test.

METHODS OF USE OF PHYSICAL CULTURE DEVICES DURING INFANT UNSTABLE HIP TREATMENT

SHKLYARENKO, A., KOVALENKO, T., ULYANOV, D.

VOLGOGRAD STATE UNIVERSITY

The research actual continuity. Unstable hip is one of immediate problems of modern children`s orthopedics. This disease taking into consideration not only dislocation but also mild cases of hip joint underdevelopment, called "dyspasia", are common for 1% of newborn. If dyspasia is revealed at the age of 12 months or earlier, the conservative (functional) treatment is applied. The essential rule of dyspasia therapy is a possibly earliest initiation of functional treatment, which assessed completely the stability of the hip and save its flexibility. Massage and therapeutic exercises are cornerstones of unstable hip therapy.

Study methods and management. The research was carried out in the biomedical department of the Slavenskiy-on-Kuban Pedagogical State Institute and in the physical education and sanative technologies of the Volgograd State University. We worked out, approved and tested for seven years reflector-functional exercises with the use of physical culture devices for new-born and infants which proved its high effectiveness in development and health improving processes. Differences in physical and mental state, emotional bond with child, high level of knowledge about infant body were taken into consideration. During exercise amplification:

- we used only approved safe methods of treatment;
- we didn`t overcome infant active protest or resistance towards load raise and exercise amplification;
- we deversified, complexed exercises adding as more suppliment solutions as possible,.

Research results and their discussion. To achieve the pre set orthopedic tasks we used movement power, its adequate rate and direction. Whereby, appropriate, biologically reasonable methods of internal adapting, protective and compensatory characteristics of infant growing organism were used to prevent and restore mutual position of hip joint (cotyloid cavity, whirlbone with surrounding muscles, ligaments and joint capsule). During the rehabilitation both physical and psychoemotional cooperation were effected. The reflector-functional exercises with the use of physical culture devices were done according to the following regulations:

- establish a contact with the child;
- begin the massage and gymnastics from the easiest exercises with graduate amplification and new elements introduction;
- avoid strong hacks, repulsions, tissues and joints prelums;
- careful and professional exercise effecting;
- use the massage cream and dusting powder.

Conclusion: Actual material obtained proves high effectiveness of reflector-functional rehabilitation in exercises with the use of physical culture devices in protective and compensatory characteristics of infant growing organism due to emergent adaptation to one-time loads and long-term adaptation to persistent repetition.

EFFECT OF QI-GONG EXERCISE AND MANUAL MANIPULATION TO GIRL'S HIGH SCHOOL WITH VERTEBRAL SCOLIOSIS ON COBB'S ANGLE, MOIRE TOPOGRAPHY

GI DUCK, P.

NAMSEOUL UNIVERSITY

The purpose of this study is to evaluate the effects of Qi-gong Exercise and Manipulation which are not surgical procedures, performed on scoliosis patients in Y girls' high school for 8 weeks. A total of 31 students, including 16 scoliosis patients aged between 16 and 19, 16 normal students, made up the study population. Qi-gong Exercise was performed on 8 scoliosis patients and manual manipulation therapy on the remaining 8 patients. The patients were treated with Qi-gong Exercise and manual manipulation therapy for 8 weeks and the effects on Cobb's angle, Moire topography have been evaluated. The results of the analysis have shown the following:

Significant differences period, period*group, and group in the change of Cobb's angle among three group($P<0.5$). No significant in the change of SMC(left), HMC(left) in Moire Topography but, Significant differences in the change of another factor among three group($P<0.5$).

Qi-gong could be variously to the patients with chronic spinal disease as well as those with scoliosis who are required to have pliability because it synthesizes the merits of Cobb's angle and muscular exercise. More diverse patients group need to be applied and more studies should be performed in oder to prove the effect of Qi-gong Exercise by means of developing appropriate exercise programs and conservative treatment.

ADOLESCENT SOCCER IS CORRELATED WITH AN INCREASE OF KYPHOSIS: A CONTROLLED CROSS- SECTIONAL SURVEY

VAGO, P., TAIANA, M., TESSERA, S., CASOLO, F., FRATTINI, G., ZAINA, F., NEGRINI, S.

UNIVERSITA' CATTOLICA MILANO - ISICO (ITALIAN SCIENTIFIC SPINE INSTITUTE), MILAN, ITALY –

INTRODUCTION: Low back pain during growth is recognised today as a possible problem, but risk factors are not yet well known. A long discussion exist about the possible influence of sport activities on spinal growth. Soccer is widely practiced by pupils in many different countries around the world, but we don't know if there is any correlation with changes in posture and/or spinal deformities.

METHODS: We evaluated 102 males practicing agonistic soccer two to three times per week in the age range 11-16, and compared them to a normal sample of 180 schoolboys of the same age range. We collected a series of already validated measurements: plumbline distances from kyphosis apex (C7, T12 and L3) and ATR according to Bunnell. We calculated the Sagittal Index (SI: sum of the distances of C7 and L3 - sagittal shape of the spine), and the Sagittal Ratio (SR: C7/L3 - relationship between kyphosis and lordosis). According to previous studies, we considered these normal references: 5° (ATR), and cm 1.5-5.5 (C7), 2.8-7.0 (L3) 5.5-11.0 (SI) 0.37-1.31 (SR). We used normality tests, ANOVA and chi-square.

RESULTS: In soccer players we found statistically significant increases of the plumbline distances from kyphosis apex in C7 (36.6±1.0 vs 33.6±0.7) and T12 (23.0±0.6 vs 21.3±0.8) as well as an increase of SR (0.80±0.03 vs 0.73±0.02). We did not find more pathological cases in soccer pupils than in normals for any of the considered parameters.

DISCUSSION: Apparently soccer adolescent players have a group a tendency to the increase of kyphosis, with an unbalance between the two sagittal curves in favour of kyphosis (increase of the Sagittal Ratio). Even if these changes were statistically significant, they were not clinically significant. We did not find an increase of pathological cases (spinal deformities), but this population was small to detect these variations.

ADOLESCENT SOCCER PLAYERS HAVE LESS LOW BACK PAIN THEN CONTROLS: A CROSS-SECTIONAL SURVEY

VAGO, P., TESSERA, S., TAIANA, M., ZAINA, F., CASOLO, F., NEGRINI, S.

UNIVERSITÀ CATTOLICA MILANO - ISICO (ITALIAN SCIENTIFIC SPINE INSTITUTE), MILAN, ITALY

INTRODUCTION: Low back pain during growth is recognised today as a possible problem, but risk factors are not yet well known Both in adults and children a U correlation has been proven between sport activities and low back pain. Soccer is widely practiced by pupils in many different countries around the world, but we don't know if there is any correlation of this specific sport with low back pain.

METHODS: We evaluated 102 males practicing agonistic soccer two to three times per week in the age range 11-16, and compared them to a normal sample of 668 schoolboys of the same age range. We proposed a validated questionnaire to collect data on low back pain prevalence and clinical charactheristics. Statistical analysis required the use of the χ2 test, with Yates' correction for 2-by-2 table when necessary. The Kruskall Wallis test for non parametric data was also applied.

RESULTS: When compared to normals, soccer players had a statistically significant reduction of most of the parameters: lifetime (30% vs 64%) and point (3% vs 12%) prevalence, chronic pain prevalence (1% vs 8%), limitation in activities of daily life (10% vs 55%), need of staying home for LBP (9% vs 24%), medical (4% vs 23%) and radiograpic (3% vs 10%) evaluations. Among LBP sufferers, intensity of pain was similar in the two populations.

DISCUSSION: According to our results, it appears that agonistic soccer players have less low back pain than controls. This is coherent with previous results in the literature, due to the fact that these adolescents were not sedentary nor practicing strenuous sport activities. In the meantime the differences found were high and these results should be compared with other sport activities.

FIRST RESULTS FOR THE COMPARISON OF MANUEL TECHNIQUES AND A BIOMECHANICAL DEVICE (FORMETRIC SYSTEM) IN THE IDENTIFICATION OF VERTEBRAL BLOCKADES

SCHROEDER, J., FAERBER, I., MATTES, K.

UNIVERSITY OF HAMBURG

Introduction: It is the purpose of this study to verify the sensitivity (rate of identically marked findings) of an automatic examination device (Formetric® system) to identify vertebral blockades. The Formetric® system is known to be helpful in the process of clinical back shape diagnosis (Asamoah et al., 2000).

Methods : N=21 volonteers (no back pain patients; age 34 ±5 y from 22 to 44 y; BMI 24 ±3 kg/m² from 17 to 31 kg/m²) participated in this investigation. Their vertebral segments (each 13: C1/Th1 to Th11/12) lead to 273 cases. Spine shape was analyzed automatically by means of Formetric® system (resolution 7.500 pts/cm²; reconstruction error <0.2 mm) (Drerup & Hierholzer, 1994). The count of borderline crossing/ reaching in the curvature (2nd mathematical deviation of lateral projection) served as a dependent variable to indicate vertebral blockades. Data were analyzed chi-square-based with the McNemar Test and the contingency coefficient C (SPSS 12.0) and with the formula for the sensitivity: Formetric signal is correct positive * 100/ (Formetric signal is correct positive + Formetric signal does not fit the positive manual finding = wrong negative).

Results: In 73% of all cases (199 of 273) there were equal results for both examination methods. In deed this high number was related to the count of vertebral segments with no advice for a blockade. Coming from the valid finding (blockade found by the expert) sensitivity marked identical results for the automatic identification. Sensitivity of the automatic spine shape analysis in comparison to the manual technique (expert) was 23%. There was a significant (p=.014) difference between both, the manual and the automatic examination method. And there was no statistical correlation between the concurrent methods (C=0,028; p=.642).

Discussion: Formetric® system is meant to be helpful in the clinical back pain diagnosis (Asamoah et al., 2000) and is called the 'Gold Standard' in back shape analysis, because of its automatic and time saving data analysis procedure (Thorwesten et al., 2007). The poor rate of identically found vertebral blockades might be caused by mistaking in the expert judgement, too (Weber, 2004). But further investigations should point out the characters of the persons examined. Blockade patients or scoliosis patients are expected to show other results than the clients examined in this investigation who showed irregularities in the course of the spinal shape only accidentally. Single case analysis for back pain patients show a much higher score in the identification of vertebral blockades (Schröder & Färber, 2009).

SPINE MOVEMENT FUNCTIONS AND ABNORMITY SPINE DEVELOPMENT IN INFANCY

KOVALENKO, T., SHKLYARENKO, A., ULYANOV, D.

VOLGOGRAD STATE UNIVERSITY

The research actual continuity. Spine movement function is exercised by muscle work and due to its anatomico-physiological characteristics. A bigger movement amplitude in spine joints demonstrates its stability reduction. However the rise in flexibility of female body can be a possible solution for its normal development. Undue fatiguability and as a result relaxtion of back and abdomen muscles cause abnormities in posture and in perspective structural spine deformations.

Study methods and management. The research was carried out in the biomedical department of the Slavenskiy-on-Kuban Pedagogical State Institute and in the physical education and sanative technologies of the Volgograd State University. The presence of motility dextrality not only in movement but also in static position (prone, sitting and standing) was investigated to evaluate changes in scoliosis progression and posture.

Research results and their discussion. The present study demonstrated that spine motion range in different planes in infancy and adolescence with different scoliosis severity varies considerably depending on the age and hypo-, hypermobility. Flexibility of girls aged 5-7, 8-11, 12-14 and 15-16 is higher than that of boys. With the increase of years, the number of girls with high flexibility (hypermobility) as for their trunk extension reduces considerably and as for their flexing it increases. The general tendency being valid, per cent of examined boys with normal and bigger flexibility is higher than that of the girls of the same age with equal spinal deformity. At the age 5-7 and 8-11 girls' high spine flexibility is often accompanied with lumbar lordosis in standing position and kyphosis in sitting position. In our opinion this state is conditioned by joints functional instability together with genetic weakness of connective tissues. We believe that it is not recommended for girls at the preschool and primary school age with scoliosis diagnosed do such exercise which have multidirectional biochemical impact on spine and train its mobility, for example calisthenics, artistic gymnastics, water and trampoline jumping, rhythmic dancing, etc. In general average spinal mobility model modifies during bone growth. It differences according to the sex. Age characteristics of spinal mobility are modified considerably with people with high spinal deformation rate (drift angle is > 30° according to Cobb method).

Conclusions:

1. Diversified avaluation of spinal mobility functions is very important at all stages of ontogenesis while choosing different ways and forms of its prevention, correction and physical rehabilitation.

2. Difficult exercise forms, unreasonable muscle loading and manipulations on a curvature spine may cause the scoliosis progression.

3. The analyze of general physiological and biomechanical regularities of curvature spine mobility helps to reestimate the existing traditional ideas on the use of symmetrical and asymmetrical exercises during physical culture classes of children suffering from this pathology.

DEVELOPMENT OF THE 3-POINT FIELD GOAL IN BASKETBALL: A DESCRIPTIVE STATISTICAL ANALYSIS OF PARTICIPATING NATIONAL TEAMS OF EUROPEAN CHAMPIONSHIPS FROM 1985 TO 2007

PAPADOPOULOS, P., LINDNER, M., FRIEDEL, B., GOEBEL, R., STAFILIDIS, S., SCHMIDT, G.J., BAUM, K.

INSTITUTE OF EUROPEAN SPORT DEVELOPMENT AND LEISURE STUDIES

Introduction: The international governing body of basketball (FIBA) introduced the three-point line in 1984. The purpose of this study was to investigate the development of the 3-point field goal (3FG) at the European Championships (EC) from 1985 to 2007.

Methods: The shooting performance of 166 teams (530 games) which participated in the EC from 1985 to 2007 was evaluated to discover the development of the 3FG. The statistics were taken from official resources (FIBA Europe).

The detailed 3-point shooting quotas of all teams were compared to the total shooting performances of all teams for each investigated tournament.

Descriptive statistics were used for data analyses.

Results: The lowest number of attempted (3PA) and made 3-point shoots (3PM) was found in 1985 (10.8 ± 5.2; 4.2 ± 2.4). 2007 almost two times more 3PA (21.8 ± 4.7) were found than 1985. Great increases of 3PA and 3PM were detected in 1987 (4.3; 1.6) and 2001 (4.8 and 1.1).

From 1985 to 1993 the 3-point shoot percentage (3P%) was on a high level (38.0%-43.0%), with the maximum of 43% in 1991. From 1993 to 1997 a decrease to 33.8% was shown. Since then the 3P% was on a lower level (32.7%-37.3%).

The least percentage of points from 3PM/total points (3PP/TP) was observed in 1985 (13.7%) and the highest value in 2007 (30.3%). Great rises of 3PP/TP were recognized in 1987 (5.6%) and 1999 (4.9%).

Discussion: The low number of 3PA and 3PM at the EC 1985 may be a consequence of the 3-point rule introduction in 1984. At this point players and teams weren't well enough trained technically and tactically. The high increases of 3PA and 3PM in 1987 was a precondition for the rise of 3PP/TP at the same time and could be considered as a result of the training progress. The rise of these values from 1985 to 1987 can be interpreted as a fast integration of the 3FG in the offensive tactics. The fact that the 3P% raised until 1991 emphasised this assumption.

Different strategic directions on defence and offence should be considered as a reason for the decrease of the 3P% from 1993 to 1997. They could also be responsible for the increased 3PP/TP in 1999 and the fact that in 1999 25% of the total points and in 2005 28% of the total points were made by 3FG.

The rise of 3PA and 3PM in 2001 can be explained by the increased number of total field goal attempts and number of total 3PA in consequence of the reduced possession time in offence to 24 sec.

Further studies should be conducted examining the effects of the development of the 3FG on other events and after the introduction of the new distance between basket and 3-point line in October 2010.

SERVE EFFICIENCY IN MEN'S VOLLEYBALL

HÄYRINEN, M., LAHTINEN, P., MIKKOLA, T., HONKANEN, P., PAANANEN, A., BLOMQVIST, M.

KIHU - RESEARCH INSTITUTE FOR OLYMPIC SPORTS

The importance of the serve is high in men's international top volleyball. The players use mainly six different serve techniques: jump serve (JS), short jump serve (SJS), jump float (JF), short jump float (SJF), float (F) and short float (SF). The purpose of this study was to evaluate the efficiency of different serve techniques in men's volleyball at three different levels: boy's youth national teams, Finnish men's league teams and men's national teams.

Serve efficiency was analyzed in nineteen matches. Eight were boy's youth national team matches (G1, 1089 serves), five men's Finnish League matches (G2, 1033 serves) and six men's World League matches (G3, 1016 serves). A six-point assessment scale was used to evaluate the efficiency of the serves (5 = ace, 4 = no attack from the opponent team, 3 = opponent can use only high ball attack, 2 = opponent can use first tempo attack with a small risk, 1 = opponent can use all attack options, 0 = error).

The serve technique distribution and the means and S.D. for serve efficiency for different serve techniques and groups were calculated. T-test for independent samples was used for statistical analysis. Also ace-error ratios, ace, positive (proportion of level 3-5 serves) and error percentages for every serve technique were calculated.

The proportions of different serve techniques for G1 were JS 42.1 %, SJS 2.7 %, JF 49.7 %, SJF 3.3 %, F 2.0 % and SF 0.2 %, for G2 53.5 %, 4.6 %, 29.6 %, 3.8 %, 7.5 % and 1.0 % and for G3 64.7 %, 4.2 %, 23.0 %, 5.5 %, 2.6 % and 0.0 %, respectively.

The serve efficiency for JS was G1 1.78±1.50, G2 1.68±1.49 and G3 1.81±1.47, for SJS G1 1.72±1.28, G2 1.65±1.26 and G3 2.02±1.42, for JF G1 2.14±1.33, G2 1.85±1.10 and G3 1.85±1.04, for SJF G1 1.64±1.27, G2 1.69±1.17 and G3 1.57±1.06 and for F G1 1.73±1.20, G2 1.97±1.25 and G3 1.77±0.86. The efficiency of JF was significantly ($p<0.01$) higher for G1 than for G2 and G3. In G1 JF was significantly more efficient than JS ($p<0.001$) and SJF ($p<0.05$).

The two highest ace-error ratios were for G1 F 1.00 and JF 0.83, for G2 F 1.33 and JF 0.47 and for G3 SJS 0.75 and JF 0.50. JS and SJS had the two highest ace percentages in every group, G1 5.7 % and 3.4 %, G2 6.7 % and 4.2 % and G3 5.3 % and 7.0 % and also the two highest error percentages, G1 23 % and 17 %, G2 26 % and 17 % and G3 22 % and 9 %. The two best positive percentages were for G1 JF 43 % and JS 35 %, for G2 F 35 % and JS 31 % and for G3 JS 36 % and SJS 33 %.

JS and JF were two most used serve techniques. Nevertheless the use of different serve techniques differs between these three groups so that JS was used more and JF less when the level of the game was higher. JF was the proportionally most used and most efficient serve technique in G1. In G2 and G3 JS was the most used technique and it was also quite effective, but it had highest error percentage. So the high use of JS can be explained partly by the target to score direct points by ace serves.

ADJUSTING REGRESSION STATISTICS TO ASSESS VALIDITY OF MEASURES IN DIFFERENT POPULATIONS

HOPKINS, W.

AUT UNIVERSITY

All concurrent validity studies and most method-comparison studies have a criterion (gold-standard or high-quality) measure for assessment of another measure, but there is widespread lack of understanding about the best approach to such assessment. The limits-of-agreement approach assesses interchangeability of two measures, but it provides no rationale for choosing the better measure; moreover, the systematic lack of agreement known as proportional bias that is often apparent in the Bland-Altman plot (of difference vs mean of the measures) can be artifactual. Amongst regression approaches, least-squares analysis with the criterion as dependent variable provides the most useful statistics: the calibration (regression) equation and standard error of the estimate help practitioners interpret individual measurements taken with the other measure, and researchers can use the correlation coefficient to adjust the magnitude of effects involving the measure. However, values of the regression statistics can be used directly in these ways only when the sample in the validity study is representative of the population in the clinical, practical or research setting. I have now derived formulae to adjust the values for other populations.

I based my approach on the following assumptions: there is a linear relationship between the criterion and other measure; uniform random error in the other measure contributes to scatter in the relationship between the measure and the criterion; and any random error in the criterion is uniform and known. The data from a validity study of one population then allow estimation of the random error in the other measure, from which one can derive the calibration equation, standard error of the estimate and correlation coefficient that would apply to a population with a different mean and standard deviation of the criterion or the other measure.

One can also derive the standard error of the estimate that would apply to a population with the widest possible range of values (infinite standard deviation). This error is appropriate for comparing validity of measures studied with samples from different populations, especially when the measures are in different units (e.g., body fat from a criterion four-compartment model regressed against measures of skinfolds, body density, or bioimpedance). The calibration equation for this imaginary population is appropriate for assessing proportional bias when the criterion and other measure are in the same units. Researchers can also adjust the regression statistics to a real reference population to compare measures.

I simulated validity studies with a spreadsheet to check that the formulae for all adjusted statistics are correct. The formulae are too complex for analytical derivation of confidence limits, but bootstrapping will provide robust estimates. Use of these adjusted statistics and their confidence limits should improve understanding and application of validity in research and practice.

CONTENT VALIDITY AND INTERNAL CONSISTENCY OF SELF-ASSESSMENT QUESTIONNAIRE FOR CLIMBING ABILITIES

CHAN, W.K., HORST, E.J., CHENG, Y.Y., NG, J.

1,3,4. THE CHINESE UNIVERSITY OF HONG KONG, 2. MILLERSVILLE UNIVERSITY , USA

Content validity and internal consistency of self-assessment questionnaire for climbing abilities

Introduction: The questionnaire of Self-assessment for climbing abilities was designed by Eric, J. Horst (Horst, 2008) in which eight components are included, they are climbing experience, technical skills, mental skills, general conditioning, sport-specific conditioning, injury risk, nutritional habits, and lifestyle and discipline. There is no measurement tool to evaluate sports climbers' climbing abilities in Asia. This study investigated the content validity and internal consistency, reliability of Eric's Self-assessment for climbing abilities questionnaire for Hong Kong sports climbing participants regarding their perception on their climbing abilities.

Research Methods: The Chinese version of the questionnaire was translated by the research team and which has been assessed by five climbing coaches in order to check the validity. Only some wordings of the questionnaires have been amended after the assessment. The questionnaire was distributed to Hong Kong sports climbing participants in different climbing association and sports climbing athletes in Hong Kong Youth team and the 2008 interschool competition participants. 106 questionnaires have been collected.

Results: 1) This research invited five experienced climbing coaches evaluated the meaning of the translated questions, in order to conduct a content validity analysis. One of the questions which related to the perception on participants' bouldering scale level has been set to answer one more question which made sure that the participant knowing the meaning of bouldering scale.

2) The internal consistency for reliability test as revealed from Cronbach's Alpha indicated that the eight skill components received poor to acceptable internal consistencies (r=0.17 – 0.77).

3) Only scores from two subscales had acceptable internal consistencies: Climbing experience = .77, Technical skills = .75. Scores for other subscales had rather weak internal consistencies: Mental skills = .36, General conditioning = .54, Sport-specific conditioning = .61, Injury risk = .17, Nutritional habits = .45, Lifestyle and discipline = .46. The low alpha values provide preliminary evidence that some items in these subscales might be problematic.

Conclusions: It is concluded that some of the components in the Self-assessment for climbing abilities questionnaire demonstrated statistic and problematic design by the use of Hong Kong climbing participants by the finding of this pilot research. This research has suggestions for questionnaire modification.

SOMATOTYPING OF BODY MEASUREMENTS OF 13–15-YEAR-OLD ESTONIAN ADOLESCENT MALE VOLLEYBALLERS FOR COMPARATIVE ASSESSMENT OF THEIR PERFORMANCE IN THE GAME

STAMM, M., STAMM, R.

TALLINN UNIVERSITY

Introduction: The subjects of the study were 198 male volleyballers, aged 13–15 years, whose teams participated in Estonian championships between the eight best teams in 2005, 2006 and 2008.

Methods: Thirteen body measurements were taken: height, weight, suprasternal height, xiphoidal height; chest, waist, hip, wrist, upper thigh and lower leg circumferences, arm circumference flexed and tensed and wrist breadth.

As a classification representing the body as a whole, we applied a classification that was based on the mean height and weight of boys of different ages and the respective standard deviations. At first, a bivariate 3×3=9 SD classification of height and weight was created; later the number of classes was reduced to five SD classes.

During all the matches, the boys' individual performance was recorded by the computer program Game (Stamm et al., 2000). The assessment of players´ proficiency proceeded as follows: during the match, the expert registered each case when a technical element (serve, reception, block, feint, attack or dig) was performed by a player.

Results: The principle for forming the classes was to differentiate between the boys according to concordance or disconcordance between height and weight. The following classes were created: (1) small – small weight and small height; (2) medium – medium weight and medium height; (3) big – big weight and big height; (4) pycnomorphs – big weight, small height; (5) leptomorphs – small weight, big height. Boys were placed into classes according to their individual heights and weights. All the other body measurements showed essential systematic differences between the classes. This classification has been acknowledged in C. Raschka's monograph Sportanthropologie (2006) as an innovative Estonian system in sports and constitutional typology (Raschka 2006). The boys´ proficiency in the game was assessed in the same body build classes. For each class the mean index of proficiency was calculated for serve, reception, attack and block performances.

Discussion: There are significant differences in proficiency between body-build classes. Big and leptosomic boys were found to be the most successful. The least successful were the boys of the small class. The boys in class 3 (big) were the most successful in block and attack. Leptosomic boys were the most successful in serve.

MEASUREMENT ERROR ASSOCIATED WITH PERFORMANCE TESTING IN WELL-TRAINED CYCLISTS; APPLICATION TO THE PRECISION OF MONITORING CHANGES IN TRAINING STATUS.

LAMBERTS, R., SWART, J., WOOLRICH, R.W., NOAKES, T.D., LAMBERT, M.I.

UNIVERSITY OF CAPE TOWN

Background: Small changes in performance, as low as 1%, are regarded as meaningful in well-trained cyclists (1,2). Being able to detect these relatively small changes is necessary to accurately prescribe training and optimize performance. The typical error of measurement (TEM) in common performance cycle tests is about 2-3% (3). It is not known whether this TEM is lower in well-trained cyclists and therefore whether small changes in performance parameters are detectable.

Methods: After familiarisation, 17 well-trained cyclists were recruited for the study. They were required to complete three Peak Power Output (PPO) tests (including VO2max) and three 40km time trials (40km TT). All tests were performed after a standardized warm-up at the same relative intensity (LSCT) and under a strict testing-protocol.

Results: Fifteen cyclists successfully competed the study and the data of 2 cyclists had to be excluded because of violated the protocol by using a potential performance enhancing drugs (4) and not completing the study. The TEM within the PPO-test was 2.2% for VO2max and 0.9% for PPO, while TEM for the 40km TT was 0.9%.

Conclusion: This study shows that the measurement of PPO and 40km TT time, after a standardized warm-up (LSCT), has sufficient precision in well-trained cyclists to detect small meaningful changes. In contrast the TEM associated with VO2max was too high to be of practical value for tracking performance, and should therefore be interpreted with caution when monitoring cyclists. The findings of this study contribute to a more accurate determination of what should be regarded as a meaningful change in already well-trained cyclists. This will allow a more accurate assessment of the effectiveness of training programs, and possibly narrows the discrepancy between what trainers, coaches and elite cyclists belief to be effective and what scientists can proof to support this conviction.

VIDEO BASED AUTOMATED DETERMINATION OF SPRINTS AND JUMPS IN BEACH VOLLEYBALL

SCHRAPF, N., TILP, M.

INSTITUTE OF SPORTS SCIENCE

Introduction: Detailed analyses of game situations are necessary for the planning and controlling of training and the development of successful game tactics. The aim of the present study is to minimize manual effort in the analysis of sprint and jumping movements. Automated action recognition is exemplarily applied in beach volleyball. Modern video analysis methods are used to generate position data from which sprints and jumps can be detected automatically.

Methods: To test the determination of sprints and jumps from professional beach volleyball athletes, action paths from 22 rallies at the World Tour Tournament 2007 in Klagenfurt were analyzed. By using a tracker based on particle filters the position of the athlete's upper bodies was calculated from video. A further calculation step allowed determining the lower body segments to get the athlete's position at the court (Mauthner & Bischof, 2007; Mauthner et al., 2007). Jumping movements could be detected automatically from calculated movement velocities and their variations in time. Errors in the position data due to jumping movements were automatically corrected by linear interpolation. Sprints (defined as movement velocities > 4.16 m/s) were then detected from the corrected data.

Results: Preliminary results show, that the players execute 0.75 ± 0.64 jumps and 0.27 ± 0.45 sprints per rally. These automated detected jump actions exceed the manual counted by 2.6%, whereas 5.9% false positives and 8.8% false negatives occurred. The detected sprint actions exceed the manual data by 10% derived from 23.1% false positives and 38.5% false negatives.

Discussion: The tests of the described method show the principal possible application of video based techniques for automatic detection of movements like sprints and jumps. However, the amount of tested data still lacks of representative quantity to describe the game structure in beach volleyball. Differences to manually determined values in jump detection are due to inaccuracy of the tracking method, especially from game scenes which are occluded by the net. In the future, improved tracking algorithms combined with adequate filters may significantly improve results. The substantial differences in sprint detection were mainly due to subjective manual assessment of sprint action. The automated sprint detection may objectify results.

MONITORING ACUTE EFFECTS ON ATHLETIC PERFORMANCE WITH MIXED LINEAR MODELING

HOPKINS, W.G., VANDENBOGAERDE, T.J.

AUT UNIVERSITY

There is a need for a sophisticated approach to track athletic performance and to quantify factors affecting it in practical settings. PURPOSE: To demonstrate the utility of mixed linear modeling for monitoring athletic performance. METHODS: Elite swimmers (3 females and 6 males; age 21-26 y) performed 2-8 time-trials in training and 2-7 in competition in the 9 wk prior to and including Olympic-qualifying trials, all in the stroke and distance of the athlete's main event. We included a double-blind, randomized, diet-controlled crossover intervention in which the swimmers consumed caffeine (5 mg/kg body mass) or placebo 75 min before two training trials ≤2 wk apart. The swimmers also knowingly consumed varying doses of caffeine in some other trials and in competitive swims. We used mixed linear modeling of log-transformed swim time to quantify performance in training vs competition, in morning vs evening swims, and with caffeine vs placebo. Predictor variables were coded as 0 or 1 to represent absence or presence of each condition and included as fixed effects. Date of each performance test was included as a continuous linear fixed effect and interacted with the random effect for athlete to represent individual differences in linear trends in performance. Outcomes were deemed unclear if the 90% confidence interval included substantial enhancement and impairment (0.3%). RESULTS: Performance times in the time-trials and competitions were highly reliable (typical errors both 0.8%). Performance time improved linearly by 0.8% (90% confidence interval 0.3% to 1.2%) per 4 wk of training, with individual differences (standard deviation) in the trend of 0.5% (0.4 to 1.2%) per 4 wk. The swimmers performed better in evenings vs mornings by 0.6% (0.1 to 1.1%) and in competition vs training by 1.4% (0.9 to 1.9%). A 100-mg dose of caffeine enhanced performance in time trials by 1.2% (-0.1 to 2.4%) and in competitions by 1.4% (0.3 to 2.5%); each additional 100 mg reduced the benefit slightly by an unclear 0.1% (-0.3 to 0.5%), and the placebo effect was also a slight but unclear impairment of 0.2% (-0.6 to 0.9%). CONCLUSION: Mixed linear modeling is a successful approach for quantifying small changes in performance in a squad of elite athletes whose performance is monitored regularly over a period of several months.

DEVELOPMENT AND STABILITY OF SPORT PARTICIPATION IN MIDDLE AGE

JEKAUC, D., WOLL, A., BÖS, K.

UNIVERSITY OF KONSTANZ

Introduction: In order to explain sport participation in middle age, there is a dominance of social cogni-tive models which try to explain short-term changes in behaviour (e.g. for several weeks or months). In contrast, Levinson's (1986) developmental model represents a productive theoretical framework to describe long-term changes in behaviour. At the centre of this theory is a concept of a life structure which is formed by the individual's environment. The fundamental components of the life structure in middle age are the individual family and work situation (Levinson, p. 6). In this theory, sport activity can be considered as a special form of leisure time which vies for time resources with family, work, and other forms of lei-sure time activities. According to Levinson's theory, changes in life structure cause changes in the constitution of leisure time. The central question of this paper is to investi-gate the hypothesis that life structure has an influence on participation in sport activity.

Methods: To examine this hypothesis, longitudinal data were collected from 726 persons aged be-tween 33 and 56 years (M = 45.0; SD = 7.5). Three measurements were taken in five year intervals (1992, 1997, 2002). In addition to a comprehensive diagnosis of the sport activity behaviour using a self questionnaire, socio-demographic variables, subjective health, in-tentions, family, and work environment were assessed.

Results: The results of the study suggest that on the one hand, sport participation is a stable char-acteristic of human behaviour. The analysis of the finite Markov chains in discrete time shows that the probability for staying active is 91% for the transition from 1992 to 1997 and 89% from 1997 to 2002. On the other hand, the sport participation is unstable because the chance for staying inactive is 59% for the period 1992-1997 and 42% for the period 1997-2002. The results of the logistic regression show that in the process of the adoption of

sport activity, the variables gender, work load, and the number of people living in the household have a significant influence on sport participation. In the process of mainte-nance, work load, health and social status have a significant effect on sport participation.

Discussion: The results of this study support Levinson's (1986) theory which states that the compo-nents of life structure, such as work load and the number of persons in the household, have an impact on sport participation behaviour.

EFFECT OF EXPECTED EXERCISE DURATION ON PHYSIOLOGICAL AND PSYCHOLOGICAL VARIABLES

LINDSAY, T., GAUL, C.

UNIVERSITY OF CAPE TOWN, CAPE TOWN, SOUTH AFRICA AND UNIVERSITY OF VICTORIA, VICTORIA, CANADA

Introduction: Consideration of the end-point of exercise may influence exercise function. Research has shown that runners expecting a longer exercise duration report lower RPE at the same time point as compared to when they expect a shorter duration at the same intensity (Rejeski & Ribisl, 1980; Baden et al,. 2004). This study examined the effect of expected exercise duration on physiological and psychological variables during cycling.

Methods: Twenty trained male cyclists completed a maximal aerobic cycling test and two 20 min bouts at the same submaximal power output (mean=69% VO2max). Subjects were told they would cycle for 20 min in the first bout (short condition) and for 40 min in the second (long condition). This involved deception as the second bout was only 20 min long. Cardiorespiratory variables, lactate, cadence, RPE, % associative thoughts, and affect (Feeling Scale, FS) were measured. Analysis was by Pearson correlations and a repeated-measures ANOVA at 2, 5, 8, 11, 14, 17, 20 min.

Results: The psychological and physiological variables showed no differences between conditions. Physiological response was consistent with non-steady state exercise. RPE increased linearly ($p<0.05$) and ranged from about 12 to 14 in both bouts. Significant correlations between RPE and FS occurred at all time points in the short condition ($r= -0.61$ to -0.79), but in the long condition, correlations were only significant at 2, 5, and 8 min ($r= -0.50$ to -0.68). There were no significant correlations between RPE and any physiological variable or associative thoughts.

Discussion: Expected duration did not alter RPE, which is inconsistent with Rejeski & Ribisl (1980) and Baden et al. (2004). This may be due to a different subject sample using different mental strategies. The significant RPE-FS correlations during the short condition were higher than reported by Rejeski & Ribisl (1980), who found a moderate but significant correlation of -0.45 at a similar intensity and RPE. In the long condition, the RPE-FS relationship ceased to be significant from 11 min onward. Hardy & Rejeski (1989) proposed that ambiguity in physiological cues during moderate exercise lessens the relationship, although it is not clear why this would emerge in one condition only. This may indicate a coping mechanism in response to a greater exercise challenge. As well, the data are consistent with the notion that RPE represents the progression toward absolute fatigue, which may happen independently of the progression of physiological variables (Noakes, 2008). In conclusion, RPE is not always affected by a change in anticipated exercise duration and seems to function as a stable measure of the progression toward exhaustion.

THE EFFECT OF AEROBIC TRAINING AND SELF AS EPISTEMIC AUTHORITY ON BODY IMAGE OF FEMALE STUDENTS

SEGAL, S.

LEVINSKY COLLEGE OF EDUCATION

Study's purpose: to determine the psychological impact of cardiovascular training on body-image in relation with self as cognitive epistemic-authority among adolescent females.

Hypothesis: Generally, improvement in cardiovascular fitness will cause improvement in body-image; however the improvement in body-image will be more significant among subjects whose self-epistemic authority is high, than subjects whose self-epistemic authority is low.

Rationale: Bandura's theory of self-efficacy (1977, 2000) emphasizes personal performance-based experiences, as the most important factor in creating the desirable cognitive and behavioral change. However, experimental findings point to individual differences in the level of behavioral change, achieved by those enactive mastery experiences. The Lay-Epistemology theory (Kruglanski & Jaffe,1988, 2000) suggests a conceptual explanatory schema to individual differences.

Method: After measuring each participant's (N=60) level of self as epistemic-authority we randomly assigned those above/below the median level into one of the three different groups:a full-training running, a half-training walking, and a no-training control group.

The independent variables:1 Self as epistemic-authority (high/low), measured by a questionnaire assessing level of self as epistemic-authority.2.Aerobic physical-fitness training. Full training: running group , half level :walking group.

The study examined the relationship between the independent variables and the dependent variable -a psychological change, a change in body-image.(Conscious & unconscious).

Variables were measured before and after the program.

Main Results: The conscious and unconscious body-image of subjects in the full-training running group, was significantly higher than that of subjects in the half-training walking and the control groups, and the body-image of subjects in the walking group was higher than that of the control group; it also found that conscious and unconscious body-image of the subjects with high self epistemic authority was significantly higher than that of subjects with low self-epistemic-authority.

Conclusion: An improvement in physical fitness brings along an improvement in psychological dimensions. This reinforced Bandura`s statement about the priority of self-actual experiencing in order to attain psychological changes. However, the degree of improvement is dependent on the extent of the subject's reliance on a source, which she perceives as of sufficient epistemic-authority to cause cognitive change.

This support the lay epistemology theory, which deals with the rules governing cognitive change.

EFFECT OF WORKING IN HOT ENVIRONMENT ON COGNITIVE FUNCTION: AN OIL AND GAS INDUSTRY STUDY

GAOUA, N., EL MASSIOUI, F., RACINAIS, S., GIRARD, O., WALSH, A., KNEZ, W., GRANTHAM, J.
ASPETAR, QATAR ORTHOPAEDIC AND SPORTS MEDICINE HOSPITAL

Introduction: Acute exposure to extreme heat can adversely affect safety-related behavior in workers and complex cognitive task performance. Although many studies explored the acute effect of heat on cognitive functions, results remain equivocal. Moreover, little is known of the effect of chronic heat exposure.
Aim: To investigate acute and chronic alterations in cognitive function in outdoor workers during the summer of a Middle Eastern country (Qatar).
Methods: 39 oil and gas workers (32 ± 6 years) volunteered for cognitive testing before and after their daily work shift on two occasions: during summer (August – average daytime temperature: 41°C) and winter (January – average daytime temperature: 22°C). Pattern Recognition memory (PRM), Spatial Span (SSP) and Stocking Of Cambridge (SOC) tests were performed.
Results: Average core temperatures during work shift were higher ($P < 0.001$) in August (37.4 ± 0.2 °C) than in January (37.2 ± 0.2 °C). However, our data showed no significant difference in any of the cognitive tests between summer and winter independent of testing time (PRM: 78.2 ± 17.8 vs 78.8 ± 17.3%, SSP: 6.2 ± 1.2 vs 6.1 ± 1.4, SOC: 8.5 ± 1.4 vs 8.9 ± 1.7 for average values in August and January, respectively). In addition, activity in summer (average normalised acceleration: 0.10 ± 0.01 g) was significantly lower ($P < 0.02$) than winter (average normalised acceleration: 0.11 ± 0.01 g).
Discussion: The reduction of activity during summer (safety rules of the company) can partly explain the absence of alterations in cognitive functions despite a higher central temperature. Consequently, 38.3°C was the highest central temperature observed during a work shift. The fact that none of the workers was hyperthermic during the course of the day could explain the absence of acute effect of heat exposure on cognitive function.
Conclusion: While acute hyperthermia can alter cognitive function, our data suggest that chronic exposure (i.e., living and working) to a hot environment doesn't alter cognitive functions in the absence of hyperthermia.

SHAPING A POSITIVE BODY IMAGE WITH THE OBJECTIVE OF PREVENTING EATING DISORDERS IN FEMALE ATHLETES

RASCHE, F.
UNIVERSITY OF VIENNA

Disordered eating may have harmful consequences on athletes' health and performance. Especially athletes participating in aesthetic or lean sports have a higher risk of suffering from eating-related problems (Torstveit, Rosenvinge, & Sundgot-Borgen, 2008). They believe that losing weight is necessary for aesthetic beauty ideals valued in certain sports (Dosil, 2008). Prevalence of disordered eating in sports is estimated and range as high as 62% among female and 33% among male athletes (Bonci et al., 2008). It is known that athletes are affected due to different reasons, also to sport specific ones. Athletes have a body ideal that is related to improved performances in their sports. Depending to their sport, they could get closer to the societal-prescribed thin ideal (Smith & Petrie, 2008). Hence it can be assumed that a negative self concept and body image are one of the crucial determinants of developing disordered eating. Enforcing a positive body image should be the ambition of programs preventing disordered eating in athletes. Thereto one unit of a six-unit prevention program deals with the development of a positive body image. This section is taking out of a program for preventing eating disorders in young female athletes aged 12 - 16. The body image unit à 90 minutes starts with a warm-up game which is called "Here comes the sun" and continues with a practical exercise called "body landscape". The warm-up game is a back massage that comes along with a story about a tree and the weather going down on it. For the exercise the athletes copy their body contour on a large piece of paper and figure a landscape. Questions like "Where is the capital of your body?" or "Where are recreation areas?" should help them performing the exercise. Afterwards the images will be discussed. Currently, a pilot study with six athletes is carried out in order to test practicability and validity of program content. Results of the pilot study concerning a positive body image are presented and discussed at the conference.

COMPARISON OF HEART RATE VARIABILITY RECORDINGS MEASURED WITH DIFFERENT DEVICES IN CHILDREN

FINKENZELLER, T., AMESBERGER, G.
UNIVERSITY OF SALZBURG

In the field of sport psychology, psychophysiological recordings address the importance to assess athletes' psychophysiological regulation status. In this context, heart rate variability (HRV) as an indicator of sympathetic-vagal balance is supposed to be the most promising tool in the diagnostic process. Besides the recording of parameters like skin conductance, temperature, electromyogram, electroencephalogram and respiration, several biofeedback devices offer the opportunity to record electrocardiograms, and to calculate HRV-parameters. Whereas wireless heart rate monitoring with elastic electrode belts appears to be reliable (Vanderlei, Silva, Pastre, Azevedo, & Godoy, 2008), empirical data on the reliability of biofeedback devices are still missing.

Aim of the study was to compare two simultaneously recorded R-R intervals and the subsequent analysis of HRV, one obtained from the Polar S810i heart rate monitor (co. polar electro), and one deriving from the nexus-4 biofeedback device (co. mindmedia). The R-R intervals of both measurement systems were analyzed with the software kubios HRV version 2.0 (Niskanen, Tarvainen, Ranta-Aho, & Karjalainen, 2004). A total of 25 male pupils (age: 12.24 ± 0.72 yr; height: 1.57 ± 0.07 m; mass: 47.2 ± 9.84 kg) completed a test series which started with a five minute relaxation phase in sitting position, followed by a seven minute ergometer test (2.5W/kg mass), and concluded by another five minute relaxation phase at the end.

For both relaxation phases, satisfactory time-domain correlations between Polar S810i and nexus-4 HRV-data were obtained (r= .80 to .97), whereas the intercorrelations of frequency-domain data display a wide range (r=.17 to .95). HRV-parameters recorded during the ergometer test, and hence reflecting physiological stress, demonstrate low correlations concerning time-domain (r=.09 to .40) and frequency-domain (r=-.02 to -.60). Kubios HRV-software analyses confirm these results with moderate to high time-domain correlations (r=.71 to .99), and low to high frequency-domain correlations (r=.46 to .97) between polar and nexus-4 data during relaxation. Additionally, HRV-parameters during physiological stress show low to moderate correlation values (r=.05 to.73).

In sum, the Nexus-4 biofeedback device seems not to be appropriate for the recording of R-R intervals, and the subsequent analysis of HRV in physical stress conditions. It is recommended to use scientific software for the analysis of HRV, such as kubios HRV.

BODY IMAGE PERCEPTION OF BRAZILIAN SAILORS' ATHLETES

OLIVEIRA, F., RENAN, R.C., AMEXOEIRA, M.F., SILVA, D.S.

FEDERAL UNIVERSITY OF RIO DE JANEIRO

Introduction: Social pressures and/or the search for a better physical performance in sports may cause the dissatisfaction with body image (BI). In some sports where the beauty, the lightness or a low body weight may contribute to the best performance, the perception of the BI can be change. Objective: The main of this study is analyzing the sailor's athletes BI satisfaction and the perceptual of Body Fat. Material and Method: Seventeen sailors athletes were evaluated (18.3±7.4years) and 12 young non-athletes (control, 19.50±1.78years). The body composition was measured by the anthropometric method (International Society for Advancement in Kinanthropometry - ISAK). The items measured were: skinfold thickness (Cescorf calipers, 0,1mm); height (stadiometer, 1mm) and total body mass (electronic scale, 50g). The body density was obtained by the Withers et al. (1956), and the relative body fat was estimated by the Siri equation (1961). The degree of satisfaction with the BI was obtained by the Body Shape Questionnaire (BSQ) with a version translated and validated to Portuguese langue. The statistical analysis was done on Microsoft Excel 2000. Data is expressed by occurrence percentage, averages, standard deviation. The Pearson correlation test was applied to check the relation among BI and %BF and the group similarity was done by t-Student test. The Ethics Committee of the Clementino Fraga Filho Hospital-UFRJ approved this study and all the parents signed an informed consent from agreeing to the procedures to be adopted and authorizing the scientific use of the study results, as required by the Brazilian Health National Board regulation nº 196/96. Results and Discussions: The athletes showed similar results (p>0.05) to the non-athletes for, age (p=0.53), total body weight (p=0.29), height (p=0.11) and body fat (%BF, p=0.79). One should highlight the significant number of interviewees that presents no BI dissatisfaction, fact that does not prevents a concern with the existence of results showing light dissatisfaction (athletes=24% control=33%), mild dissatisfaction (athletes=6% control=8%), and severe dissatisfaction (athletes=6% control=0%). There was a positive correlation between the result of BI dissatisfaction and the higher %BF (athletes=0.65; non-athletes=0.58), which might not be explain changes in BSQ because the %BF levels was classified as the expected standard in terms of gender and age. Conclusions: The normal %BF presented in the tow groups analyzed is not a justification of the BI dysfunctions detected. The BI dissatisfactions needs to be fighting off in the sports environment and among young people because, in general, it is precursor of the eat disease.

THE ROAD TO EXCELLENCE: EXPERT PERFORMANCES IN TENNIS AND ALPINE SKIING

MARCONI, M., CONZELMANN, A.

UNIVERSITY OF BERN

Introduction: Within different domains (e.g. music) Ericsson (1996) described the „road to excellence". Taking this expertise research into consideration, the career path of top-performance ath-letes in tennis and alpine skiing were analysed in two different studies with a retro-spective approach. The career in sports is viewed as part of the entire life-course (Mayer, 1990) that embraces various careers in (individual) fields of life. The sports career is em-bedded in the top-performance sports system but also involves a certain dependency on other aspects of life (e.g. family, profession).

Methods: The data was collected by postal enquiry. The questionnaires, adapted to the different characteristics of tennis and alpine skiing, were sent to active and former athletes (tennis: n=70; alpine skiing: n=51). These include questions concerning activities and incidents in various areas of life, particularly sports, but also family and education / profession.

Results: Certain steps from one to the other period in a career in sports can vary considerably, for example 'age at the beginning with sports' (tennis/alpine skiing: mean=6.9/3.4, range=3-12/2-7) or 'age at the beginning with adult competition' (tennis and alpine skiing: mean=15.4, range=13-18). The individual career paths show partly distinct differences compared to the career path intended in the talent development programmes, diverse chronological sequences in performance development and gender-specific charac-teristics. Com-

pared to less successful athletes, top athletes have a higher rate of development and, from the beginning of their career, increased training units close to competition.

Discussion: The talent development programmes should consider the individuality of the career paths as well as the gender-specific aspects. Furthermore, it is recommended that the rate of development is determined by testing the athletes over time. Finally, the specialisation in the specific kind of sport should start as early as possible.

THE MODERATING EFFECTS OF GENDER AND SPORT TYPE ON THE RELATIONSHIP BETWEEN CONFIDENCE TO AVOID DRINKING AND BINGE DRINKING IN SPORTS SCIENCE STUDENTS

OH, H.J., TAYLOR, A.H.

UNIVERSITY OF EXETER

Introduction: Binge drinking (ie, ≥ 5 drinks per occasion) is a major health issue among student populations, particularly for males in team sports (Brenner & Swanick, 2007). Confidence to inhibit drinking in different situations is negatively related to excessive drinking (Oei & Morawska, 2004), and alcohol awareness campaigns seek to build avoidance self-efficacy (A-SE). However, it is not known if this relationship is consistent for male and females, and athletes in different sports. In this study we examined the moderating effects of gender and sport type (team, individual and non sport participation) on the relationship between A-SE and binge drinking.

Methods

First year undergraduate sports science students (N=354; 54% male), completed questionnaires to assess sport participation, A-SE, using the revised (multi-scale) Drinking Refusal SE Questionnaire (in different situations)(DRSEQ-R)(Oei et al., 2005), confidence to avoid alcohol (CTAA)(0-100% over 1-2, 3-4,…13-14 days)(Bandura, 2006) and binge drinking.

Results: Multiple regression analysis indicated that DRSE under social pressure scale (β=-.13, R^2=.21, p<.01) was the main predictor of binge drinking and was not moderated by gender and sport type. However, the DRSE in opportunistic situations scale (β=-.01, R^2=.31, p<.05) and confidence to go without drinking for 13-14 days (β=-.05, R^2=.33, p<.05) were found to be significant predictors of binge drinking for male, but not for female students. CTAA for 13-14 days predicted binge drinking for team sport and non-sport participating students, but didn't for those in individual sports.

Discussion: This is the first study to exam the moderating role of gender and sport type on the relationship confidence to restrain from drinking in different situations and binge drinking. Male sports science students with low A-SE to avoid drinking, particularly with others, and also when it is readily available, are more likely to binge drink. Interventions could be targeted at increasing A-SE in social and opportunistic situations to prevent binge drinking. In contrast there was only support for targeting interventions at increasing A-SE in social situations for females. Interventions targeted at increasing A-SE in social situations appear as relevant for team, individual and non sport students. Males, and team and non-sport participants, appear more susceptible to binge drink if they have less confidence in prolonged abstinence.

EFFECTS OF A COGNITIVE-BEHAVIOURAL INTERVENTION PROGRAMME ON THE ANXIETY LEVEL AND PERFORMANCE OF GYMNASTS IN A COMPETITIVE ENVIRONMENT

SMYTH, P., MASTERSON, L., KEARNEY, P.

UNIVERSITY OF LIMERICK

Introduction: This study arouse out of the concern of a gymnastics coach that her gymnasts were underperforming in competition due to anxiety. The purpose of the study was to assess the effects of a cognitive-behavioral intervention programme on performance, anxiety and confidence in the competitive sport environment.

Methods: Ten female gymnasts aged 12-17 yrs were pre-tested in a competitive sport environment for state anxiety and self confidence on the CSAI-2 test (Martens et al., 1990) and on balance beam performance. The competitive environment included an audience made up of parents, gymnasts, "march on" music and two qualified judges who scored performances. At a gymnastic camp on the following week all gymnasts underwent training which included practice on the balance beam. In addition half of the group underwent cognitive-behavioral training based on Suinn's (1994) visual motor behavior rehearsal (VMBR) programme. The other half of the group did not undergo this training and acted as a control. VMBR combines muscle relaxation, controlled breathing and use of mental imagery to visualise a relaxed scene, a successful competition scene previously experienced and an upcoming competition scene. As manipulation checks, gymnasts were asked to rate clarity of images, levels of relaxation and the feel of imaged movements. They were also asked to practice the procedures at home and to record comments in a log which would be discussed at the beginning of the next session. Participants were retested at the end of the week and again one week later (retention) in the same competitive environment as the pre-test.

Results: The intervention group showed significant improvements in performance on the balance beam along with reduced cognitive and somatic anxiety and increased confidence. The control group showed no improvements in performance and no changes in anxiety and confidence.

Discussion: The findings provide support for the effectiveness of a psychological intervention programme for controlling anxiety and enhancing confidence and performance in competitive sport situations. There is also support for incorporating psychological training into the physical practice of skills and for involving young performers more intimately in their psychological training. One limitation of the study however is that the possibility of a placebo effect was not controlled for.

THE EFFECTS OF GENDER AND SPORT PARTICIPATION ON CONFIDENCE TO AVOID DRINKING AND BINGE DRINKING

OH, H.J., TAYLOR, A.H.

UNIVERSITY OF EXETER

Introduction: Binge drinking (≥5 drinks per occasion) is common among students (Ham & Hope, 2003), and particularly team sportsmen (Brenner & Swanick, 2007), from mostly North American evidence. Although avoidance self-efficacy (A-SE) is an important determinant of drinking behaviour (Oei & Morawska, 2004) less is known about if gender and sport type influence A-SE. Our aim is to examine if binge drinking and A-SE differ by gender and sport type (team, individual and non sport participation) in a UK sample.

Methods

First year undergraduate sports science students (N=354; 54% male; 48%, 17% & 35% in team, individual and no sport), completed questionnaires to assess sport participation, A-SE, using the revised (multi-scale) Drinking Refusal Self-Efficacy Questionnaire (in different situations)(DRSEQ-R)(Oei et al., 2005), and binge drinking.

Results: Chi2 analysis revealed no differences between males (62%) v females (55%), or team (59%) v individual (53%) v non (62%) sport participants binge drank on 4 sessions in the past 30 days. A 2-way ANOVA revealed a significant interaction effect of sport type and gender on binge drinking, $F(2, 348) = 3.31$, $p<.05$.and main effect of sport type $F(2, 348) = 3.59$, $p<.05$. Non-sport students had more binge drinking sessions than the other groups. Team sportsmen reported more binge drinking sessions than those in individual sports, but female binge drinking was consistent across sport type. Across sport types, females in individual sports were more likely to binge drink than males. A 2-way ANOVA also revealed a significant interaction effect of sport type and gender on DRSEQ for emotional relief, $F (2, 348) = 3.06$, $p<.05$, and a main effect of sport type, $F (2, 348) = 6.98$, $p<.01$. Overall, the non-sport group (particularly males) had the least A-SE for emotional relief and the team athletes had the highest.

Discussion: The findings differ from previous studies (Brenner & Swanick, 2007) and indicate a worryingly similar prevalence of binge drinking for males and females, which may be specific to the UK and sample. Only male (not female) team sport participants binge drink more than those in individual sport. Overall, sport participants appear to do less binge drinking than non sport students, especially among males. In situations in which drinking may provide emotional relief, non sport males students had least confidence to avoid alcohol, and those in team sports had the highest. The findings add to our understanding of how sport impacts on binge drinking.

TEAM COHESION AND USE OF MENTAL IMAGERY IN A GROUP OF TURKISH SOCCER PLAYERS

KIRAZCI, S., MICOOGULLARI, O.

MIDDLE EAST TECHNICAL UNIVERSITY

There has been intense body of literature on team cohesion and its relationship with different variables. However, the relationship between team cohesion and use of mental imagery on soccer players has drawn less attention in the literature. Although team cohesion and use of mental imagery have been seen critical for successful psychological performance for athletes; these two concepts have generally been studied separately in most of the studies. Therefore, purpose of the present study was to investigate the relationship between team cohesion and use of mental imagery in a group of Turkish soccer players.

Group Environment Questionnaire (GEO, Carron, Widmeyer, & Brawley, 1985) and Sport Imagery Questionnaire (SIQ, Hall, Mark, Paivio, & Hausenblas, 1998) were administered to a sample of 199 Turkish male soccer players.

Mean age of participants and their sporting year were 25.62 (SD=2.44) and 6.78 (SD=2.67) respectively. Descriptive statistics was used for the GEO & SIQ subscales of the participants. Pearson product moment correlations and multiple regression analysis were used to assess correlations among subscales of GEQ namely; individual attractions to the group as task, individual attractions to the group as social, group integration as task, and group integration as social and SIQ namely; cognitive specific, cognitive general, motivation specific, motivation general-arousal, and motivation general-mastery.

Results revealed that means of individual attractions to group-task, individual attractions to group-social, group integration-task, and group integration were 23.05 (SD=5.9), 22.97 (SD=4.71), 22.82 (SD=6.77), and 20.26 (SD=5.58), respectively. Moreover, the means of cognitive specific, cognitive general, motivation specific, motivation general-arousal and motivation general-mastery subscales of SIQ were 49.35 (SD=8.95), 28.11 (SD=6.66), 18.72 (SD=5.54) and 18.06 (SD=3.13) respectively. Results of correlation analysis revealed no significant relationships among team cohesion and use of mental imaginary subscales

Results were discussed in relation to studies conducted in Turkey and in other countries.

HORSE-RIDING, EMOTIONAL INTELLIGENCE AND FIELD-DEPENDENCE

LABORDE, S., OLIVIER, A.

1. UFR STAPS, UNIVERSITY OF CAEN, FRANCE, 2. GERMAN SPORT UNIVERSITY, COLOGNE; GERMANY

Horse-riding, emotional intelligence and field-dependence

Introduction: Intelligence (EI), representing the way people manage their own emotions and others' emotions, may be moderated by the perceptive style, as measured by the degree of field-dependence. This relationship was investigated in horse-riding, an activity in which emotions are predominant, especially concerning the affectivity between the rider and the horse; and where the perceptive style is a key to understand rider's behavior.

Objectives: This study is aimed to know if near-expert horse riders with high trait EI rely more on external or internal cues to process information, which can be measured by field-dependence.

Methods: First EI of French near-expert horse riders (N=50) was assessed by the French version of the TEIQue (Trait Emotional Intelligence Questionnaire, Mikolajczak, Luminet, Leroy, & Roy, 2007). Extreme scores were selected, and two groups were constituted, high trait EI (n=18) and low trait EI (n=18). Field-dependence of these participants was then assessed by the Rod-and-Frame Task (Witkin & Asch, 1948).

Results: An ANOVA was performed with 2 independent variables, gender and EI, and one dependent variable, field-dependence score. A gender effect was found: female horse riders are significantly more field-independent than male horse riders ($F(1; 32) = 20.058$; $p<.0001$). The interaction effect between gender and EI was significant ($F(1, 32) = 6,075$; $p<.05$). Further mean comparisons were processed; high trait EI male horse riders are significantly more field-independent than low trait EI male horse-riders ($F(1; 14) = 4.63$; $p < .05$); whereas high trait EI female horse-riders have a tendency to be more field-dependent than low trait EI female horse-riders ($F(1; 18) = 1.66$; $p < .25$).

Discussion: The relationship between EI and field-dependence in horse-riding appears to be gender specific; high trait EI male relying more on bodily cues, and high trait EI female having a tendency to rely more on contextual cues. These findings can explain the differences in managing horse's emotions, and one's own emotions in competition. Further research is needed to explore the influence of EI and field-dependence in horse-riding performance, with the necessity to take into account gender differences, as underlined by this study.

THE EXAMINATION OF THE EFFECT OF CHANGES IN PRACTICE VOLUME ON THE PROFILE OF MOOD STATE AND PHYSICAL FUNCTIONING IN ADOLESCENT GIRLS WHO PLAY KARATE

MUSAVI SETARE, MATINHOMAEE, H.

ISLAMIC AZAD UNIVERCITY CENTERAL BRANCH OF TEHRAN

Purpose:The present study aimed at examination of the effect of changes in practice volume on the profile of mood state and physical functioning in adolescent girls who play karate

Material and method:45 adolescent girls who played karate with the average of age 13.05+3.21,height 150.92+11.31 and weight 44.12+10.57 who had constant practice for at least 2 years, after initial test and receiving letter of satisfaction were selected as testees for this research. First,during a session,goals and total measures which will be performed were elucidated for testees and while receiving the written letter of satisfaction from testees' parents,in the beginning mood were measuredThese statistics of the course,factors of speed,agility,aerobic power,technical functioning and mood were measured.These statistics were considered as witnesses.During the first week,the testees with approximate pressure of 20% for 3 days a week were practicing.Then during the second week,the pressure of practice volume increased to 40% and for 4 days a week,practicing continued.During the third week,the pressure of practice volume reached 70% and for 5 days a week practice was prolonged.In the forth week,the pressure of practice volume was 100% and practice was conducted for the 7 days of the week.

At the end of this stage , various tests of augmentation of practice volume were performed.During the fifth week,the pressure of practice volume was decreased to 30% and practice continued within a period of 2 days a week.At the end of this stage ,diminution of practice volume was tested.During the sixth week,practice discontinued completely.After 2 weeks of stopping practices,examinations were redone at this stage.For hypotheses testing and answer finding,statistical model of analyzing of variance variable (ANOVA) with repeated measurements was used.

A significant level existed in the whole stages($p<0.05$).

Results:The first finding indicated that changes in practice volume leads to meaningful change in anaerobic power.This alteration at the time of augmenting practice volume was significant.

Agility was influenced by alterations in practice volume and after the period of augmenting practice volume,agility decreased significantly.This diminution continued to the end of this period but the most diminution was related to the period of augmentation of practice volume.Only after increasing practice volume,was aerobic power of testees increased significantly.But technical functioning of testees' hands had meaningful augmentation from the beginning to the end of this period and the most rate of alteration was observed during diminution of practice volume and during stopping practices.only after the period of alterations,was technical functioning of feet increased and this alteration was meaningful after the period of increasing practice volume.In spite of the observed alterations in six mood elements and total mood disorders,any meaningful difference was not observed in none of elements and measurement times.

SUBJECTIVITY IN SPORT: THE IMPACT OF THE COACH'S SUBJECTIVITY IN ONE TRIATHLON TEAM CONSTITUTION

DOBRÁNSZKY, I.
UNIVERSIDADE DE SÃO PAULO

The Sport Psychology researches have been analyzing the process of group communication on a one-way direction, not considering the athlete as an active individual, where his/her behavior is a direct result of the incentives presented by the environment. It is believed that understanding the productions of the subjective senses and how the communication processes in a sporting team are organized is relevant to comprehend the subjective configurations - both of the group subjectivity and of the athletes individually. Both subjectivity forms go through processes of constant transformation striving for a balance that considers the individual and group needs simultaneously. The present study has as objective analyzing the relation and the production processes of subjective sense between coach and athletes of a triathlon team considering 1) the organization of the team communication processes, i.e. to understand the athlete-team, athlete-athlete, coach-team, coach-athlete relationships; 2) the understanding of the group climate and how it affects the athletes' subjectivity; 3) and how these processes influence the sporting performance. This study emphasizes the constructive-interpretative and dialogical character of the knowledge, based on González Rey's interpretation of qualitative research. The field research comprised a five-month follow-up of 8 athletes of a triathlon team and their coach in a countryside town of the state of São Paulo that participate in regional, national and international competitions. For the accomplishment of this study the tools used were: conversational dynamics, term used to emphasize the procedural and open character of the relationships with the participant; complement of sentences, which allowed acquiring information about the production of sense of the individual; and a field diary. The tools supplied subjective sense indicators which, in our analysis, led us to the construction of the following subjective senses nuclei: 1) the impact of the coach's subjectivity on the team constitution; 2) the competitive moment and its influence on the team subjective configuration; and 3) the interference of the family on the athlete's subjective formation. The impact of each one of those subjective sense nuclei on the athlete and the team were the main results of this research, which mainly concluded that the coach's production of subjective sense had strong influence in the communication process among him and the athlete, the team, and the athlete's family. The coach's dispute for the attention and recognition of the direct and indirect participants created an atmosphere of intra-personal competition that generates individualism, jealousy and envy. When those indicators are associated with others present in the competitive atmosphere, such as the winner's exaltation, the depreciation of the defeated and the promptness they configure a social subjectivity which represents the contemporary society.

THE INFLUENCE OF EFFORT TYPE ON THE PLASMATIC CHOLESTEROL LEVELS FOR ELITE ATHLETES

ALEXANDRESCU, L., BUHOCIU, E.
SPIRU HARET UNIVERSITY

Introduction: During the longer term effort (anaerobic type of effort, with preponderant isotonic component), the muscle mostly uses fatty acids. Consequently, the concentration of fatty acids in the blood, decreases during the effort, and starts increasing right after the effort's cessation, in order to prepare the energetic background of later efforts. The purpose the present work is to study the total cholesterol variations in the blood of athletes who perform the isometric type of effort, effort limited in time by its maximal intensity, the muscular metabolism being mainly anaerobic.

Methods: The analyzed groups of athletes were selected based on the type of effort required by various sports. This selection was justified by the characteristics of sports with a predominant isometric component, which determine a specific body composition, influencing the plasmatic values of total cholesterol. These values are also determined by the structure of the training sessions and the feeding of the athletes, with the purpose to increase the force and/or muscular mass.

Results and Discussions

Based on this study on professional athletes, we can draw a few conclusions applicable to the general population, regarding the best fitted type of effort for each individual, depending on the functional parameters, age, body type and possible associated diseases:

- effort must be sustained by a proper diet: in sports with significant body development and muscular mass increase, the effort has to be supported with protein and glucidic aport, whereas in sports with a mainly aerobic effort, we recommend a predominant glucidic support.
- athletics with a predominant aerobic component, performed at a moderated or sub maximal intensity, with cardiac frequency monitored, are recommended to anyone irrespective of age, if there are no particular medical restrictions.
- for hypercholesterolemia prevention, continuous efforts are recommended, with a duration of 30-40 minutes, adapting their intensity to the training level and effort tolerance of each individual.

COMPLEMENTARY OR CO-ACTIVATIVE SYNERGISM AMONG THE TRICEPS SURAE MUSCLES DURING PROLONGED PLANTAR FLEXION

KIRIMOTO, H.

NIIGATA UNIVERSITY OF HEALTH AND WELFARE

Introduction: During prolonged isometric contractions at low workloads, a unique kind of neuromuscular regulation activity called, "alternative activity," is known to dramatically increase and decrease activity levels among synergistic muscles, almost throughout the whole muscle unit (Tamaki et al, 1998, Kirimoto et al, 2006). Although the complementary activity among such synergistic muscles is believed to be purposive neuromuscular regulation for maintaining uniform joint torque over a long period of time, the mechanism of occurrence is not well understood. Therefore, the aim of this study was to investigate the relationship between "common drive" (De Luca and Erim, 1994) from the central nervous system (CNS) and the synergistic behavior of the triceps surae muscles during sustained isometric contraction.

Methods: Nine human subjects performed isometric sustained contraction at an ankle joint angle of 110° plantar flexion under constant load (10% of maximal voluntary contraction) for 60 min. Simultaneously, surface electromyographic (EMG) data were obtained from the lateral gastrocnemius (LG), medial gastrocnemius (MG), and soleus (SOL) muscles. The surface EMG signals ware recorded with active parallel-bar (1 by 10mm in size and located 10mm apart) differential electrodes. The synergistic behavior of the triseps surae muscles were assessed cross-correlations of the mean EMG between three muscle combinations: LG-MG, LG-SOL and MG-SOL.

Results: When the data were divided into 1-min blocks, the partial correlation data revealed that LG-SOL correlated over the period of the contraction, suggesting the presence of co-activation synergism. In contrast, LG-MG demonstrated a tendency toward the complementary synergism (Rxy (0) < -0.7). The short duration central peaks in the cross-correlogram were seen in approximately 80% of co-activation synergism period (Rxy (0) > 0.7), however, central peaks were seen in only 8% of complementary synergism period (Rxy (0) < -0.7).

Discussion: These results suggest that the motoneuron pool of LG and SOL are modulated by common drive from the CNS in the co-activation synergism period. The finding that few central peaks were seen the complementary synergism period mainly in LG-MG suggests that complementary activities of synergists are related to the modulation from peripheral afferents rather than the CNS.

EUCAPNIC VOLUNTARY HYPERPNOEA TESTING WITH THE NEW EUCAPSYS DEVICE IN TRAINED AND UNTRAINED FEMALES

KIPPELEN, P., BOLGER, C., AYRES, J.G., DEVEREUX, G.

BRUNEL UNIVERSITY

The eucapnic voluntary hyperpnoea (EVH) test is the bronchial provocation challenge currently recommended by the International Olympic Committee – Medical Commission (IOC-MC) for laboratory -based asthma diagnosis in athletes (1). This test requires athletes to hyperventilate dry air with 5% CO2 for 6-8min at 30 times their baseline forced expiratory flow in one second (FEV1) (2). So far, most of the diagnostic centres for asthma have developed their own EVH set-up following previous recommendations (2). The main drawback of home-made EVH set-ups is that they require the use of expensive gas tanks containing the specific inspiratory gas mixture. Recently, a new device for EVH challenge – EucapSys (SMTEC.SA, Nyon, Suisse) – has been made commercially available. This device acts as a mixing chamber and produces adjustable hypercapnic mixtures at a reduced running cost.

The aim of this study is to assess the effectiveness and reliability of EucapSys and whether it is a safe alternative to the established system for EVH testing, both in athletes and in untrained individuals.

Twenty eight trained (31.1+/- 1.7yr (SEM); 9.0+/- 1.1h of training per week) and 22 untrained females (23.3+/- 1.4yr) performed an 8-min EVH test on the EucapSys. Inspired fraction of CO2 (FICO2), end-tidal CO2 (PETCO2) and ventilation (VE) values were continuously monitored using a breath-by-breath gas analyser (CPX-Ultima, MedGraphics). Recovery from the challenge was spontaneous with spirometry measured in duplicate at 2, 5, 10, 15 and 20min after the challenge.

All subjects were able to successfully complete the 8min test. Athletes reached a ventilatory level of 88.6 +/- 2.4L.min-1 and untrained subjects of 81.3+/-2.2L.min-1 (P=0.029). FICO2 was stable around 4.8+/- 0.0% in both groups throughout the test. PETCO2 was kept within the normal range of 35-45mmHg in all participants (mean for both groups was 40.1+/-0.3mmHg). Ten athletes and nine untrained subjects had a positive response to the EVH challenge (defined by a 10% fall or more from baseline FEV1 during two successive recovery time intervals). No significant difference in FICO2 or PETCO2 were found in those subjects with a positive and a negative response (P=0.256 and 0.225, respectively).

In conclusion, the EucapSys can safely and effectively be used for asthma testing, in both athletes and untrained female subjects.

CHANGES IN GUT HORMONE LEVELS AND NEGATIVE ENERGY BALANCE DURING AEROBIC EXERCISE IN OBESE YOUNG MALES

UEDA, S., YOSHIKAWA, T., KATSURA, Y., USUI, T., NAKAO, H., FUJIMOTO, S.

OSAKA CITY UNIVERSITY GRADUATE SCHOOL OF MEDICINE

We examined whether changes in gut hormone levels due to a single bout of aerobic exercise differ between obese young males and normal controls, and attempted to determine the involvement of hormonal changes during exercise in the regulation of energy balance in these obese subjects. Seven obese and seven age-matched subjects of normal weight participated in exercise and rest sessions. Subjects consumed a standardized breakfast, which was followed by constant cycling exercise at 50% VO2max or rest for 60 min. At lunch, a test meal was presented, and energy intake (EI) and relative energy intake (REI) were calculated. Blood samples were obtained at

30 min intervals during both sessions for measurement of glucose, insulin, glucagon, ghrelin, peptide YY (PYY), and glucagon-like peptide-1 (GLP-1). Plasma levels of PYY and GLP-1 were increased by exercise, whereas plasma ghrelin levels were unaffected by exercise. The areas under the curve (AUC) of the time courses of PYY and GLP-1 levels did not significantly differ between the two groups. In contrast, EI and REI were decreased by exercise in both groups, and energy deficit was significantly larger in obese subjects than in normal controls. The present findings suggest that short-term energy balance during a single exercise session might be regulated not by increased amounts of these gut hormones per se.

DETERMINING OPTIMAL HANDBALL PLAYER RATES OF BODY SIZE: A PHANTOM ALTERNATIVE?

MASSUÇA, L., FRAGOSO, I.

TECHNICAL UNIVERSITY OF LISBON

A range of relevant anthropometric factors can be considered which are subject to strong genetic influences (e.g. stature) or are largely environmentally determined and susceptible to training effects (see Reilly, Bangsbo and Franks, 2000). However, in the throwing events like handball, the anthropometric profile of elite players is first based in height and weight, followed by span and hand measures (Blanco, 2004).

The aim of the current study were (i) to make a conditional characterization and to describe the relation between height and weight of male handball players of different levels, (ii) to assess its ability to distinguish different level adult players and (iii) to test Phantom and Lentini Combined Methods: 561 male handball players (WC 2007, n = 395; LPA 2007-08, n = 184) were studied (mean age = 25.99 years, s = 4.64; height = 188.46 cm, s = 7.11; body mass = 89.07 kg, s = 9.97). WC 2007 was classed as those who had participated in the XXTH Men's Handball World Championship 2007 (in Germany). LPA 2007-08 players were classed as those who were signed for a Portuguese Professional Handball Club in season 2007-08. Two anthropometric measurements for each participant were taken during year 2007. These included height and body mass. To study the sportsmen proportionality were used (i) height and weight relation, (ii) body mass index, (iii) optimal weight, (iv) Phantom Method and (v) Lentini Combined Method. Statistical analysis involved variables description, though mean and standard deviation. The t-test for equality of means was performed to compare level groups (Independent Sample Test) and to compare results of Phantom and Lentini Methods (Paired Sample Test). For all analyses, 5% was adopted as the significance level and analyses were carried out with SPSS (Statistical Package for the Social Sciences) 15.0 software for Windows.

The results showed: (i) significant difference in body size (height and weight, all $p < 0.01$) and no significant differences in body mass index and optimal weight (all $p > 0.05$) variables between groups, (ii) significant difference between groups in Phantom Z value of height ($p < 0.01$) and no significant differences when considered the Phantom Z value of weight ($p > 0.05$), (iii) that Lentini combined method normalize the data pulling the results to the mean Z value (height and weight, all $p < 0.01$) comparing with Phantom method, and allows similar statistical results than original data. The results suggest that the use of Lentini combined method seems to be useful to study the sportsmen proportionality, and the body size of handball players participated in the XXTH Men's Handball World Championship 2007 (mean height = 189.13 cm, s = 7.20; body mass = 90.05 kg, s = 9.60) can be used as male reference data.

RESPONSES OF CYTOKINES TO INFLUENZA VACCINATION IN ELITE BOYS GYMNASTS

ARZANEGI, P., AZARBAYJANI, M.A., AGHA ALINEJAD, H., RASAEE, M.J., HOUSEINI, M.

ISLAMIC AZAD UNIVERSITY

Introduction: Decreases in immune responsiveness with exercise contribute to the increased incidence and severity of infectious disease among elites athelets (Murphy et al., 2008). The efficacy of this adjuvant strategy for vaccination in humans requires investigation (Edwards et al., 2007) .The objective of this study was to determine whether exercise were associated with altered immune response [IL-2, IL-6and IFN-gamma] to influenza vaccine.

METHODS: Therthy boy gymnasts (aged 9.8±0.88 years, heigh 139.19 ±4 cm,weight 33.79± 7.15kg ,and Vo2max=39.82 ±4 ml/kg/min)were categorized into two groups: (1)triaining,vaccine[TVG],(2) training[TG], and third groups : (3) vaccine[VG]. Then gymnasts performed gymnastic training for of eight weeks and were vaccinated pre and four weeks after training. Cytokines concentrations were measured pre-vaccination and at 4- and 8-week follow-ups. Then Serum was frozen on -70 until analysis cytokines production. Cytokines were measured by enzyme-linked immunosorbent assay(ELISA).

RESULTS: The results demonstrated that , IL-6and IFN-gamma decrease among three groups ,but IL-2 were not affected by vaccination and training ,also were not significantly different in the three groups.

Discussion: Othere studies have been shorter term (12 weeks-6months) and at lower intessities (50-60% Vo2max)atrend towards improwed immune response has been observed (Kohut et al.,2007).During exercise,the neuroendocrine milieu is altered resulting in increased sympathetic nervous system activation,and increase in plasma levels of othere hormones(cortisol)(Bruunsgaard et al.,1997).These results suggest that exercise,vaccine maynot influence immune response to influenza immunization. The practice of regular, vigorous exercise was associated with decrease immune response following influenza vaccination in prepubertal gymnasts.

SKILL DIFFERENCES OF FREESTYLE COMPETITIVE SWIMMERS DETECTED BY MEANS OF A SPEED METER

TANAKA, T., YOSHIMURA, Y., YASUKAWA, M., OISHI, K.

TOKYO CRO, INC.

A speed meter that measures a subject's moving velocity by pulling a fine wire over a generator (Maglischo, 2003) for a distance of 25m was developed for use with competitive swimmers. In our previous study, the authors used the speed meter to check for skill differences between competitive swimmers of international achievement and collegiate breaststroke swimmers. The results showed that this method was useful for identifying skill differences among a group of swimmers as well as reasons for improvement for each swimmer. In the present study, the authors used the speed meter and an underwater video analysis system to determine the skill differences between short distance freestyle competitive swimmers of national achievement and collegiate swimmers. The speed meter recorded their intracyclic velocity changes during a 25m maximum effort freestyle swimming. The underwater video analysis system was also used to check their stroke techniques during these maximum efforts. Based on the video data, the authors divided the stroke cycle into three phases, i.e., 1) downsweep phase, 2) insweep phase, and 3) upsweep phase. Average velocities during each phase, based on the speed meter data, were compared individually among four swimmers. In consequence, no statistical differences were observed among all swimmers for the insweep phase (Test of contrasts, p=0.0628) and upsweep phase (p=0.8707). However, the mean velocities of national achievement swimmer showed significantly higher value for the downsweep phase (p=0.0287). It was suggested that improvements in freestyle swimming were dependent mostly upon improving downsweep phase.

SALIVARY AND PLASMA CORTISOL AND FREE TESTOSTERONE DURING A WINTER SWIMMING TRAINING SEASON

RAMA, L., ALVES, F., ROSADO, F., TEIXEIRA, A.

FACULTY OF SPORT SCIENCES AND PHYSICAL EDUCATION OF COIMBRA

Objectives

Studies on the impact of training load on endocrine response have led to inconclusive findings. The aim of this study was to measure the response of salivary and plasma cortisol and free testosterone during a swimming winter season, in order to test the sensibility of these markers to training variation, fatigue and adaptation.

Methods: 19 well-trained swimmers, 13 men (17,2±1,3 years, 174,9±5,8 height, and 65,8±6,8 mass) and 6 women (15,8±0,8 years, 163,0±9,4 height, 54,6±5,0 mass), were recruited for this study. The training load, volume, intensity and participation in competition events, were monitored during 29 weeks of a winter swimming season. Blood and saliva samples were taken at rest, at the same time of day, before the first afternoon workout of the week (16:00 h), at four testing moments: before the beginning of training season (t1) after the first 7 weeks of incremental training load(t2), after 6 weeks of an intermediate intense training mesocycle (t3) after a major competition (t4). Salivary cortisol and testorone were determined by Elisa and plasma values were determined by Chemiluminescence. At t2, t3 and t4 the swimmers completed a graded swimming protocol (7x200), in order to determine the lactate velocity curve and the associated parameters. In this study we adopted a single group repeated measures design in which athletes served as their own control subjects. All ethical presuppositions that a study of this scope compels have been verified.

Results: Training volume was significantly higher at t2 and t4 and intensity increased significantly at t4 ($p<0,05$). Plasmatic and salivary cortisol showed significant correlation (r=0,505, to r=0,902; $p<0,01$) in all testing moments. Male swimmers had higher plasma and salivary cortisol values in harder training phases when compared to t1 ($p<0,05$). The salivary and free plasmatic testosterone were also significantly correlated (r=0,703 to 0,747) at the 4 testing moments but showed no variation during the training season. When compared to the beginning of the season, salivary T/C only decreased significantly in t4 ($p<0,05$), but in the case of plasmatic T/C we found significant lower values in all intermediate moments of the season when compared to the initial one. The results of the graded swimming protocol revealed that the highest maximal and DMax swimming velocity were observed at t3 which coincided with the highest salivary cortisol and lowest T/C values.

Conclusion

Free Testosterone levels at rest do not seem to be affected by training during the swimming season. High Cortisol levels did not impair the maximal and submaximal performance capacity. The stress induced by hard training phases increased the cortisol values both in plasma and saliva, but a real increased in the magnitude of training load is needed to have a significant impact in salivary cortisol content. In conclusion, salivary cortisol alone, at rest, could be a useful marker of the stress induced by training load.

TECHNICAL-COORDINATIVE SKILLS AND PERFORMANCE: IMPROVEMENTS AND CORRELATIONS IN SWIMMING

SCURATI, R., MICHIELON, G., LONGO, S., INVERNIZZI, P.L.

FACULTY OF EXERCISE SCIENCES - UNIVERSITY OF MILAN

INTRODUCTION: The improvement of the swimming performance is certainly related to the physiological responses to training, but a very important role is also played by the technical-coordinative components and by the kinesthetic awareness. These abilities, basics during the learning process, are essentials in competitive swimmers in order to better feel and optimize the movements, increasing propulsion and reducing resistance [1-2].

The aim of this study was to assess the improvements of the technical-coordinative skills in young swimmers over a sport season, as well as their correlations to the performance.

METHODS: 10 young female swimmers (Mean±SD; age 8.4±0.5 years; height 132.5±5.6 cm; weight 33.3±6.1 kg; BMI 18.8±2.1) participate in the study. They practiced a traditional swim training. In order to assess their kinesthetic awareness and their technical-coordinative skills, subjects underwent a few representative tests three times over the sport season (T1=November, T2=February and T3=May) such as: i. diving and gliding underwater in a streamline position (DG); ii. pushing off from the wall and gliding underwater in a streamline position (PG); iii. diving, gliding and swimming front crawl for 15m (DGC); iv. diving, gliding and swimming breaststroke for 15m (DGBR); v. diving, gliding and swimming backstroke for 15m (DGBK). The best race performance (BRP) in the 50m front crawl was collected in the meantime. Data have been compared and the correlations between the technical-coordinative skill tests and BRP have been investigated.

RESULTS: In the within-test analysis, significant improvements were found among all T1, T2 and T3 ($p<.05$).

In the comparison between each test and BRP in the 50m front crawl, no significant correlations were found in DG and PG ($r=-0.58$ and $r=-0.59$ respectively, $p>.05$), whereas significant correlations ($p<.05$) were found in DGC ($r=0.77$), DGBR ($r=0.74$) and DGBK ($r=0.87$).

CONCLUSION

The repeated measure comparison at T1, T2 and T3 shows that a non-specific swimming training may contribute in obtaining adequate improvements of the technical-coordinative skills and the kinesthetic awareness.

The poor correlation between both DG and PG with BRP could be due to the fact that in very young swimmers (like our subjects were) the starting phase in a 50m event is little significant with respect to the swim phase, considering the total time needed to complete the competition.

Moreover, in very young swimmers, the training is not focused on the early specialization. That could be the reason of high correlations found between BRP in the 50m front crawl with DGC, as well as DGBR and DGBK.

THE INFLUENCE OF AGE AND WATER POLO CRAWL TECHNIQUES ON HEART RATE IN WATER POLO PLAYERS

SCURATI, R., INVERNIZZI, P.L., MICHIELON, G., LONGO, S.

FACULTY OF EXERCISE SCIENCES - UNIVERSITY OF MILAN

INTRODUCTION. The swimming techniques adopted by water polo players usually do not reflect the classic swimming techniques. Additionally this sport is a highly energy demanding activity (1,2). Therefore heart rate, that reflects energy demand, may be different when measured during crawl or some of its water polo adaptations. For this reason attention is given to improve these adaptations during water polo training sessions; however these techniques could elicit different responses in terms of heart rate.

PURPOSE. The purpose of this study was to look at the influence of age and water polo crawl techniques on heart rate in water polo (WP) players.

MATERIAL AND METHODS. Ten under 20 (U20, mean±SD, age 18.2±0.4 years, height 176±7 cm, body mass 73.1±12 kg) and ten under 13 (U13, mean±SD, age 11.8±0.4 years, height 154±9 cm, body mass 48.5±8.6 kg) WP swimmers volunteered for this study. Each participant performed four 25m trials at a constant speed of 1m/s in four different crawl techniques used in WP: crawl (C), crawl head up (CU), crawl head up with ball between arms (CA), crawl head up pushing a ball (CP). Heart rate (HR) was monitored during each trial with a Polar® Team System heart rate monitor and used for further analysed.

RESULTS. Between groups: HR was significantly lower in U20 than U13 for all four techniques (C: 104±13 vs 122±11 bpm $p<0.05$; CU: 117±13 vs 132±13 bpm $p<0.05$; CA: 123±9 vs 137±8 bpm $p<0.05$; CP: 125±8 vs 145±10 bpm $p<0.05$; U20 and U13 respectively). Within each group, for U20 HR values were 104±13 (C), 117±13 (CU), 123±9 (CA) and 125±8 (CP) bpm and have been found to significantly differ between each other ($p<0.05$) except for CA and CP ($p>0.05$). For U13 HR values were 122±11 (C), 132±13 (CU), 137±8 (CA) and 145±10 (CP) bpm and have been found to be significantly different between each other ($p<0.05$) except for CU and CA ($p>0.05$).

CONCLUSIONS. The between groups comparison showed that age affects HR in the four different stroke techniques analysed, revealing that young WP swimmers spend more energy than the older ones in spite of the technique used. The within group comparison pointed out that the differences between each technique may be related to the age and the specificity of training in the two groups. U13 matches are characterised by static positions and ball control therefore this could be the explanation why we did not find any differences between CU and CA. On the other hand U20 matches due to their higher performance level are characterised by rapid movements of the players and the ball (pushing and throwing), thus the training focuses on more specific WP techniques, possibly explaining the lack of differences between CA and CP.

IMPROVEMENT OF KINESTHETIC AWARENESS IN SYNCHRONISED SWIMMING

INVERNIZZI, P., SCURATI, R., LONGO, S., MICHIELON, G.

FACULTY OF ECERCISE SCIENCES - UNIVERSITY OF MILAN

INTRODUCTION: Kinesthetic awareness is very important in swimming in order to better "feel the water", improving the propulsive actions and reducing the drag forces [1]. Synchronized swimming requires flexibility, aerobic as well as anaerobic conditioning and abilities [2]. In particular kinesthetic awareness allows to maintain a fine body control and to better operate the actions of propulsion based on lift forces.

Improvements of the kinesthetic awareness and the conditional capacities subsequent to a classic synchronized swimming training program have been investigated in this study.

METHODS: Twelve 11 to 17 years old subjects practicing synchronized swimming participate in the study. Before and after a traditional six-months synchronized swimming training, subjects underwent a series of tests (in order to assess kinesthetic awareness, technical and coordinative abilities, strength and power) such as: i. diving and gliding underwater in a streamline position (DG); ii. pushing off from the wall and gliding underwater in a streamline position (PG); iii. sculling while floating on the back for 15m (SC); iv. swimming the front crawl

stroke at 90% of the maximum for 25m (CR90%); v. swimming front crawl stroke only with legs for 25m (LCR); vi. swimming front crawl stroke with close hands for 25m (CHCR); vii. swimming breaststroke for 25m in modified coordination (MBRST), viii. swimming front crawl stroke only with arms for 25m (ACR). Pre and post training results were then compared.

RESULTS: No differences were found in PG, LCR and CHCR (p>.05).

Significant improvements were found in DG (pre vs. post, 7.7±2.4 vs. 8.9±1.7 m, p<.05), SC (29.4±4.0 vs. 28.3±4.1 sec, p<.05), CR90% (the gap in percentage to the attended performance have been considered, 6.2±2.8 vs. 3.2±1.6 %, p<.05) and MBRST (30.2±5.2 vs. 28.9±5.4 sec, p<.05).

In ACR no differences were found in the performance (22.9±3.5 vs. 22.0±2.7 sec, p>.05), whereas improvements were found in counting the number of the arm strokes needed to swim the distance (34.9±5.1 vs. 32.8±5.1 n, p<.05).

CONCLUSION: The results suggest that six-months of traditional training in synchronized swimming would not significantly affect the conditional capacities such as strength and power (PG, LCR, CHCR and even ACR did not differ between pre- and post- training). On the contrary, training would mostly improve the kinesthetic awareness and the coordinative abilities. The significant improvements in ACR's number of arm strokes (although the performance did not differ) and in DG could mainly depend on the progress of the technical actions related to the kinesthetic awareness evolution.

INVESTIGATION OF SELECTED PHYSIOLOGICAL PARAMETERS OF TURKISH MALE MASTERCLASS SWIMMERS

ERTAS DOLEK, B., CAKICI, K.C.

GAZI UNIVERSITY

The purpose of this study is investigating the relationship between the age related categories of male master class swimmers in accordance with height (cm), weight (kg), body mass index (BMI), basal metabolic rate (BMR), body fat percentage (BFP), fat mass (FM), fat-free mass (FFM) and total body water (TBW).

In the study, 29 male master class swimmer, from 8 categories (C1 to C8), with an average age of 41,9 (±11,1), are included. The data is collected on 2nd International Masters Swimming Cup, October 28-29, 2008 in Istanbul with Tanita BC 418 Segmental Body Composition Analyzer with Bioimpedance analyze (BIA) method. Minitab 15.1 statistics software package programme is used to analyze the data.

Variance analysis method is applied to the male masters swimmers' age, height, weight, BMI, BMI, BMR, BFP, FM, FFM and TBW data according to age group factor. Duncan's multiple range test (MRT) is applied to the group means if necessary. It is found that the mean height value of the age category C6 is statistically significantly correlated with the mean height values of age categories C7 and C8 (p≤0,01). Also, mean BMR, FFM, TBW values of C1 and C7 are found to be statistically significantly correlated (p≤0,01). No relationship between the mean VA, BMI, BFP and FM values of age groups are found.

INFLUENCE OF TWO DIFFERENT REST INTERVALS ON FATIGUE DURING MAXIMAL SWIMMING

EVANGELIDIS, P., STAVRINOU, P., TAMBAKI, M., THEOS, A.

UNIVERSITY OF ATHENS

INTRODUCTION: Performance in repeated sprints is affected by recovery duration (2). A recent study has shown that fatigue (as a means of drop in power output) during eight 6 sec cycling sprints with short rest intervals, was significantly greater than with longer rest intervals (1). Similar findings were presented in another study held in swimming (3). However, the rest intervals used were much longer than what can be found in a typical swimming training (10-30 sec). The purpose of the present study was to examine the influence of two different rest intervals on performance and fatigue during repeated sprint swimming.

METHODS: Sixteen swimmers (9 boys & 7 girls) age: 15.6 ± 0.7yrs, performed 3x66 m sprint swimming in two different conditions and in a random order. During the first condition, the rest period between sprints was 10 sec (S), while on the second condition the rest period was 30 sec (L). Differences between the two conditions in performance time and fatigue index (percent increase of performance time from the first to the third sprint) were analyzed using T-Test. Results are presented as mean ± SE.

RESULTS: Total performance time was significantly different between the two conditions (S=144.0 ± 4.0 vs L=138.7 ± 3.7 sec, p<0.0001). Despite the difference in performance time, fatigue index did not differ significantly between the two conditions (S=9.6 ± 1.6% vs L=7.4 ± 1.5%, p=0.25).

DISCUSSION: The results of the present study suggest that different recovery periods influence performance time, as it was expected (3). The fact that fatigue index did not differ between the conditions suggest that even a rest period as short as 10 seconds might induce almost the same fatigue as a longer interval despite its important impair in performance. The relatively low number of repeated sprints may have contributed to the non-significant difference in fatigue between the two conditions and therefore further research is needed.

EFFECTS OF WEIGHTED ROPE JUMP TRAINING ON ANAEROBIC POWER, SPEED, FLEXIBILITY AND AGILITY IN ADOLESCENT VOLLEYBALL PLAYERS

COLAKOGLU, F.F, ATALAY GUZEL, N., KARACAN, S., BALTACI, G.

GAZI UNIVERSITY

Introduction: The aim of this study was to investigate the effect of a 12-week rope jumping and weighted rope jumping exercise programme on anaerobic power, speed, flexibility and agility performance of female adolescent volleyball players.

Methods

Twenty-five female volleyball players (mean age: 14,66±1,16yrs) who had at least 2 years volleyball experience participated in this study and were divided into there groups. Group 1 took on the weighted rope jumping (WRJ; (n=8)) programme as well as volleyball training, Group 2 on rope jumping (RJ; (n=9)) programme as well as volleyball training and Group 3, the control (C; (n=8)) participated only volleyball training. The exercise sessions were carried out 3 times each week for 12 weeks. The anaerobic power of the subjects was measured by using vertical jump test. 30 m. sprint test, seat and reach test, hexagonal obstacle and zigzag tests were applied to the subjects as described in the literature. Data indicating the effects of these exercise programs on the performance parameters and somatotype was statistically analyzed by ANOVA and Kruskal-Wallis test.

Results: There was a significant difference a considerable increase in the values of flexibility and anaerobic power at the end of training of the two groups (p<0,01). Also speed and agility performance of two groups were significantly different at the end of training (p<0,01). Compared to control and training groups, the values of WRJ group were highly increased for the mean of anaerobic power and zig-zag test (p<0,01).

Discussion: As a result; we showed that performance parameters of the groups taking 12-week weighted rope jump exercise programme would be considerable improved. Therefore, the results of this study indicate that a weighted rope jumping exercise programme has a potential improvement anaerobic power and agility of volleyball players.

EFFECTS OF VOLLEYBALL TRAINING ON JUNIOR ATHLETES IN PREPARATION FOR THE WORLD CHAMPIONSHIP

STANGANELLI, L.

STATE UNIVERSITY OF LONDRINA

Introduction: The Brazilian volleyball teams have obtained great performances at international level. Recently Brazil won The Junior World Championship for Male Volleyball held in Morocco. The athletes follow and very strong program of training for this competition. During this period and according to the macrocycle, a battery of test is applied in order to verify the level of training-induced adaptations on variables important to perform this game. The main objective of this study was to verify how the athletes adapted after 8 weeks of training developed before the world championship.

Methods: The sample was composed of 10 male athletes (Age: 19.4±0.6 years; Height: 1.97±0.9 m; Weight: 93.9±1.4 kg). The study was approved by the university human ethics committee and all subjects signed an informed consent document. The battery of tests was applied 8 weeks apart (Test 1 and Test 2) and included Anthropometric measures, medicine-ball Throw, shuttle-run test, squat jump, contermovement jump and two specific tests for height of spike and block reach. The data was analyzed by descriptive statistics and a Paired t test was used to compare all the group of means. The significance level was set at p≤0.05.

Results: The results showed that SJ (T1: 41.1±3.8 cm-T2: 36.7±3.4 cm – p=0.00) and CMJ (T1: 44.2±4.0-T2: 40.8±3.9 cm – p=0.02) presented means that were statistically significant but with a decrease of performance. On the hand, the medicine-ball throw (T1: 7.09±0.8 m-T2: 7.09±0.6 m – p=.993), the shuttle-run test (T1: 6.77±0.28 s-T2: 6.90±0.13 s – p=.159), the height of spike reach (T1: 3.37±0.20 m-T2: 3.35±0.20 m – p=.132) and the height of block reach (T1: 3.13±0.17 m-T2: 3.12±0.16 m – p=.435) did not present any statistical significance.

Discussion: The importance on testing elite athletes is that the results not always are according to those verified in the literature. The way human body adapts to the training loads requires frequent studies. Particularly, these results may infer that 8 weeks of training did not influence the performance of the athletes. But some aspects must be considered: First: the moment that the battery of test was applied (one day before departure to Morocco) when some athletes performed the tests with excessive care trying to prevent any injury and Second: The week before the test 8 athletes of the team was under a strong cold which probably have affected their performance during the test. Thus, when evaluating athletes there are some aspects that can not be controlled by the researcher such as health and psychological status that affects them at specific moments of the macrocycle.

THE EFFECTS OF DIFFERENT MUSCULAR TRAINING MODES IN VOLLEYBALL STRENGTH TRAINING

MARIAN, C., LARISA, V., ION, M., AUREL, I.

UNIVERSITY OF PITESTI

Introduction: The muscular training is one of the most important factors and in some cases the most important admixture of sport training, with a view to reaching high performances, influencing the way the preparation is undergone. This training must be completed on a uniformly and balanced basis for each of the physical aptitudes solicited by the performance sport. The purpose of this paper is that of improving the muscular preparation by introducing alternate contraction regimes inside the training of the junior volley players (16-18

years). For the performance level (juniors), the strategic objective is centered on: improvement of the game actions which are integrated to the collective tactics and subordinated to the efficiency requests of competitions, doubled by the necessity of accomplishing a high level of specific physical and psychical training.

Methods and Instruments

In order to evaluate the junior female sport performances, the tests method was used, by making use of the Bosco Protocol, applied on the force measuring platform Quattro Jump tip Kistler 9290AD.

Results and discussions:

The height indicator (h)

The jump height indicator registered significant increases for la SJ, CMJ and CJb at t = 8,504 la SJ, 10,385 la CMJ and 9,403 at CJb for p < 0.001. In the final CJs the evolution is significant, t = 2,373 p < 0.05. The power indicator (P)The average of the power indicator for SJ raises significantly t = 2,876, p < 0.05 For CMJ the average of the power indicator increases significantly t = 2,564, p < 0.05. The Pre-stretch Effect (Re-Use Elastic Energy) (EP) indicates the importance of the benefit produced by the pre-stretch (CMJ compared to SJ). The test results show insignificant evolutions at the level of the experimental group: t = 1,536, p > 0.05.

The leg Equilibrium Index Equilibrium of the functional structure of the leg including three joints (hip, knee, ankle) and the upper and lower leg (thigh, calf) The average values of 1,85 and 1,84 in the two testings do not go through significant changes t = 0,067, p > 0.05, but show that the neuromuscular function of the knee, ankle and lower limbs are weaker than the hip and thigh.

CONCLUSIONS:

Applying programsal

mes of muscular training inside the preparation of young female volley players I, has contributed to improving the level of the technical executions and of their tactical behavior, a fact confirmed by the fulfillment of the game tasks and performance objectives, and it has also helped to decrease the number of accidents, thus creating premises for prolonging the sporting career.

SEASONAL IMPROVEMENTS AMONG WOMEN'S COLLEGIATE SOCCER PLAYERS USING A ONE DAY PER WEEK AEROBIC INTERVAL TRAINING MODEL.

FAVERO, T., JACKSON, K.

UNIVERSITY OF PORTLAND

Introduction: In the United States, the women's collegiate soccer season is 14 weeks long followed by 4 weeks of playoffs. Teams regularly compete twice per week leaving little time for technical and tactical training or physical training and recovery. One recent report showed a significant decline in VO2max among women soccer players despite 3 cardiovascular training sessions per week (Miller et al.). The aim of this study is to test the efficacy of a 1-day per week conditioning program that combines aerobic and interval training (Helgerud et al and Dupont e al).

Methods: Sixteen female division I soccer athletes (age 19.43 years) agreed to participate in a study passed by the Universities Human Subjects committee. Athletes were evaluated just prior to and following the competitive season. Athletes were assessed for body weight, % fat mass and aerobic capacity using a incremental treadmill VO2max test. The one day per week training program was administered every Tuesday following a rest day on Monday. Competitions are typically Friday and Sunday. The training program consisted of repeat intervals at paces between 80-120% VO2max. Total time for interval work (# intervals x interval time) was not less than 16 minutes per session. Elevated Heart rate time was typically no less than 45 minutes which included active recovery.

Results: There were no changes in body mass (60.30 +/- 5.93 vs. 60.52 +/- 5.59) or % body fat (15.46 +/- 2.64 vs 15.16 +/- 2.70) when comparing pre season to post season tests. Aerobic capacity increased significantly from 50.89 +/- 3.04 to 52.46 +/- 3.01 from pre-season to post season (p < 0.05). Maximum heart rate and maximum ventilation (VE) remained unchanged during the season.

Discussion: Conditioning for soccer remains varied and complex given the strength, speed, agility, aerobic and technical requirements of the game. Compared to most professional or club soccer leagues, the U.S. collegiate competitive season is short and the number of contests average 1.8 per week. Athletes are expected to have one day off per week and have an easy recovery day between games. Time for physical training is typically limited during the competitive season. We demonstrate that a one-day per week conditioning program based upon aerobic development as described by Helgerud et al and implemented using an interval model similar to that described by Dupont is sufficient to improve the aerobic capacity of a women's collegiate team. Our result suggests that a thoughtfully designed one- day per week training program can improve team aerobic fitness during a short competitive season.

THE EFFECTS OF A SHORT-TERM ISOMETRIC TRAINING PROGRAM ON THE NEUROMUSCULAR FUNCTION OF ELITE GREEK JUMPERS AND LONG DISTANCE RUNNERS

PATIKAS, D., PARASCHOS, I., BASSA, E., GALAZOULAS, C., SKOUFAS, D., KOTZAMANIDIS, C.

ARISTOTLE UNIVERSITY OF THESSALONIKI, GREECE

Introduction: The improvement of performance in track and field sports requires specific training, depending on the features of the event. Rate of force development (RFD) is crucial for jumpers, whereas long distance runners' RFD is expected as less developed. Short-term effects of training may influence performance. However, it is still unknown how such athletes respond to a short-term training protocol. The aim of the present study was to examine the effect of a two days strength training protocol on the neuromuscular function and especially on the RFD of the plantar flexor muscles in elite jumpers and long distance runners.

Methods: Two groups of elite Greek track field jumpers (n=9, age: 24.8±3.1 years, height: 182.3±7.4 cm, body mass: 74.3±2.7 kg) and long distance runners (n=9, age: 22.1±2.8 years, height: 177.9±6.7 cm, body mass: 64.8±7.3 kg) participated in the study. The participants were tested 48 h before and after an isometric, ballistic type, strength training protocol consisted of 2 sessions with 48 hours interval in between. Testing and training were conducted on the plantar flexor muscles of the ankle. Torque and EMG amplitude as well as frequency component using spike analysis for the gastrocnemius, soleus and tibialis anterior were measured during the maximal voluntary contraction. Additionally, the maximal M-wave (Mmax) and the twitch torque properties were measured after a supramaximal electrical nerve stimulation over the tibial nerve.

Results: Maximal voluntary isometric torque remained unchanged, while, the voluntary maximal RFD recorded 100 ms after the onset of contraction improved in the long distance runners only. This was accompanied by an increase in the gastrocnemius EMG frequency as well.

The peak twitch torque, contraction time, half relaxation time and Mmax remained unchanged in both groups. However, before training jumpers presented higher twitch torque, shorter contraction time and shorter half relaxation time, compared to the values of the long distance runners.

Discussion: Our findings indicate that RFD is enhanced after 2 sessions of strength training program, with no parallel increase in maximal strength, only in persons with low level of strength (Blazevitz et al., 2008). Considering the examined muscles, it seems that such adaptations are evident in muscles with larger proportion of fast motor units, such as gastrocnemius (Paasuke et al., 1999). This supports the notion that spinal and supraspinal centers may contribute to the adaptations observed after a short-term, ballistic, isometric training.

THE EFFECT OF HIGH VS. LOW INTENSITY TRAINING ON AEROBIC CAPACITY IN WELL TRAINED MALE MIDDLE- DISTANCE RUNNERS

ENOKSEN, E., TØNNESSEN, E., SHALFAWI, S.

1. NORWEGIAN SCHOOL OF SPORT SCIENCES, 2. BODØ UNIVERSITY COLLEGE

Introduction: Research show that the inter-individual variance and strongest predictors of middle- and long-distance running performance depend on; VO2max, % of VO2max, VO2max velocity, running economy (RE), lactate threshold (LT) and LT velocity (Saltin et al. 1995; Bassett, and Howley 2000; di Prampero 2003). A review of literature show that the development of training methods have traditionally been based on short-term studies among untrained or moderate trained individuals coupled with anecdotal evidence from experienced coaches and successful athletes. Therefore, the purpose of the present study was to examine the effect of two different intervention training regimes on VO2max, VO2max velocity, RE, LT velocity and running performance on a group of well-trained male middle-distance runners. Methods: Twenty-six well-trained male middle-distance runners participated in the present study. The subjects were all highly committed to training, running 90 ± 14 km per week. All participants were tested on VO2max, VO2max velocity, RE, LT, LT velocity and a performance test on treadmill. The participants were matched according to their pre-test results, then randomly assigned into one of two groups, a high volume (60 km) low intensity training group (HVLI-group); and a high-intensity low volume (40 km) training group (HILV-group). The training volume and distribution of intensity in the intervention period (10 weeks) was by performing 33 % of the total workout at 82-92 % of HR max and 67 % performed at 65-82 % of HR max for the HILV-group, and 13 % of the total workout at 82-92 % of HR max and 87 % was performed at 65-82 % HR max for the HVLI-group. Results: No marked differences were found between groups in all measures made in this study. Furthermore, the HILV-group had a marked increased in VO2max velocity and LT velocity after the training period when compared to pre-test. Both groups had a marked improvement in RE. The performance test showed that the HILV-group made 456 m (1.38 min) and the HVLI-group 273 m (54 sec) in progress. The production of lactic acid (La) was notably higher in the HILV-group (0.9 mmol) when compared to pre-test. Conclusion: The findings in this study show that male middle-distance runners improves in VO2max velocity and LT velocity better when they train around anaerobic threshold than training with low intensity for a short period of 10 weeks.

LACTATE AND AMMONIA AFTER 150M SPRINT IN 200M AND 400M TRACK AND FIELD ATHLETES

PAKZAD-MAYER, Y., CHAN, Y.S., JANG, J.T.

NATIONAL TAIWAN SPORT UNIVERSITY

Introduction: Most of Taiwan's 200m and 400m track and field athletes focus on a training based on a 150m intervall training. During this distance athlete can increase and keep their speed. So it is a useful method to train speed. During the last 20 years studies analysed the behavior of NH3 and lactate during exercise using different study designs. On this basis the following research was done to examine if NH3 and lactate measurments can be used to examine athlete's anaerobic capacity. Additionally, repetition training was chosen to observe wheather the rest period does influence the NH3 outcome.

Method: 10 track and field male subjects age 17.00±1.325 volunteered to participate in this study. Each subject had to do a 5x150m max repetition training after a 30 minutes warm up. During repetitions a 5 minutes resting period was granted. La, NH3 was measured at rest and after the 5th repetition. During each repetition the speed was measured.

Result

Lactate rose from 1.31±0.33 mmol/l at rest (R) to 18.79±3.81 mmol/l after the 5th repetition (5x). The ammount of NH3 (μmol/l) rose from 31.60±16.03 (μmol/l) in (R) to 168.60±52.31 (μmol/l) in (5x). The speed steadily decreased on each stage from 8.38±0.60 (m/s) at the first repetition (1x) to 7.67±0.56 (m/s) at the last (5x). There was a linear relationship between NH3 and lactate output during training (r = 0,77). The p value was significant (p=0,016).

Discussion: Many studies have shown that with increasing intensity the NH3 value increases as well (1). This was interpreted as a matter of used muscle fibres (2).At higher workload more fast twitch fibres are recruited and hence, this results in a larger amount of NH3 due to the activation of the AMP deaminase (3). On the other hand the glyconeogenesis might also be responsible for the increase of NH3. Since ATP will be used up within the first 10s, 200m and 400m runners have to generate the energy by using proteins. Previous studies have found a correlation between NH3 and lactate in high intensity tests (1, 2, 3). A 150m running distance, however, has not been analysed yet. The finding of this study confirm that a correlation between this two parameters exist during max workload. If NH3 value after 150m sprint can be used as a predictor of 200m and 400m sprinters needs further studies.

ACUTE EFFECTS OF WHOLE-BODY VIBRATION ON SPRINT RUNNING KINEMATICS IN SPRINT ATHLETES

GERAKAKI, M., PARADISIS, G., TZIORTZIS, S.

UNIVERSITY OF ATHENS

Introduction: Whole-body vibration (WBV) is a neuromuscular training method and has been promoted as an alternative or additional strength training method. The focus of many investigations was to determine the acute impact of a bout of whole-body vibration on athletic performance and the concerning parameters. Additionally, acute exposure to WBV, has been shown to induce transient increases in strength and power (Bosco et al, 1999) and has been suggested as a mode of warming up before practice, training and competition activities of athletes (Bazett-Jones et al., 2008). The aim of this study was to investigate the acute effects of WBV on sprint running kinematics in sprint athletes. The main hypothesis was that a single session of WBV would cause neuromuscular enhancement and improvement on sprint performance.

Methods: The participants were 35 sprint athletes (21.9 ± 4.3 yrs, 176.7 ± 5.1 cm, 72.3 ± 7.5 kg) (personal 100m best time: 11.00 – 11.50 s, training experience > 3 yrs). The participants were randomly assigned into the experimental (E – with vibration) and control (C – without vibration) group. Both groups performed a single session of WBV consisted of two dynamic exercises (half squat / lunge) for total duration time of 90 s (Power Plate platform - 50Hz, 2mm). Sprint performance tests were performed from both groups, before (pre) and after (post) the WBV session and measured during a 60 m sprint. The time and average velocity at distances of 10, 20, 30, 40, 50 and 60 m were obtained using the Brower timing systems (Brower, USA) where the step length and step rate of the distance interval 40–50 of each participant was recorded by a video camera (Sony–HDR SR10E) and calculated using the Peak Motus. Data were analyzed with descriptive statistics (mean, SD) and with t-test in order to examine the differences between the two groups (E & C) and between the pre-post performance tests. The significance level for the tests was set at 0.05 ($p < 0.05$).

Results: The results showed that a single session of WBV had no effect in both E & C groups on 60m sprint performance. Despite this, time in 50 m increased significantly 0.87% ($t = 2.116$, $p = 0.49$) (pre: 6.35 ± 0.24 s, post: 6.41 ± 0.24 s) and running speed decreased significantly 0.90% ($t= 2.202$, $p = 0.041$) (pre: 7.88 ± 0.31 m/s, post: 7.81 ± 0.30 m/s) for the E group. The step length and step rate in 40 – 50m interval did not affected for the E group, instead of the decreased running speed (pre: 2.34 ± 0.22 cm - 4.01 ± 0.32 Hz, post: 2.35 ± 0.18 cm - 3.95 ± 0.32 Hz).

Discussion: The results of this study, showed that 90 s of continuous WBV produced no improvement on sprint running performance of 60m sprint, although it produced significant changes in the time (0.87%) and the running speed (-0.90%) of 50m sprint. The step length and the step rate in 40-50m interval were not affected.

ANTHROPOMETRIC CHARACTERISTICS AND BASIC MOTOR ABILITIES DIFFERENTIATING YOUNG FEMALE SPRINTERS FROM THE GIRLS IN THE GENERAL POPULATION

RAKOVAC, M., BABIC, V.

UNIVERSITY OF ZAGREB, FACULTY OF KINESIOLOGY

Introduction: Timely selection of talented children and early sports specialization are indispensable for achievement of top sports results. Identifying anthropometric and basic motor characteristics of sufficient predictive value to be used in selection of athletes most likely to succeed is necessary within the sports talent identification process.

Based upon a large-scale testing of the girls aged 11 to 13 years in the city of Zagreb, in which the girls most gifted for athletic training were identified and selected according to the results of the 60m run test, the aim of this study was to determine the differences in anthropometric characteristics and basic motor abilities between the talented girls and non-selected girls.

Methods

The study sample was drawn from the population of 8184 girls aged 11 to 13 years, all pupils of the 5th and 6th grades of elementary schools in Zagreb, which were previously tested by means of the 60m run test in order to identify and select the ones most gifted for athletic (sprint) disciplines.

Our final sample consisted of 189 girls, divided in two groups: selected/talented girls (N=85) and randomly picked non-selected girls (N=104). Six anthropometric measures (body height, body weight, leg length, shoulder width, upper arm circumference in relaxed position, upper arm skinfold) were taken, and 8 basic motor ability tests (agility, polygon backward, hand tapping, standing long jump, medicine ball throw, flexibility, 60' sit ups, bent arm hang) were performed.

Discriminant analysis was carried out to determine the differences in the measured variables between the two groups.

Results: The differences between the two groups were statistically significant ($p<0.001$). The anthropometric characteristic significantly negatively related to success in sprint running was upper arm skinfold (.30). The motor ability tests that most strongly differentiated the two subject groups were: standing long jump (.87), polygon backward (.48), agility (.45), medicine ball throw (.43) and bent arm hang (.40).

Discussion: The girls selected for athletic training based upon their successfulness in the 60m sprint test differed significantly from the non-selected girls. The most highly differentiating anthropometric measure was upper arm skinfold, accentuating the negative relationship between the body fat percentage and sprint running results. Motor ability tests representing speed and explosive power (standing long jump, polygon backward, agility, medicine ball throw, and bent arm hang) were good predictors of sprint results. It is suggested to consider these tests in the selection of 11 to 13-year old children potentially gifted for the sprint disciplines.

MORPHOLOGICAL CHARACTERISTICS AND SPECIFIC MOTOR ABILITIES DIFFERENTIATING YOUNG FEMALE SPRINTERS FROM THE GIRLS IN THE GENERAL POPULATION

BABIC, V., RAKOVAC, M.

UNIVERSITY OF ZAGREB

Introduction: Elite level sport is extremely selective and exclusive. Orientation, identification and selection of the individuals with potential to succeed start very early. Most of the children are usually discouraged in later years. Anthropometric measures and specific motor abilities should be among the predictive variables used in talent identification protocols to select athletes most likely to excel.

Based upon a large-scale testing of 8184 girls aged 11 to 13 years in the city of Zagreb, in which the girls most talented for athletic training were selected according to the results of the 60m run test, the aim of this study was to determine whether there are differences in anthropometric characteristics and specific motor abilities between the talented girls and non-selected girls.

Methods: The sample included 189 girls (a group of 85 selected/talented and 104 randomly picked non-selected girls from the population of 8184 girls previously tested by means of the 60m run test) aged 11 to 13, from a pupil population of the 5th and 6th grades of elementary schools in Zagreb. A set of 6 morphological measurements (body height, body weight, leg length, shoulder width, upper arm circumference in relaxed position, upper arm skin fold) and 8 specific motor ability tests (long jump, standing long jump, 20 m run, 2 kg medicine ball throw, 30 m single leg jumps evaluated as time needed to perform and as number of jumps (left and right leg)) were performed.

Discriminant analysis was carried out to establish whether there were statistically significant differences between the two groups.

Results: The differences between the two investigated group were significant ($p<0.001$). The tests contributing most highly to the successfulness in sprint running were: 20 m run (.80), standing long jump (.68), number of one leg jumps – left and right (.64), time in left leg jumps (.62), long jump (.61) and time in right leg jumps (.54). Upper arm skin fold showed a significant negative contribution (.23).

Discussion: It is well known that results in sprint depend on fast start reaction, ability to achieve speed and maintain it as long as possible until the finish line. According to different research findings, it is known that the motor abilities of explosive strength, coordination and quickness contribute mostly to successfulness in sprint. The results of our study show that all tests representing those motor abilities are statistically significant in discriminating girls successful in sprinting from the girls in the general population. Among the anthropometric measures, body fat tissue contributed negatively to sprint results. Mentioned tests could be used as predictors in protocols for identifying potential sprinters.

THE RELATIONSHIP BETWEEN RUNNING SPEED AND MEASURES OF VERTICAL JUMP IN PROFESSIONAL BASKETBALL PLAYERS

SHALFAWI, S., ENOKSEN, E., TØNNESSEN, E.

BODØ UNIVERSITY COLLEGE; NORWEGIAN SCHOOL OF SPORT SCIENCES

Objective: To examine the relationship between leg-power, jumping height, and reactive strength as measures of jumping performance with sprint speed over 10-m, 20-m, and 40-m. These distances are considered to be indicative of starting speed, initial acceleration, and maximum sprinting speed capabilities, respectively, of the athlete.[1,2]

Participants: Thirty three male professional basketball players who have been professionals for at least two years.

Design: The subjects were tested on 10-m, 20-m, and 40-m sprint, counter-movement jump (CMJ), and static vertical jump (SJ). Jumping height, peak power, and reactive strength were obtained from the measurements of CMJ and SJ. All participants have been involved in intensive resistance and sprint training three times a week, and were considered to be in peak condition at the time of testing. Tests were carried out in an inside court, which was 70-m in length and 40-m in width.

Results: The results indicate that there was a marked relationship between sprinting speed and measures of peak power relative to body mass ($P<0.05$), but no marked relationship with peak power in absolute terms. Measures of jumping height had a marked relationship with sprinting speed in both absolute terms and relative to body mass. None of the reactive strength measures had a notable relationship with sprinting performance. Furthermore, the results showed that concentric contraction is of greater importance for starting and acceleration speed from zero to 10-m than for acceleration and top speed through 20-m to 40-m. And the eccentric followed by concentric contraction was of greater importance for the top running speed from 20-m to 40-m than for start and acceleration speed. However, the results indicate that the more the athlete increases in acceleration speed, the more important relative power becomes to performance during acceleration.

Conclusions: The results of this study indicate that while there is a strong and marked relationship between 10-m, 20-m and 40-m sprint, there is also a considerable variation within the factors that contribute to performance over these distances. This may indicate that, separate training strategies could be implemented to improve running speed over these distances. Furthermore, it is recommended that when attempting to increase running speed, special attention should be paid to power per kilogram of body mass of the athlete. However, strength and conditioning coaches may need to implement a concentric only and stretch shortening cycle jump squat testing battery to better analyze and plan the sprint and resistance training.

TRAINING CHARACTERISTICS OF NORWEGIAN JUNIOR CROSS COUNTRY- AND TRACK RUNNERS ON EUROPEAN TOP LEVEL

TJELTA, L.

UNIVERSITY OF STAVANGER

Purpose: To describe training characteristics of the four 2008 Norwegian best cross country- and long distance junior runners (17,8 +/- 1 year). The subjects won the team competition in the Nordic Championship 2008. They were second in the team competition in the European Cross Country Championship 2008 (finishing no 2, 10, 16 and 20). These runners were also the best junior runners in Norway on distances from 1500m to 5000m. Their average time on 3000m was 8.19:01 +/- 4:99 sec. One of them was Junior World Champion in mountain running in 2008, and one was Norwegian Junior Champion in cross country skiing. Methods: The runners filled out questionnaires about their training habits, training history and training characteristics. They and their coaches were also interviewed. Results: During the build up period for the season 2008 they ran 130 +/- 32 km/week-1. This was done in 11 +/- 2 sessions. 80 +/- 3 % of their weekly training distance (km/week-1) was continuous running with a heart rate (HR) between 60-75 % of maximum. Two to four weekly sessions were done as interval sessions with a HR between 80 - 90 % of maximum. The total distance at these intensities in each interval session was between 8 and 14 km (26 to 47 min). During the competition season the total weekly running distance was 105 +/- 24 km/week-1. One to three sessions a week during the competition period were races or training at specific race paces. In the competition period they all ran from one to three interval sessions of the same kind as in the building up period. The training in the three last months before the European Cross Country Championship was very similar to the training in the building up period, although the volume was a little higher (140 +/- 37 km/week-1). They competed in 23,8 +/- 6,8 track and cross country competitions in 2008. Three competed in skiing during the winter. All the runners conducted general strength training. They have been trained for distance running for 4 +/- 2,2 years. Most of their training they did alone, but all preferred to do the interval sessions in a group. In 2008 three of four tested VO2max, and the average was 79,2 +/- 4,8 ml • kg-1 • min-1. All four have background from other sports. All have personal coaches. Conclusions: Among the best Norwegian junior runners and their coaches there is a consensus that a high weekly training volume based on continuous running combined with two, three or four interval sessions a week during the building up period is a success factor. The best Norwegian cross country junior runners were also the best track runners. The way these junior runners train are founded upon training principles which have been successful for outstanding Norwegian runners like Grete Waitz, Ingrid Kristiansen, Marius Bakken and Susanne Wigene.

ANALYSIS OF A SPRINT QUALIFICATION ROUND IN CROSS-COUNTRY SKIING USING A DIFFERENTIAL GLOBAL NAVIGATION SATELLITE SYSTEM

ANDERSSON, E., SUPEJ, M., HOLMBERG, H.C.

SWEDISH WINTER SPORTS RESEARCH CENTRE, MID SWEDEN UNIVERSITY, SWEDEN; UNIVERSITY OF LJUBLJANA, LJUBLJANA, SLOVENIA; SWEDISH OLYMPIC COMMITTEE, STOCKHOLM, SWEDEN

Introduction: Cross-country (XC) skiing is a sport that comprises many different skiing techniques, between which skiers must continuously swap during a race, depending on the course topography (Holmberg, 2005). In freestyle XC skiing there are five different techniques, called gears (G1-5) (Rapp et al., 2009). A new opportunity for more specific performance analyses of the skier's speed, accelerations and positions is provided by the Differential Global Navigation Satellite System operating Real Time Kinematic corrections (DGNSS RTK).

At present, there are no studies that have analyzed sprint XC skiing in the field combined with the use of video cameras that are synchronized with a DGNSS. The aims of the present study were: 1) to make a descriptive analysis of skiing kinematics, frequency and duration at specific gears during a sprint qualification race in freestyle XC skiing, 2) to evaluate the influence of short sprint (Vmax) abilities versus overall performance in a sprint race.
Methods: Nine Swedish male elite XC skiers (four of them top world class skiers), specialized in the sprint or the distance events, volunteered as subjects in the study (mean ± SD: age 25.9 ± 3.5 yr, height 180.7 ± 5.4 cm, weight 74.5 ± 6.2 kg, VO2max 5.5 ± 0.6 l/min and 73.3 ± 5.8 ml/kg/min). The study started with a measurement of the subject's aerobic capacity in the laboratory, followed by specific sprint tests on snow. These were: 1) two 20-m Vmax tests performed in the G3-technique, 2) two 20-m Vmax tests performed in the double poling (DP) technique and finally 3) an individual race over 1425 m.
Results: The mean frequencies at specific gears were: G2 1.02 ± 0.05; G3 0.66 ± 0.04; G4 0.72 ± 0.07; G5 1.07 ± 0.08 Hz. The mean distributions (%) of total race time at specific gears were: G2 16.9 ± 9.3; G3 36.2 ± 7.7; G4 3.2 ± 2.9; G5 18.3 ± 3.2; "G6" (curve technique) 13.1 ± 1.1; "G7" (downhill standing) 9.9 ± 2.2%. There was a significant correlation between DP-Vmax and race time (r = -0.71, P = <0.05). DP-Vmax correlated positively with the skier's percent of race time at G3 and negatively with the skier's time at G2 (G2: r = - 0.83, P = <0.05, G3: r = 0.71 P = <0.05). Flying G3-Vmax correlated with the skier's sprint rank (FIS) (r = - 0.73, P = <0.05).
Conclusions
The main findings were 1) there was a great range in the choice of skiing technique, G3 or G2, between skiers in the uphill sections, 2) A high Vmax is of importance for success over sprint distances and the DP-Vmax correlations verifies the importance of the upper body in freestyle sprint XC skiing.

MAIN DIFFERENCES BETWEEN DISTANCE AND SPRINT WORLD-CLASS CROSS-COUNTRY SKIERS

FABRE, N., BORTOLAN, L., PELLEGRINI, B., SCHENA, F.
UNIVERSITY OF TRENTO

Introduction: The best predictors of a cross-country skiing sprint performance have already been studied (1,2). However and to our knowledge, specialists of sprint and distance races have never been compared. The purpose of this study was to determine the main physiological and biomechanical differences between distance and sprint cross-country skiers. Methods: Ten elite male skiers from the national Italian ski team [6 from the world-cup distance group (D) and 4 from the world-cup sprint group (S)] were evaluated on the basis of a roller-skiing test on treadmill using the double poling technique. The start speed was fixed at 10 km/h and increased by 0.5 km/h every 30-sec work period until exhaustion with a constant inclination of 6%. Oxygen uptake was continuously measured. Biomechanical data [maximal poling frequency and maximal poling force (Fmax)] were obtained using load cells inserted under the poles handgrips. The total power output was calculated across each speed as the power required to overcome rolling resistance and to lift the body against gravity. Results: Body-weight (BW) and Fmax were significantly higher (P<0.05) for the group S (78.5±5.8 kg and 156.0±9.8 N, respectively) compared to the group D (70.0±5.0 kg and 136.4±13.7 N, respectively). S and D groups did not significantly differ in peak oxygen uptake (4.4±0.4 L/min and 4.8±0.4 L/min, respectively), maximal power (328.4±21.2 W and 330.1±25.7 W, respectively), maximal poling frequency (63.9±4.4 cycles/min and 68.0±5.9 cycles/min, respectively) and Fmax/BW (2.0±0.1 N/kg and 2.0±0.1 N/kg, respectively). When peak oxygen uptake (VO2peak) and maximal power (Pmax) were expressed relatively to BW, values of the S group (56.3±4.3 mL/min/kg and 4.2±0.3 W/kg, respectively) were significantly lower (P<0.01) than the values of the D group (70.8±2.9 mL/min/kg and 4.7±0.1 W/kg, respectively). Finally, among the parameters measured during this test, Fmax appeared as the best predictor (irrespective to the S or D group) of sprint racing performance (estimated by means of the specific sprint International Ski Federation ranking). The correlation showed that 70% of the variability of the performance in sprint races could be explained by absolute Fmax (r2=0.70). Discussion: The higher BW and Fmax appeared to be the main different parameters (among those measured with this kind of test) between a sprint and a distance specialist in cross-country skiing. Moreover, BW-to-power (aerobic and mechanical) ratio was optimized in distance skiers. Expressed in absolute value, no difference was observed in VO2peak between sprint and distance skiers. Thus, as suggested by Stogll T. et al., the sprint performance seems to be mainly dependent of muscular factors but a high aerobic capacity is a prerequisite.

POLING FORCES AND BREATHING INTERACTIONS DURING A DOUBLE-POLING TIME-TRIAL TEST

FABRE, N., BORTOLAN, L., PELLEGRINI, B., SCHENA, F.
UNIVERSITY OF TRENTO

Introduction: This study mainly aimed to assess the interactions between locomotion and ventilation during a roller-skiing time-trial on treadmill using the double poling technique, on a breath-by-breath and poling-by-poling basis. Methods: Six (2 women and 4 men) well trained cross-country skiers performed a time-trial test roller-skiing on a motor driven treadmill and using the double-poling technique. The treadmill slope was fixed at 4% and the speed corresponded to 90% of the maximal speed achieved during a previous incremental double-poling test to exhaustion. Ventilatory flow was continuously collected by directly acquiring the optoelectronic signal from the turbine flowmeter of a portable metabolic system. Poling signal were obtained using load cells inserted under the poles handgrips. Both signale were acquired at 100Hz and synchronized together. Instantaneous breathing frequency (IBF) for each breath was calculated as the inverse of the breath duration. Instantaneous poling frequency (IPF) was similarly calculated from the poling signal. Entrainment was assessed by calculating the ratio of each IBF to the corresponding IPF. Cycles were considered to be entrained when the computed ratio was ±10% of an integer value. The data were then divided into entrained and unentrained groups, irrespective of the subject. Results: A total number of around 1700 breathing and poling cycles were collected, of whom, 4% were considered unentrained. IBF/IPF ratio was always closed to the integer value one. An important variability (i.e., high standard-deviation value) in the difference between the time at the onset of expiration phase and the time at the peak poling force (PPF) has been observed for the unentrained cycles (0.07±0.37 sec) compared to the entrained cycles (0.07±0.12 sec). Non-parametric tests (Kruskal-Wallis followed by Dunn's multiple comparisons)

showed that the PPF, the mean poling force over the poling phase (MPF) and the tidal volume (VT) were significantly higher (P=0.014, P=0.004 and P=0.012, respectively) when breathing and poling rhythms were entrained (2.66±0.47 N/kg, 1.12±0.13 N/kg and 2.16±0.41 L, respectively) compared to when they were unentrained (2.49±0.57 N/kg, 1.07±0.17 N/kg and 1.99±0.57 L). IPF was not significantly different between the entrained and unentrained groups (0.87±0.13 Hz and 0.93±0.21 Hz, respectively, P=0.146) whereas IBF was lower (P=0.013) for the entrained group compared to the unentrained one (0.87±0.13 Hz and 0.96±0.30 Hz, respectively). Discussion: The evident coordination (i.e, IBF/IPF ratio closed to one and low % of unentrained cycles) observed between ventilation and locomotion rhythms in the present study confirmed the findings of a previous study with the skating technique (1). More interestingly, these results emphasized the negative influence of unlocked locomotor and ventilatory rhythms on both breathing and poling patterns.

EFFECTS OF GENERAL FORCE CHARACTERISTICS ON TOP SPEEDS IN CROSS-COUNTRY SKIING

MIKKOLA, J., LAAKSONEN, M.S., HOLMBERG, H.C., VESTERINEN, V., NUMMELA, A.

MID SWEDEN UNIVERSITY, SWEDEN / KIHU-RESEARCH INSTITUTE FOR OLYMPIC SPORTS, FINLAND

Due to high racing speeds in cross-country skiing sprint (XCSS) the proportional use of V2 technique in free technique XCSS competitions is stressed. When using V2 technique most of the propulsive force is produced by upper body (Smith 2003) and therefore, the neuromuscular characteristics, especially in the upper body, are emphasized. To test neuromuscular and anaerobic abilities in runners, Rusko et al. (1993) have developed maximal anaerobic running test (MART), which have been later modified to XCS (Mikkola et al. 2007). The purpose of this study was to investigate the relationships between general force-velocity characteristics and sport specific speed as well as anaerobic performance when using V2 technique in XCS. Sixteen high level male XC skiers performed two sport specific tests on roller skies using V2 technique on a flat indoor tartan track: 30 m maximal skiing speed test (v30) and maximal anaerobic skiing test (MAST, 10 x 150 m with increasing speed / 100-s recovery). In MAST, the maximal velocity (vMAST) and maximal blood lactate concentration (LAmax) were determined. In addition, power (at 50% of 1RM) and maximal (1 RM) force production of lower and upper body by leg press (LP) and bench press (BP) were determined. Maximal isometric trunk extension (FTE) and flexion (FTF) forces were measured using a specific dynamometer. vMAST correlated strongest with the v30 ($r = 0.84$), FTF ($r = 0.77$) and 1 RM BP ($r = 0.75$) ($p<0.001$). Also BP power ($r = 0.70$, $p<0.01$) and FTE ($r = 0.62$, $p<0.05$) correlated significantly with vMAST. Respectively, the strong correlations between v30 and FTF ($r = 0.84$) and FTE ($r = 0.83$) ($p<0.001$) were observed. In addition, v30 correlated significantly with BP power (0.78, $p<0.001$) and BP 1RM ($r = 0.64$, $p<0.01$). Only weak, non-significant correlations between vMAST and LAmax ($r = 0.15$) as well as between LP variables and vMAST or v30 ($r < 0.48$) were observed. This study suggests that not only specific, but also general force-velocity characteristics, especially in trunk and upper body, are important determinants of maximal speed and anaerobic performance in V2 technique on flat terrain. The present results are in line the study of Stöggl et al. (2007) indicating the strong connection between XCSS performance and specific explosive strength and maximal power. Thus, neuromuscular characteristics of the upper body may be crucial especially in XCS sprint which includes short sprints and skier against skier actions. In addition, the present correlations between v30 and vMAST (strong) and between vMAST and LAmax (weak) indicate that in XCS neuromuscular and technical aspects may limit the top velocities (in MAST) more than metabolic characteristics.

STRAIGHT SPRINTING IS THE MOST DOMINANT ACTION IN GOAL SITUATIONS IN PROFESSIONAL FOOTBALL

FAUDE, O., KOCH, T., MEYER, T.,2

1. UNIVERSITY OF SAARLAND, 2. UNIVERSITY PADERBORN

Speed and power abilities are considered important determinants of successful football players. However, this assumption is largely based on plausibility, because power and speed are suggested to be relevant in decisive situations in football games. Surprisingly, only scarce scientific data is available substantiating this view. The present study aimed at analysing the influence of speed and power in goal situations in professional football by means of video analyses.

During the second leg of the season 2007/08 videos of 397 goals in the first German national league were analysed by visual inspection. For the assisting as well as the scoring player the situations directly preceding the goal were evaluated by visual video analysis. The observed actions were categorised into the following main categories: no powerful action, rotation (around the body´s centre-line), straight sprint, change-in-direction sprint (> 50 degrees from straight sprint line), jump, or a combination of those categories (intra- and inter-rater-reliability: kappa coefficients between 0.67 and 1.00).

For 315 goals (79.3%) at least one powerful action of either the scoring or the assisting player was observed. 31 goals (7.8%) resulted directly from a standard situation. In 226 of 366 goals (61.7%) at least one powerful action (total N=262) of the scoring player was observed. The majority of those actions were straight sprints (N=161, Chi-square test: $p<0.001$ compared to other categories) followed by jumps (N=57) as well as rotations and change-in-direction sprints (N=22 each). Most straight sprints were conducted without an opponent (N=109, $p<0.001$) and without the ball (N=121, $p<0.001$). The most frequent combination of powerful actions was a sprint followed by a jump (N=18). Similar results were obtained for the assisting player. 38 goals (10.4%) were assisted by a standard situation. In 195 of 328 goals (59.5%) at least one powerful action (total N=227) of the assisting player was observed. Again, the most dominant actions were straight sprints (N=155, $p<0.001$) followed by rotations (N=30), jumps (N=24) and change-in-direction sprints (N=18). Most of the straight sprints were conducted with the ball (N=93, $p<0.01$).

The present results show that straight sprints are the most important powerful actions in goal situations in professional football. It might be speculated that other power abilities which are shown to be of minor importance when scoring goals (rotations, change-in-direction sprints or jumps) may be more important in defensive situations where players must react on the opponent´s behaviour. However, this issue should be content of future research.

In conclusion, the results of the present study show that power and speed abilities are important in decisive situations in professional football. In particular, straight sprinting seems the most dominant action and, hence, should be included in fitness testing and training.

DOES PLYOMETRIC TRAINING IMPROVE STRENGTH PERFORMANCE? A META-ANALYSIS

SAEZ-SAEZ DE VILLARREAL, E., REQUENA, B.

UNIVERSITY PABLO DE OLAVIDE (SEVILLA)

Plyometric training (PT) improves strength performance. However, the effectiveness of PT depends upon various factors. A meta-analysis of 15 studies with a total of 24 effect sizes (ES) was carried out to analyze the role of various factors on the effects of PT on strength performance. The inclusion criteria for the analysis were: a) studies using PT programs for lower limb muscles b) studies employing true experimental design and valid and reliable measurements; c) studies including enough data to calculate ES. When subjects can adequately follow plyometric exercises, the training gains are independent of fitness level. Subjects in either good or bad physical condition, benefit equally from plyometric work, although men obtain similar strength results with women following PT. With relation to the variables of performance, training volume for less than 10 weeks and with more than 15 sessions, as well as the implementation of high intensities programs- with more than 40 jumps per session-, were the strategies that seem to maximize the probability to obtain significant greater improvements in performance ($p < 0.05$). In order to optimize strength enhancement, the combination of different types of plyometrics with weight-training would be recommended, rather than utilizing only one form ($p < 0.05$). However, no extra benefits were found to be gained from doing plyometrics with added weight. The responses identified in this analysis are essential and should be considered by the strength and conditioning professional with regard to the most appropriate dose-response trends PT to optimized strength gains.

NEUROMUSCULAR AND METABOLIC FATIGUE WITH THE SAME ABSOLUTE AND RELATIVE INTENSITY AFTER STRENGTH TRAINING

IZQUIERDO, M., IBAÑEZ, J., CALBET, J.A.L., GONZÁLEZ-IZAL, M., NAVARRO-AMEZQUETA, I., MALANDA, A., GONZÁLEZ-BADILLO, J.J., HÄKKINEN, K., KRAEMER, W.J., GOROSTIAGA, E.M.

GOVERNMENT OF NAVARRA

Introduction: Muscle hypertrophy (1,3), increases in maximal strength and power output (2-3) and enhanced agonist EMG activity (1,3) are typical adaptations during short-term heavy resistance training (i.e. 7-10 weeks). However, the effects of resistance training on dynamic exercise-induced fatigue with the same absolute and relative loading as in pretraining remain to be elucidated. This study examined the effects of heavy resistance training on dynamic exercise-induced fatigue task (5X10RM leg-press) after two loading protocols with the same relative intensity (%)(5x10RMRel) and the same absolute load (kg)(5x10RMAbs) as in pretraining in men(n=12).

Methods: Maximal strength and muscle power, surface EMG changes [amplitude and spectral indices of muscle fatigue], and metabolic responses (i.e.blood lactate and ammonia concentrations) were measured before and after exercise.

Results and Discusion

The main findings of this study were that after short-term heavy resistance training, when the relative intensity of the fatiguing dynamic protocol was kept the same 1) the magnitude of exercise-induced loss in maximal strength was greater than that observed before training, 2) the peak power lost after 5x10RMRel (58-62%, before and after training) was greater than the corresponding exercise-induced decline observed in maximal dynamic (23-34%) and isometric strength (12-17%), but this was followed by a more rapid and complete recovery, 3) the magnitude of the exercise-induced neuromuscular changes were similar than before training, as well 4) higher accumulation of blood lactate and ammonia concentration after training were observed. After a short-term strength training period, the main mechanisms responsible for the increased capacity to work with the same relative intensity are mainly of a peripheral nature, since similar neural adjustments but higher accumulated fatigue and metabolic demand (i.e. blood lactate and ammonia accumulation) were observed after multiple sets of dynamic fatiguing high-power contractions with the same relative load as in pretraining. This result may indicate that rate of fatigue development (i.e. power and MVC) was faster and more profound after training despite using the same relative intensity. The fact that the same relative loading leads to increased rate of fatigue development after training has important practical implications. This may suggest that despite the enhanced ability to produce maximal strength and muscle power after a strength training program, it is important to note that when prescribing training programs a similar relative load as in pretraining could lead to a greater rate of fatigue development and, therefore, may induce different training effects.

MAXIMAL DYNAMIC FORCE DEVELOPMENT IN THE SHOULDERS UNDER STABLE AND UNSTABLE CONDITIONS

RUSTAD, O., SEILER, S.

UNIVERSITY OF AGDER

Purpose: The use of surface instability has gained popularity in strength training. However, the impact of unstable conditions during training on functional changes in force production is not well established and methods of isolating instability to specific joint complexes are lacking. In this study we have quantified the impact of surface instability on maximal force development of the shoulder complex during a weight bearing (closed kinetic chain) push-up task. In addition, the test-retest reliability of maximal dynamic force measurements was quantified under both conditions.

Methods: 20 physically active university students (14 males, 6 females) performed 2 maximal dynamic force tests under stable and unstable conditions. Maximally explosive push-ups were performed on a force platform while holding push-up bars (Stable condition). This

condition was compared with the same movement while holding hand grips hanging from to slings attached to the ceiling (Unstable condition). Body angle and hand width were identical under both conditions. The slings were equipped with force transducers and unilateral peak force production was summed. Movement was initiated from an outstretched position, lowering to 90 degrees elbow flexion and explosive extension. Subjects performed 3 series of 3 maximal efforts for each test, on two separate days separated by 48 hours or more. Pearson r were used to investigate test-retest correlation, Paired Samples T-test were used to evaluate potential learning effects, while Coefficient of Variation was used to estimate typical variation. The results from test day 2 were used to quantify the impact of instability on maximal force.

Results: Test-retest comparisons showed no systematic bias for either condition from day 1 to day 2. Test results were highly correlated (r= 0.94 and 0.90 for stable and unstable conditions respectively). Coefficient of variation was 8% for the stable test and 5% for the unstable test. Unstable conditions resulted in a 30% reduction in peak force compared to stable conditions (1061 ± 414 vs. 743 ± 148 N, $p<0.01$).

Conclusions: This study demonstrates that unilateral instability directly applied to the shoulder complex results in a loss of maximal force of approximately 30% during a dynamic maximally explosive push-up. The test methods employed are reliable and establish a model for quantifying the impact of specific training interventions on stable vs. unstable force production in the shoulder girdle.

ANALYSING TRAINING EFFECTS ON PERFORMANCE IN STRENGTH TRAINING BY MEANS OF TWO DIFFERENT ANTAGONISTIC MODELS

PFEIFFER, M., FEHR, U., VOIGT, L.

UNIVERSITY OF BAYREUTH

Introduction: Initially, Banister et al. (1975) proposed describing the relationship between training and performance by means of two antagonistic functions: Fitness as a positive and Fatigue as a negative response to training (FF-Model). In the recent past another antagonistic model, the PerformancePotential-Model (PerPot), has been developed by Perl (2001). In an endurance training study, model fit and prediction accuracy of the models were satisfactory (Pfeiffer, 2008). However, the PerPot showed better results. To compare the two models with regard to some critical considerations a study in the field of strength training was carried out.

Methods: Two male and two female subjects volunteered for an 8-wk course of strength training (monolateral biceps-curls and leg extension). The training (input) was measured by force plate/sensor and quantified as force impulse (Ns). Before each training performance (output) was determined as peak power (N), generated in a Maximal Voluntary Contraction (MVC). Intraclass Correlation Coefficient (ICC) and mean relative deviation (RD, %) between modeled and real performances were calculated for each subject, exercise, and left/right extremity (16 data sets) to verify model adequacy. Based on the model parameters and the training load, the performances of the last two weeks were simulated individually. Prediction accuracy was estimated by mean relative deviation between predicted and real performances of the last (RDp1, %), and last two weeks (RDp2, %).

Results: A significantly better average model adequacy was achieved by PerPot (ICC: $M = .73$, $SD = .16$; RD: $M = 3.68$, $SD = 1.46$) in comparison to the FF-Model (ICC: $M = .67$, $SD = .28$; RD: $M = 4.29$, $SD = 1.96$), ICC: $t(15) = -2.2$, $p = .045$; RD: $t(15) = 3.3$, $p = .005$. The prediction accuracy for the final one and two weeks was also higher for PerPot (RDp1: $M = 3.93$, $SD = 2.86$; RDp2: $M = 4.67$, $SD = 2.93$) compared with the FF-Model (RDp1: $M = 5.97$, $SD = 3.53$; RDp2: $M = 5.96$, $SD = 3.98$), RDp1: $t(15) = 2.7$, $p = .015$; RDp2: $t(11) = 2.3$, $p = .040$.

Discussion: Our findings confirm better results for PerPot as reported by Pfeiffer (2008). They were not in line with Ganter et al. (2006), who in a field study (cycling) proposed a lower prediction quality for PerPot. Local delay optimizations suggest that in cases of lower model adequacy there are two different phases of time delay on training.

HORMONAL BALANCE AND ENERGY BALANCE IN BODYBUILDERS BEFORE COMPETITION

Jarek Mäestu1, Eliakim Alon2, Jaak Jürimäe1, Toivo Jürimäe1

1-Institute of Sport Pedagogy and Coaching Sciences, Centre of Behavioral and Health Sciences, University of Tartu

2-Department of Pediatrics, Meir Hospital, Kfar Saba, Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel

Most of the time of the year bodybuilders spend in the hypertrophy phase, where the aim is to gain and to increase the muscle mass. During the special preparatory period before the competitions bodybuilders aim to reduce their subcutaneous body fat to minimum in order to enhance muscular definition (Newton et al. 1993). This can be obtained by negative energy balance in the body through restricting energy intake and increasing energy expenditure. However, no studies have investigated the energy expenditure of a bodybuilder during the preparation for the competition. This would allow the calculation of the energy balance and the anabolic-catabolic hormonal balance that are critical for maintenance muscle mass during severe weight restriction period.

The aim of this study was to determine the simultaneous effect of caloric intake, energy expenditure and the biochemical parameters that affect the anabolic-catabolic balance in male bodybuilders during their preparation for a target competition.

Fourteen male bodybuilders took part in 11 week energy restricted study. The subjects were divided into the energy restricted group (EG) (n=7) who were preparing for the competition, aiming to reduce their body fat percent and into the control group (CG) (n=7) who continued to train regularly and did not change their dietary or training pattern. Participants were tested 11 weeks (T1), 5 weeks (T2) and 3 days (T3) before competition for diet, body composition and fasting hormonal assessment. Body mass and body fat percentage of EG were significantly ($P < 0.05$) decreased during the study period. In EG, IGF-1 and insulin decreased significantly during the 11 week weight reduction period ($P < 0.05$). Testosterone was decreased only from T1 to T2 (from 20.3±6.0 to 18.0±6.8 nmol/L). Changes in IGF-I concentration were significantly related to changes in insulin (r=0.741), fat mass (r=0.705), lean body mass (r=0.696) and body mass (r=0.652).

Changes in insulin concentrations were significantly related to changes in fat mass (r=0.630) and lean body mass (r=0.725). It was concluded that severe energy restriction to extremely low body energy reserves decreases significantly the concentrations of hormones of the three anabolic pathways despite relatively high protein intake. Monitoring of insulin and IGF-1 concentration is suggested in order to prevent losses in muscle mass in energy restricted conditions.

CHANGES IN MUSCLE POWER FATIGUE AND SEMG PARAMETERS DURING DYNAMIC FATIGUING CONTRACTIONS

GONZALEZ-IZAL, M., MALANDA, A., NAVARRO-AMEZQUETA, I., GOROSTIAGA, E., MALLOR, F., IBAÑEZ, J., IZQUIERDO, M.

PUBLIC UNIVERSITY OF NAVARRE AND RESEARCH, STUDIES AND SPORT MEDICINE CENTER, GOVERMENT OF NAVARRA

Introduction: Several surface electromyography (sEMG) techniques have been applied to assess muscle fatigue. Although dynamic contractions are more relevant to daily function, many of the studies have used isometric ones due to the technical limitations of sEMG (2). The purpose of this study was to examine changes on muscle power output and sEMG parameters during a dynamic fatiguing protocol.

Methods: 15 physically active males performed 5 sets consisting of 10 repetition maximum leg press, with 2 minutes of rest between sets. Mechanical power output and bipolar sEMG from vastus medialis (VM), and lateralis (VL) and biceps femoris (BF) were recorded. Different sEMG parameters were obtained: Mean average voltage (MAV), median spectral frequency (Fmed), Dimitrov's spectral index (FInsm5) (1), negentropy index to describe the non-gaussianity of a distribution and others obtained from a time-frequency analysis (Choi-Williams distributions) such as mean (MFM) and variance (MFV) of the instantaneous frequency and frequency variance (FV). FInsm5 was log-transformed because it did not follow a normal distribution.

Results: Significant (P<0.05) muscle power output and Fmed (averaged for VM and VL) decrements were found between the last 5 repetition of each set and the first 5 repetition of the protocol. In contrast, significantly (P=0.06) MAV (averaged for VM and VL) increments were found between the last 5 repetitions of each set as well as the first 5 repetitions of the 4th and 5th sets, and the first 5 contractions. Significantly (P<0.05) log-FInsm5 (averaged for VM and VL) increases were found between the last 5 repetitions of each set and the first 5 repetitions. However, the MAV of the BF significantly (P<0.05) increased only during the 5 repetitions of the last 1st, 2nd and 3rd sets compared to the neural activity recorded during the first 5 repetitions. The log-FInsm5 values of the BF recorded during repetitions of the 3rd, 4th and 5th sets were significantly higher (P=0.06) than those obtained from the first 5 repetitions of the 1st set. No significant differences were found between the Fmed values of the BF. A multiple regression analysis showed that the log-FInsm5 as a single parameter predictor accounted for 37% of the performance variance of changes in muscle power whereas the log-FInsm5 and MFM accounted for 44%.

Discussion: The main result of this study was that the log-FInsm5 provided an accurate and sensitive estimation of muscle fatigue during dynamic fatiguing contractions, more than the other sEMG parameters studied. According to the decrement obtained in BF neural activation, we can hypothesize that during fatiguing dynamic contractions, there was an inhibition of antagonist muscle activation to facilitate the development of muscle power output by agonist muscles.

RELIABILTIY OF ECCENTRIC AND CONCENTRIC 1 RM BENCH PRESS TESTS WITH FREE WEIGHTS

PATTERSON, C., PROELLER, A., GEIGER, D., PLATZER, H.P., RASCHNER, C.

UNIVERSITY OF INNSBRUCK

INTRODUCTION: Eccentric muscle contractions are important in sport. Eccentric strength training is very effective for athletes (2) and can be performed with free weights, but few scientific studies have investigated eccentric strength testing with free weights. Isokinetic testing of concentric and eccentric strength is reliable (1). Eccentric testing in the squat has been performed using a lowering duration of at least 3.5 s (2). The purpose of this pilot study was to compare 1RM in concentric and eccentric bench press and to determine if maximal concentric and eccentric bench press tests with free weights are reliable.

METHODS: 10 male members (23.5 ± 3.7 years, 105.6 ± 17.8 kg) of a semi-professional American football team were tested twice with 7 days between tests. The athletes performed concentric bench press (BPC) and eccentric bench press (BPE). BPC was performed with a 4 s lowering phase to the chest, followed by immediate (no bounce off the chest) pressing of the bar to a locked elbows position. EBP was performed with the bench attached to a force plate and the bar was lowered with constant speed for at least 4 s. If the measured force changed by more than 50 N during the BPE test, the trial was invalid. For all tests the buttocks were always in contact with the bench. Paired t-tests were used to determine if BPE was greater than BPC. To assess test-retest reliability of these tests, intraclass correlation coefficients (SPSS) were determined for BPC and BPE, comparing the values from the first test to those of the second.

RESULTS: BPE was 124% and 123% of BPC for tests 1 and 2, and significantly greater ($p < 0.01$). The BPC results (kg) were (mean ± SD) 123.0 ± 19.2 and 127.0 ± 19.2 for tests 1 and 2, respectively. The BPE values were 152.5 ± 22.8 and 156.5 ± 21.9. The ICC's for BPC and BPE were: r = 0.96 and 0.98.

DISCUSSION: Comparisons between concentric and eccentric 1RM in the literature vary, depending on the lift and the method of testing. The present study showed BPE was almost 25% higher than BPC. It should be noted that the lowering phase of 4 s duration in BPC reduced the stretch shortening cycle but did not eliminate it, so BPC was not purely concentric. Perhaps further investigations to develop a concentric test are needed. The ICC's would indicate that the eccentric bench press test is reliable. Further work in this direction includes eccentric 1RM squat tests with free weights, and the development of a relatively simple and safe method for maximal eccentric strength training with free weights.

TIME TO EXHAUSTION DURING SUBMAXIMAL ISOMETRIC FATIGUING EXERCISE IS INCREASED AFTER WHOLE BODY VIBRATION TRAINING

COLSON, S.S., HÉBRÉARD, L., PETIT, P.D., TESSARO, J., PENSINI, M.

UNIVERSITY OF NICE-SOPHIA ANTIPOLIS

Introduction: The acute effects of exhaustive whole body vibration (WBV) exercise have been examined (Rittweger et al., 2000; 2003), However, only one study reports that WBV training prevents increases in fatigability during bedrest (Mulder et al., 2007). Therefore, the aim of this study was to examined the effect of 6 weeks of WBV training on knee extensor muscles endurance time during a submaximal isometric fatiguing contraction and mechanisms (i.e., central and/or peripheral) contributing to task failure.

Methods: 11 active males performed a fatiguing isometric contraction with the knee extensor muscles at 50% of maximal voluntary contraction (MVC) until exhaustion before (PRE) and after (POST) 6 weeks of WBV training. At PRE and POST, the electromyographic (EMG) activity and muscle activation obtained under MVC were recorded before and after the fatiguing task to assess central fatigue. Torque and EMG responses obtained under electrically evoked contractions were examined to analyze the peripheral fatigue.

Results: Knee extensor MVC torque did not increase significantly between PRE and POST (+9.4%, $P>0.05$), which meant that the average target torque sustained during the fatiguing contraction did not increased either between the testing sessions. Endurance time increased significantly in between PRE and POST (+29.6%; $P<0.01$). At PRE, a significant torque decreased (-17.3%; $P<0.01$) was found during MVC after the fatiguing contraction whereas no significant difference was observed at POST. EMG values of agonist muscles were differently affected by the fatiguing contraction, whereas antagonist muscle coactivation and overall knee extensor muscles activation were not modified. Differential effects on single-twitch contractile properties were observed after the fatiguing contraction between the testing sessions.

Discussion: Before the training period (PRE), the decrease of MVC after the fatiguing exercise seemed ascribable to a complex association of central fatigue and potentiation mechanisms (Rassier and MacIntosh, 2000). In contrast, after the WBV training period (POST), although the endurance time increased significantly, the MVC was not decreased anymore. This result suggests that knee extensor muscles fatigability was reduced (Mulder et al., 07). Our results suggest that, although peripheral adaptations could partly contribute to task failure, ischemic mechanisms might have also occurred. In conclusion, our WBV training was effective to increase the endurance time and to reduce the amount of fatigue at exhaustion.

LEG DOMINANCY, FAST ISOMETRIC TORQUE PRODUCTION AND SQUAT JUMP HEIGHT.

DE RUITER, C., DE KORTE, A., SCHREVEN, S., DE HAAN, A.,2

1. RESEARCH INSTITUTE MOVE, VU UNIVERSITY AMSTERDAM, THE NETHERLANDS, 2.INSTITUTE FOR BIOMEDICAL RESEARCH INTO HUMAN MOVEMENT AND HEALTH, MANCHESTER METROPOLITAN UNIVERSITY, MANCHESTER, UNITED KINGDOM

Introduction: In publications involving knee extensor dynamometry testing, it is common practice to indicate whether the dominant or the non-dominant limb was investigated, which suggests that limb-dominancy is an important performance determining factor. However, there are several indications in the literature that strength is not consistently higher in the dominant compared to the non-dominant leg. In principle strength differences between legs may be due to differences in the muscles themselves and/or be due to side dependent differences in neural activation. We set out to investigate this using electrical stimulation and hypothesized that there would be no differences between the dominant and non-dominant leg for maximal unilateral isometric knee extensor torque, the rate of torque development during maximally fast isometric contractions and unilateral squat jump performance.

Methods: Limb dominancy was established using the step up, balance recovery and ball kick test. On two days, 8 males (21.5±2.2 years, mean±SD) performed unilateral maximal isometric knee extensions (120° knee angle) with superimposed maximal electrical stimulation (femoral nerve, 3 pulses at 300Hz) to determine voluntary activation (VA) during MVC for both limbs. In addition, maximally fast isometric contractions and unilateral squat jumps starting from 120° knee angles (SJ120) were performed. Torque time integral over the first 40 ms after torque onset (TTI40) during voluntary and maximal electrical nerve stimulation (eight pulses at 300 Hz) was used to quantify the steepness of isometric torque rise.

Results: Limb dominancy tests were very consistent: 6 subjects were clearly right-legged and 2 left-legged. ANOVA repeated measures revealed no significant ($p>0.05$) effect of test day and none of the parameters was (or tended to be) significantly different between the dominant and non-dominant limb. The averaged values of the best attempts of both days for dominant and non-dominant legs respectively were: 217±16 and 225±25 Nm (MVC), 87±5 and 89±3 % (VA), 0.52±0.12 and 0.49±0.08 Nm.s (stimulated TTI40), 0.09±0.05 and 0.09±0.05 Nm.s (voluntary TTI40), 21.0±3.2 and 21.3±2.6 cm (SJ120). Between both limbs there were significant relationships for voluntary TTI40 ($r2=0.94$) and SJ120 ($r2=0.88$). In addition TTI40 and SJ120 were significantly related to each other for both limbs ($r2=0.69$ and 0.75).

Discussion: It was concluded that unilateral (fast) torque generating capacity, muscle activation and squat jump performance were very similar between limbs, but differed substantially among subjects, with high correlations between fast voluntary isometric torque development and jump height. These findings further challenge the concept of limb dominancy in dynamometry testing in sports and rehabilitation.

DOES WHOLE-BODY EXERCISE AFFECT RESPIRATORY MUSCLE FUNCTION? A STUDY OF VARIOUS ATHLETIC POPULATIONS.

TERBLANCHE, E., KROFF, J.

STELLENBOSCH UNIVERSITY

Introduction: There is no conclusive evidence that lung function and respiratory muscle (RM) function are affected by regular land-based exercise. It appears that swimmers possess greater lung volumes than predicted, yet results on respiratory muscle strength and endurance are discrepant. It is also known that significant morphological differences exist between competitive athletes and non-athletes. However, the same reference equations, which are primarily based on morphological characteristics, are used for athletic and non-

athletic populations to predict RM strength and endurance. The aim of this study was to compare the RM strength and endurance of various athletic populations and to establish whether current reference values are adequate to predict RM function in athletes.

Methods: One hundred and sixty subjects (aged 18 to 30 years) from eight different sport codes participated in this study. All athletes were well-trained at the time of the study. Maximal inspiratory pressure (MIP) was measured as an indication of RM strength and maximal voluntary ventilation in 12 seconds (MVV) was measured as an index of RM endurance. Kinanthropometric variables, such as stature, body mass, and various circumferences and breadths were included in the assessments.

Results: There were no significant differences in MIP, MEP or MVV between endurance and non-endurance athletes (MIP: 122 + 36 cmH2O vs 126 + 28 cm H2O; MVV: 168 + 34 L/min vs 186 + 32 L/min). Although swimmers had slightly higher MIP and MVV values than land-based athletes, the differences were not statistically significant. In all cases, athletes had superior respiratory muscle strength and endurance compared to age-matched sedentary controls. Multiple regression analyses revealed that gender, mesomorphy and exercise sessions per week predicted 35% (SEE = 26.6 cmH2O) of the variance in MIP, while gender, relative sitting height, FEV1 and PEFR predicted 78% (SEE = 18.2 L.min-1) of the variance in RM endurance (MVV).

Discussion: This is the first study to show that there are little differences in the RM function of endurance and non-endurance athletes, but swimmers are likely to possess superior RM function compared to other athletes. However, evidence exist that whole-body training does affect RM function, provided that the exercise and training is of high intensity. Importantly, we developed reference equations that provide more suitable reference values for athletes than previously reported.

EFFECTS OF 8 WEEKS OF HEAVY RESISTANCE CIRCUIT TRAINING VS. TRADITIONAL STRENGTH TRAINING ON PHYSICAL PERFORMANCE AND BODY COMPOSITION

ALCARAZ, P.E., PEREZ-GOMEZ, J., CHAVARRIAS, M., BLAZEVICH, A.J.

1. UNIVERSIDAD ALFONSO X EL SABIO, VILLANUEVA DE LA CAÑADA, MADRID, SPAIN, 2. UNIVERSIDAD DE EXTREMADURA, 3. UNIVERSIDAD CATÓLICA, 4. EDITH COWAN UNIVERSITY

INTRODUCTION: Circuit training effectively reduces the time devoted to strength training while allowing an adequate training volume to be achieved. Nonetheless, circuit training has traditionally been performed using relatively low loads for a relatively high number of repetitions, which is not conducive to maximal muscle size and strength gain. PURPOSE: To compare the effects of 8 weeks of heavy resistance circuit training (HRC) vs. traditional strength training (RT) on physical performance parameters, cardiovascular response and body composition. METHODS: Twenty-six healthy subjects with strength training experience were randomly assigned to a HRC (n = 15) (23.4 ± 4.0 years; 76.9 ± 9.5 kg; 177.5 ± 4.0 cm) or to a RT (n = 11) (22.8 ± 2.7 years; 73.1 ± 7.0 kg; 175.0 ± 6.9 cm). Training consisted of weight lifting 3 times a week during eight weeks. Prior to and at the end of the training program, maximum dynamic strength(1RM) on bench press and half squat exercises, peak power output in both exercises using resistances of 30%, 45%, 60%, 70%, and 80% of 1RM and body composition (DXA) were determined. In addition, a shuttle run was carried out. T-tests for dependent and independent samples were used (P ≤ 0.05). RESULTS: There were no between-group differences. The data confirm that upper limb (UL) and lower limb (LL) 1RM significantly increased in both groups (HRC = 19.5 ± 10.6 kg, and 44.2 ± 24.1 kg; and RT = 17.7 ± 9.0 kg, and 45.0 ± 21.3 kg, respectively). In addition, UL peak power at 30% and 45% of 1RM was significantly higher in post-test for the groups, and significantly higher at 70% and 80% of 1RM in RT group, while LL peak power was not increased significantly at none analyzed loads. Shuttle run test was significantly higher after the training in both the HRC and the RT groups (HRC = 29.6 ± 44.6 s vs. RT = 36.7 ± 48.8 s). Regarding body composition, significant decreases were found in the % body fat in the HRC group (1.53 ± 1.60%), and a tendency to signification (p = 0.082) was established in the RT (1.09 ± 1.87%). HRC also increased lean mass by 1.456 ± 1.945 kg (p=0.002), and RT increased lean mass by 1.179 ± 1.619 kg (p=0.036). CONCLUSION: The HRC and RT were effective methods to improve 1RM, peak power output, cardiovascular response and lean mass, while the HRC seemed to be more appropriate than RT for reducing % Body fat. ISOKINETIC PROFILE OF KNEE EXTENSORS AND FLEXORS AMONG PORTUGUESE ADOLESCENT ROLLER-SKATE [RS] HOCKEY PLAYERS BY LEVEL OF PRACTICE

SIMÕES VAZ, V., VALENTE DOS SANTOS, J., MOREIRA CARVALHO, H., GONÇALVES, R.S., PÁSCOA PINHEIRO, J., COELHO E SILVA, M.

FACULTY OF SPORT SCIENCE AND PHYSICAL EDUCATION, UNIVERSITY OF COIMBRA; SCHOOL OF HEALTH AND TECHNOLOGY, POLYTECHNIC INSTITUTE OF COIMBRA; MEDICAL SCHOOL, UNIVERSITY OF COIMBRA

Introduction: The ability to perform RS hockey specific skills is highly dependent of lower limb strength. The dynamic functionality of hamstrings and quadriceps muscles estimates the stability of the knee and is believed to be related with high performance levels (Aagaard et al., 2000). Isokinetic dynamometer provides a large number of parameters and is being used as one of the most informative and reliable assessments of muscle strength. The current study examines the effect of competitive level in the hamstrings-to-quadriceps ratio in adolescent RS hockey players.

Material and methods

The sample is composed by 63 subjects representing two distinct groups: Elite (n=32; 15.3±0.6 yrs, 6.6±0.9 yrs of practice), Local (n=31, 15.6±0.5 yrs, 6.2±1.2 years of practice). Muscle strength was assessed using a Biodex System 3Pro® isokinetic dynamometer. After a 8-min warm-up in a cycle-ergometer and stretching exercises, subjects performed 5 trials at 60°/s for hamstrings and quadriceps, concentric and eccentric modes, and the best peak torques of knee extensors [KE] and knee flexors [KF] were retained for analysis. Descriptive statistics and ANOVA were used to examine the isokinetic profile of elite and local players. Alpha level was set at 5%.

Results: When compared to their local peers, elite players attained better peak torque values, in the concentric modes of left KE [F=5.715, p<0.05], and of left KF [F=5.364, p<0.05]. H:Q ratio in the eccentric mode of the left lower limb was significantly higher for the local group [F=4.565, p<0.05]. No differences were found in the other isokinetic parameters.

Discussion/Conclusion

The results of the present analysis suggested that the elite RS hockey players perform higher absolute values in all strength variables of knee extensors and knee flexors under concentric and eccentric conditions. Results did not support evidence of muscular unbalances in both groups.

CHARACTERISTICS OF JUNIOR BASKETBALL TALENTS

STADTMANN, T., REMMERT, H., FERRAUTI, A.

RUHR UNIVERSITY OF BOCHUM

The aim of our project "Basketball-Talents" is to evaluate and optimize the U16 German basketball talent program. To analyze the output of the talent system a multidimensional performance assessment was designed. This assessment includes a physical condition testing, a psychological diagnostic, a sociological questionnaire, regularly training documentation and a questionnaire for coaches to evaluate the tactical and technical skills of the players.

The present study is focused on the results of the physical condition testing. In this study we compare the results of male (m) and female (w) players of the under 15 (U15) and under 16 (U16) age groups. Players are divided into two performance groups of regional selected (RS) and national selected players (NS). The sample sizes were: U15m (RS 127, NS 66); U16m (RS 57, NS 93); U15w (RS 68, NS 93); U16w (RS 39, NS 82). Additionally we highlight the results of a small elite sample of players selected for the national team (NT).

The following characteristics were analyzed: body height (bh), body weight (bw), range of arms (ra), 20 m sprint time (20 m), 20 m agility-run (20 ar), 20 m agility dribbling (20 ad), jump & reach (jr), chest pass (cp), mid distance shot precision (sp) and the multistage fitness test (mf). Selected results (mean values, standard deviation) of RS and NS were calculated and compared by using a t-test for independent groups.

NS players were significantly ($p<0.05$) taller and heavier and had a higher ra than RS players (U15m, U15w, U16w). NT players were even taller than NS players in boys (196±11 cm vs. 187±10 cm) and girls (183±7 cm vs. 175±7 cm). NS compared to RS players reached significantly better results in the basketball specific tests cp (U15m, U16m, U15w), sp (U15m, U16m, U15w) and ad (U16m, U15w). 20 m sprint and agility run performance did not differ clearly between RS and NS and showed a striking decrease in NT. Endurance performance in NT tended to be lower compared to NS.

We conclude that body height, body weight and range of arms in combination with the basketball specific skills seem to be important criteria for the selection of junior basketball players. General sprint and endurance capacity are of lower importance. On the other hand both factors are offering a further potential for an athletic improvement.

AN ANTHROPOMETRIC AND PHYSICAL COMPARISON BETWEEN MALE CHILDREN OF PRE-DURING-POST PEAK HEIGHT VELOCITY.

SIMPSON, B., DOUGLAS, A., PRICE, A., HILL, R.

ASPIRE

PURPOSE: Research has shown that inter-individual differences in performance and anthropometric measurements are present when boys of contrasting maturity status are compared (Beunen & Milana, 1988). The primary purpose of this study were to examine the differences between early to late maturing children in anthropometric and physical parameters by using age at peak height velocity (PHV) as a reference. PHV is the most commonly used indicator of somatic maturity during the adolescent growth spurt in height. METHODS: Measurements were collected during the first phase of ASPIRE's annual Talent Identification program in 2007 (128 males, age 14.5 + 0.3yr). All children were assessed on four anthropometrical (stature, sitting height, body mass and arm span), five physical tests (counter movement jump (CMJ), 40m sprint, medicine ball throw, distance throw, and the 20m MSFT). Self assessed training experience including years of training and amount of training per week were also collected. Children were grouped according to their current stage at PHV during the time of test. Groupings were constructed using 1 year intervals, pre PHV = -1.5 to -0.5yrs from PHV, during PHV =-0.5 to 0.5yrs from PHV and post PHV = 0.5 to 1.5yrs from PHV. Ages at PHV were predicted using a sex-specific regression equation as described in Mirwald, et al. RESULTS: Anthropometric differences between all PHV groups were found in stature, body mass and sitting height ($p<0.05$). When comparing leg length between pre- and during- PHV no differences were found, while post-PHV were significantly different to both groups ($p<0.05$). No differences were found between groups in counter movement jump, 40m sprint, distance throw and 20m MSFT. However, differences were found between all groups in the medicine ball throw ($p<0.05$). No differences were found between groups in years of training and amount of weekly training. CONCLUSION: Differences in stature, body mass and sitting height are in line with attained growth and velocities on a time axis relative to PHV. While assumed leg length could occur closer to PHV. The estimation for age at PHV formula was developed from longitudinal data of Canadian children and may not be of practical use for Middle Eastern children. Genetics, training experience, physical activity levels and nutrition status could be some of the primary reasons why little or no differences were found when comparing physical parameters.

THE EFFECTS OF BODY SIZE AND MATURATION ON AEROBIC POWER AMONG PORTUGUESE ADOLESCENT ROLLER-SKATE [RS] HOCKEY PLAYERS

VALENTE DOS SANTOS, J., SIMÕES, F., VAZ, V., CUPIDO SANTOS, A.M., CASTANHEIRA, J., FIGUEIREDO, A., COELHO E SILVA, M., FONTES RIBEIRO, C., ELFERINK-GEMSER, M., MALINA, R.6

2.FACULTY OF SPORT SCIENCE AND PHYSICAL EDUCATION, UNIVERSITY OF COIMBRA, 3SCHOOL OF HEALTH AND TECHNOLOGY,4.MEDICAL SCHOOL, UNIVERSITY OF COIMBRA,5.UNIVERSITY OF GRONINGEN,6.TARLETON STATE UNIVERSITY

Introduction: Research with Portuguese young athletes from team sports showed that mean heights and body masses of adolescent basketball players exceeded the age specific 75th percentiles of reference data (Coelho e Silva et al., 2008). More recently and based on a sample of 13- to 14-years-old soccer players, Figueiredo et al. (2009) noted a potential interaction between growth, maturation and success in sports. The current study examines the effect of maturation on multiple aerobic measurements in a sample of adolescent RS hockey players.

Material and methods

Anthropometry (stature and body weight), aerobic performance (20-meter shuttle run, SR) and aerobic power (Peak VO2 assessments provided by a direct, maximal and progressive treadmill exercise test and following the criteria defined by Armstrong & Welsman, 2001) were measured. Stage of pubic hair [PH] development was assessed at clinical examination (Tanner, 1962). Players were grouped by chronological age [CA]: CA1: 14.5-15.4 years (n=25); CA2: 15.5-16.4 years (n=38). The effects of CA and PH were tested using t-student while ANCOVAs were used to examine the effect of sexual maturation controlling for CA and for CA and body size simultaneously. Alpha level was set at 0.05.

Results: During late adolescent years, body size, aerobic performance and aerobic power parameters were not sensitive to variation in CA. When compared to players at stage 4 of PH, those classified at PH5 were significantly taller [t=-3.419, p<0.01], heavier [t=-2.650, p<0.01] and attain higher values of Peak VO2 when expressed in L.min-1 [t=-3.140, p<0.01], although they did not perform better in the 20-m SR. After controlling for CA, results persisted [height: F=10.845, p<0.01; weight: F=6.060, p<0.05; Peak VO2: F=8.832, p<0.01; 20-m SR: F=0.178, n.s.]. The effect of sexual maturation is not anymore significant when controlling for CA and body mass [20-m SR: F=0.001, n.s.; Peak VO2: F=3.491, n.s.], CA and height [20-m SR: F=0.915, n.s.; Peak VO2: F=3.055, n.s.], CA, weight and height [20-m SR: F=0.568, n.s.; Peak VO2: F=2.441, n.s.].

Discussion/Conclusion

The interpretation of aerobic power in young people is confounded by the need of properly partition out body size variation. Research focused in the merits and pitfalls of various scaling techniques is needed. The current study suggested that the influence of sexual maturation on aerobic power expressed in L.min-1 is a consequence of maturity-related variation of body size, which challenges conventional interpretation of changes in aerobic power with growth and maturation.

EVOLUTION OF EXPLOSIVE STRENGTH AND MAXIMUM OXYGEN CONSUMPTION IN HIGH AND MEDIUM LEVEL BASKETBALL PLAYERS

MONDONI, M.

UNIVERSITÀ CATTOLICA SACRO CUORE

Introduction: Basketball players' performance strongly depends on explosive strength and maximal oxygen consumption (VO2-MAX) [1]. Some authors have found that these assets proportionally increase with players' qualification [2].The aim of this research was to monitor the improvements due to training programs in two different qualification level players: medium and high. A test of explosive strength and the estimation of VO2-MAX were considered.

Methods: 43 basketball players were assigned to 2 groups. Group A consisted of 22 high level athletes (1st and 2nd division, 27.2±5.2 y, 1.94±0.08 m; 88.3±8.90 kg, BMI 23.4±1.5). Group B was made up of 21 medium level players (3rd and 4th division, 23.9±4.6 y, 1.92±0.06 m; 88.5±8.90 kg, BMI 23.8±1.5). Within each group, all subjects performed the same program of technical and physical conditioning (8 training sessions a week for A, 3 for B). The explosive strength and VO2-MAX of each athlete were measured at the beginning (t0) and at the half (t1) of the competitive season. The explosive force was assessed by measuring the height (H) of the jump (Optojump, Microgate, Bolzano, Italy) in countermovement vertical jump test (CMJ). Each athlete performed 3 trials and their best attempt was taken into account. The VO2-MAX was indirectly estimated following the protocol proposed by Leger et al [3]. Significant differences between pre and post tests within groups were evaluated through Wilcoxon tests (P<0.05). The comparison between A and B concerning the increase of H and VO2-MAX was performed by using the Mann-Whitney test (P<0.05).

Results: Group A had a significant increase of both H and VO2-MAX, who passed respectively from (median and IQR) 48.0 (14.7) cm and 56.9 (3.5) ml/min/kg in t0, to 49.5 (13.4) cm and 60.5 (4.6) ml/min/kg in t1. Group B did not evidence significant changes between the pre (48.3 (4.3) m and 56.3 (3.6) ml/min/kg) and post (48.2 (7.4) m and 55.4 (4.8) ml/min/kg) session.

Discussion: Results suggested that in high level basketball players the number of 8 training section during the week appears effective for increasing the performance of CMJ and VO2-MAX. In contrast, training programs of group B were not enough to enhance explosive force and maximal oxygen consumption. This may be related to the lack of physical conditioning within weekly workouts.

RELATIONSHIPS BETWEEN ANTHROPOMETRIC PARAMETERS AND BONE DENSITY IN 7-8-YEAR-OLD RHYTHMIC GYMNASTS

PARM, A., SAAR, M., PÄRNA, K., JÜRIMÄE, J., NEISSAAR, I., JÜRIMÄE, T.
UNIVERSITY OF TARTU

Introduction: Better bone density in childhood might prevent osteoporosis in later life (Baxter-Jones et.al., 2008). Prepubertal years are an opportune time to increase bone mineral density (BMD) through exercise (Bass et.al., 1998). High-impact exercise has strong impact to BMD and bone mineral content (BMC). Rhythmic gymnasts perform a lot of jumps and is known as high-impact bone loading sport. The aim of the study was to investigate the influence of anthropometric (skinfolds, girths, lengths and breadths) and body composition (fat %, fat mass, lean body mass - LBM) parameters to the BMD and BMC in young rhythmic gymnasts and same age controls.

Methods: Participants of this study were 89 7-9 year-old girls from different schools and sport clubs. They were devided to the rhythmic gymnasts (n=46) and controls (n=43). Body height and body mass were measured and BMI was calculated (kg/m²). All anthropometric parameters were measured according to the protocol recommended by the International Society for Advancement of Kinanthropometry. BMI (g/cm³) and BMC (g) were determined by DXA. BMD and BMC were measured at lumbar spine (L2-L4) and femoral neck area.

Results: Gymnasts have significantly higher values in L2-L4 and femoral neck BMD compared to controls. Gymnasts have also higher BMC values in L2-L4 and femoral neck compared to controls. Gymnasts had significantly lower values in skinfolds. Anthropometric values and bone parameters have significantly more relationships in controls compared to gymnasts.

Discussion: Our results suggest that young rhythmic gymnasts body height, LBM and BMI are the same as in controls. However, in controls body fat mass and fat % are significantly higher and BMD and BMC in L2-L4 and femoral neck have lower values than gymnasts. From the anthropometric parameters skinfold thicknesses are thicker in controls, on the girths, lengths and breadths there are very few significant differences between rhythmic gymnasts and controls.

GENDER EFFECTS ON VASTUS LATERALIS MUSCLE ARCHITECTURE IN PRE-PUBERTAL CHILDREN

TZIAGKALOU, E., ARABATZI, F., SAÈZ-SAEZ DE VILLARREAL, E., KANNAS, T.H., KELLIS, E.
LABORATORY OF NEUROMECHANICS

INTRODUCTION: Muscle force production is affected by architectural arrangements of fibers within the muscle (1). Many studies have examined the relationship between architectural arrangement and muscle force (1). To our knowledge, there are no data on differences in muscle architectural properties and force production in children, between boys and girls (2). Morse et al. (2) have been shown that children display different pennation angle as well as fascicle length compared with adults. The determination of the relationship between level of force and architectural characteristics may assist in identifying the mechanisms underlying growth effects on strength capacity in relation to gender. The purpose of this study was to examine the effects of gender on pennation angle, fascicle length and thickness values during isometric force production in pre-pubertal children.

METHODS: Twenty boys and girls (age= 11,2 ± 0,26 years, mass= 48,78 ± 9,15kg, height= 156,7 ± 7,28cm) participated in this study. All tests were performed on a Kin Com dynamometer. In vivo muscle architecture was assessed using B-mode ultrasonography. Isometric torque of the knee extensors was assessed at angles of 0° (full extension), 45° and 90°. The subjects performed three efforts at 100%, 0%, 40%, 60% and 80% of MVC. The total duration of each effort was 5 seconds. Subsequently pennation angle, thickness and fascicle length were evaluated.

RESULTS: Analysis of variance with repeated measures showed that, fascicle length in point of gender changed as the level of muscle effort and knee angle were altered ($p < 0.05$). Particularly, fascicle length ranged from 2.7 cm to 2.1 cm and from 2.6 cm to 1.9cm, for 0°, 45, 90° knee angles and for girls and boys respectively. The results showed a higher fascicle length in girls for all knee angles compared with boys ($p < 0.05$). There were not significant differences in pennation angle and thickness between boys and girls as the level of muscle effort and knee angle were altered.

DISCUSSION/CONCLUSION: To our knowledge, this is the first study which examined the relationship between different level of isometric force production and three important factors of muscle architecture in pre-pubertal boys and girls. Absolute fascicle length of the VL was smaller for boys compared with girls. The relationship between fascicle length and force was semi-linear and it is consistent with previous findings in adults (1, 2). The above results suggest that any gender differences in strength in pre-pubertal stage of maturation might be due to small differences in muscle architecture.

INVESTIGATION OF SELECTED PHYSICAL PARAMETERS OF JUNIOR <11-12 YEARS OLD> MALE BASKETBALL PLAYERS AND SEDENTARY COUNTERPARTS

ERTAS DOLEK, B.
GAZI UNIVERSITY

The purpose of this study is, to compare the height (in cm), weight (in kg), vertical jump test score (in cm), standing long jump test score (in cm), overhead medicine ball (2kg) throw (in cm) and 30 meters (approximately 100 feet or 33 yards) run (in sec) parameters' mean values of male junior basketball players and sedentary counterparts.

17 basketball players (playing basketball for 1 year) and 17 sedentary boys, totally 34 subjects, are included to the research. Mean age (A), height (h), weight (w), vertical jump test score (VJTS), standing long jump test score (SLJTS), overhead medicine ball throw (OMBT) and 30 meters run values (30 m) of, all the boys included to the research (N=34), are 11,59 ± 0,49 years, 147,15 ± 8,84 cm, 35,67 ± 4,78 kg, 26,09 ± 5,84 cm, 139,94 ± 14,98 cm, 398,09 ± 99,89 cm and 6,25 ± 1,23 secs respectively (Table 1). For the training group (TG), these values are

11,59 ± 0,50 years, 140,58 ± 5,25, 37,26 ± 3,16, 27,88 ± 5,96 cm, 140,35 ± 14,14 cm, 469,41 ± 88,98 cm and 5,65 ± 0,36 secs and for the sedentary group (SG) 11,59 ± 0,70 years, 153,70 ± 6,47 cm, 34,07 ± 5,62 kg, 24,29 ± 5,27 cm, 139,50 ± 16,20 cm, 326.70 ± 43,04 cm and 6.84 ± 1.50 secs respectively.

It is found that all the descriptive data of the TG and SG are normally distributed. According to the independent sample test (p≤0,05), no statistically significance between the w, VJTS and SLJTS of TG and SG have been found. On the other hand, statistically significant difference between TG and SG is found for the OMBT and 30 m run tests (p≤0,05). As a result of the research, it is concluded that, after a 1-year-basketball-training program, total body power, anaerobic power and sprint characteristics of the boys are developed.

CHARACTERISTICS OF FITNESS PARAMETERS IN BASKETBALL PLAYERS OF DIFFERENT DIVISIONS

VAßE, V., MÜLLER, S., SCHWIEDER, T., MÜLLER, L., BRANDES, M.

INSTITUTION OF SPORT SCIENCE

Abstract

For playing basketball, pronounced skills in physical endurance, acceleration and vertical jumping are required (Foran & Pound, 2007). Commonly, it is assumed that these fitness parameters in basketball increase in higher divisions and reach highest level in professionals. Thus, the present study compared selected fitness parameters of basketball players from different german divisions.

The overall number of 27 subjects consisted of nine subjects from the divisions Pro-A (25.2 ± 4.1 years, 197.3 ± 7.6 cm, 94.6 ± 11.1 kg) 2nd regional division (19.3 ± 3.5 years, 187.3 ± 9.0 cm, 82.3 ± 14.9 kg) und district division (18.6 ± 2.2 years, 187.3 ± 9.1 cm, 80.0 ± 11.8 kg) respectively. The nine subjects of each team consisted of three centers, forwards and guards, respectively.

All subjects were tested regarding their physical endurance capacity and anaerobic threshold at 3.5mmol/l blood lactate (maximum treadmill test), their acceleration capacity (20m agility drill) and their vertical jump capacity (jump and reach test) at the same specific date of the season.

Subjects of Pro-A achieved peak values in endurance capacity (14.6 km/h at 3.5 mmol/l), acceleration capacity (4.76 s) and vertical jump capacity (66.1 cm), followed by subjects of 2nd regional division (14.4 km/h, 5.05 s, 58.0 cm) and subjects of district division (13.7 km/h, 5.19 s, 53.9 cm). Wilcoxon signed-rank test solely revealed a significant difference in acceleration capacity between Pro-A and district division. The different player's positions were compared with each other in endurance capacity (Center: 14.2 km/h, Forward: 14.0 km/h, Guard: 14.5 km/h), acceleration capacity (5.1 s, 4.96 s, 4.91 s) and vertical jump capacity (57.2 cm, 62.3 cm, 58.4 cm). The differences did not reach the level of significance.

The findings prove that fitness parameters of basketball players in higher divisions are pronounced compared to players of lower divisions. However, the fact that only the difference in acceleration capacity reached statistical significance suggests that the fitness characteristics do not determine the division in basketball. In contrast, Kalapotharakos et al. (2006) did not reveal significant differences in soccer teams of the first Greek league but significant differences between teams of the bottom and midrange of the league. Furthermore, differences were found between the top teams and both other teams.

In conclusion, technical and tactical skills might have a greater influence on the division in basketball and similar games than presumed.

Basketball is a sport with many complex demands that require a combination of fitness, skills, team strategies and motivational aspects. However key areas that are likely to play an important role in a basketball player´s success are muscular strength, fitness and body size. Purpose. The aim of the present study was to evaluate seasonal variation in anthropometric and physiological variables, and identify differences between the first and reserve team in elite young male basketball players. Methods. 15 top-level male players (Spanish team) guards (n=2), forwards (n=7), centers (n=6) (mean ± SD), age (14 years), height (189.1 ± 6.3 cm), body mass (74.6 ± 9.3 kg) participated in this study. The subjects were divided into two different categories: first team player (FT) (n=7) and reserve team player (RT) (n=8). All the players participated in the same training program (5 h per day). Four times during the season (September, December, March and June), each player performed various tests including countermovement jump (CMJ), Abalakov (ABK), horizontal jump (HJ), course Navette test (CN), and strength explosive arm test (SEAT). In addition anthropometrical data were recorded. Results. At the end of the training program the values were (Mean ± SD): [Height: 188.2 ± 5.4 vs. 190.6 ± 4.5 cm; 190.1 ± 7.6 vs. 192.1 ± 6.6 cm]; [Weight: 74.1 ± 12.0 vs. 77.8 ± 11.0 kg; 75.1 ± 6.0 vs. 81.6 ± 5.5 kg]; [Body fat: 8.2 ± 1.2 vs. 8.0 ± 1.1 %; 7.6 ± 0.6 vs. 7.5 ± 0.4 %]; [ABK: 39.0 ± 4.5 vs. 43.6 ± 4.4 cm; 38.8 ± 5.9 vs. 47.3 ± 6.0 cm]; [HJ: 1.46 ± 0.3 vs. 1.76 ± 0.4 m; 1.38 ± 0.3 vs. 1.81 ± 0.4 m]; [CN: 9.8 ± 2.1 vs. 11.7 ± 2.0 paliers; 10.3 ± 2.4 vs. 12.0 ± 2.0 paliers]; [SEAT: 5.8 ± 0.8 vs. 6.5 ± 0.4 m; 5.5 ± 0.6 vs. 6.4 ± 1.0 m], FT and RT respectively. Pre and post training intra-group increased in both groups their height, max. speed, strength explosive arm, leg power and aerobic performance significantly (P<0.05).

Conclusions. The progression of the both groups along the season was quite similar, with no significant differences in any anthropometric or physiological variables between them. At the end of the season and close to the international championship players presented the best Results.

AN INTERNATIONAL COMPARATIVE STUDY OF FITNESS AND SKILL IN ELITE MALE U16 BASKETBALL PLAYERS

PETERS, D.M., DONOVAN, M., BALCIUNAS, M., STONKUS, S.

UNIVERSITY OF WORCESTER, UNIVERSITY OF AGDER, LITHUANIAN ACADEMY OF PHYSICAL EDUCATION

Introduction: Fitness and skill are considered key components of basketball game play and eventual team success, with tests related to key performance indicators (KPI) validated through their ability to discriminate between levels of performance. Purpose: To compare group performance on sport specific fitness tests and KPI-related skill tests in elite male youth basketball players from one high ranked and one low ranked basketball nation. Method: Thirty three male U16-year-old elite and/or national representative players from a high ranked basketball nation (in top five of Division A at the 2005 World Championships, n=16) and a low ranked basketball nation (between 6-10th place in Division B at the 2005 World Championships, n=17) completed four sport specific fitness tests: 20 metre sprint (Sprint); countermovement standing vertical jump (CMJ); standing vertical jump from 90 degree squat (SVJ); Abalakov jump (AJ); and three KPI-related skill tests: ball dribbling (BD); jump shot (JS); and free throws (FT) using protocols adapted from Balciunas et al., (2006). The best score or time from three attempts was used for group comparison using paired samples t-tests ($p<.05$). Results: There were no significant group differences found between the Division A and Division B teams for height (1.92±.07m vs 1.86±.09m, p=.07), weight (72.6±5.4kg; Div B 74.2±9.1kg, p=.55), 20m sprint time (3.13±.20secs vs 3.15±.09secs, p=.66), CMJ (40.4±3.1cm vs 40.5±4.8cm, p=.93), SVJ (38.5±3.3cm vs 38.9±4.7cm, p=.79) and BD (7.79±.49secs vs 7.82±.51secs). Significant group differences between the Division A and Division B nations were apparent for BMI (19.8±1.2 kg.m2 vs 21.3±1.3kg.m2, t=3.32, $p<.01$, eta2=.26), AJ (50.4±3.7cms vs 45.1±5.0cms, t=3.42, $p<.01$, eta2=.27), JS (12.2±2.7 vs 8.5±3.6, t=3.31, $p<.01$, eta2=.26) and FT (22.8±3.4 vs 18.8±6.6, t=2.25, $p<.05$, eta2=.14). Conclusions: As a group, and being similar in positional representation, the higher ranked nation demonstrated a lower weight to height ratio, suggesting a taller and leaner player profile, although more accurate body composition measurement is recommended in future studies. The higher-ranking nation were also found to perform better at arguably the most game specific vertical jump (the Abalakov jump) and the two most 'score-outcome related' skill tests. Relative body composition and these three tests may therefore be the most useful for discrimination between levels of performance in elite male youth basketball. Without suggestion of causality, specific physical training and technique/skill practice are recommended for less successful basketball teams in order to improve these seemingly performance related fitness and skill attributes.

Balciunas. M., Stonkus, S., Abrantes, C. & Sampaio, J. (2006). Long term effects of different training modalities on power, speed, skill and anaerobic capacity in young male basketball players. JSSM, 5, 163-170.

COMPARISON BETWEEN DIRECT AND PREDICTED MAXIMAL OXYGEN UPTAKE MEASUREMENTS

SANTTILA, M., HÄKKINEN, K., KYRÖLÄINEN, H.

UNIVERSITY OF JYVÄSKYLÄ

Introduction: It is wellknown that maximal oxygen uptake (VO2max) plays an important role in the performance level of soldiers daily physical activities. Direct bicycle ergometer or treadmill running tests have been used as golden standard measurements of VO2max. In addition, several predicted VO2max measurements, which are based on the assumption that there is a linear relationship between heart rate and oxygen consumption during various intensities, have been developed since the 1950s (Åstrand et al. 1954). The aim of the present study was to compare the results of the direct measurement of VO2max to the respective predicted values during a bicycle ergometer test.

Methods: A total of 68 male soldiers participated in the study. Their mean age was 19.2±0.9 yrs., height 1.79±0.06 m, body mass 73.8±12.4 kg and body mass index 23.0±3.8%. The subjects gave signed informed consent before the testing. Aerobic performance (VO2max) of the same subjects was tested twice within two months intervals by a bicycle ergometer. The initial work load was 50W, and it was increased by 25W every second minute until exhaustion (MILFIT/FitWare, AinoActive, Helsinki, Finland). Oxygen uptake was measured continuously using a gas analyzer (SensorMedics, Yorba Linda, California, USA). Heart rate was recorded continuously by heart rate monitor (Polar Electro, Kempele, Finland). Volitional exhaustion was the main criterion indicating that VO2max was achieved, and the highest mean VO2 over one minute was set as VO2max. Exhaustion was ensured by a respiratory exchange ratio above 1.05 and the ratio of perceived exertion more than 17.

Results: In the first tests, the predicted mean (±SD) VO2max value was 45.2±7.7 ml-1kg-1min-1 and the direct value 44.8±8.5 ml-1kg-1min-1, which correlated significantly ($r=0.84$, $p<0.001$) with each other. The absolute and relative differences between the methods were -0.42 ml-1kg-1min-1 (p=0.46) and 0.9%, respectively. Thereafter, in the second test the predicted and direct VO2max values were 47.4±6.7 ml-1kg-1min-1 and 48.7±7.3 ml-1kg-1min-1 ($r=0.80$, $p<0.001$). The absolute and relative differences between the methods were 1.28 ml-1kg-1min-1 ($p<0.05$) and 2.7%, respectively. The mean values of the predicted VO2max values and direct VO2max values were inside the 95% confidence interval for the mean values of the variables for both tests (test1 43.2- 46.9 and test2 46.4-49.7 ml-1kg-1min-1). The mean values and differences of the predicted and direct VO2max values were not significantly correlated at week 0 ($r=0.14$, p=0.24) or week 8 ($r=0.11$, p=0.36). Both of these indicate that the measurements were statistically very similar.

Discussion: The present predicted VO2max measurements only slightly overestimated or underestimated the VO2max values of the direct measurements. Based the data we can conclude that the present protocol is fairly accurate and valid to predict VO2max values in male subjects.

SPINE AND ARMS FLEXIBILITY IN ELDERLY: PART OF THENAPA II. PROJECT

NEMCEK, D., LOJEK, M.

COMENIUS UNIVERSITY, FACULTY OF PHYSICAL EDUCATION AND SPORT

Introduction: Insufficient muscle load influences negatively also bone system and in higher age can support osteoporosis and arthrosis. By increasing age many body changes can appear, like salt is contain in joints, degenerate muscles, ligaments and tendons are losing its flexibility. That limits range of movements in different joints, including spine and arms. Also motor performance in elderly is affected,

where all motor abilities are decreasing, including flexibility. Long-term regular participation in physical activities can slow down this negative progress. Research was supported by project "THENAPA II – Dissemination and exploitation of results 142475-LLP-1-2008-1-BE-ERASMUS-EAM".

Methods: 65 elderly (14 men and 51 women) participated in research. We provided measurements of flexibility using two tests for spine flexibility (sagittal flexion and left, right lateral flexion) and one test for arm flexibility (left and right shoulder). We compared the level of flexibility between two groups of respondents (active n=45 and inactive n=20) using t–test (test for independent samples). Active elderly participated in physical activity once per week. Average age of target group was 69 years.

Results: Active group of elderly people demonstrated better results in all tests comparing inactive elderly. Two from five flexibility indicators were statistically significant ($p<0.05$), concretely left lateral flexion and sagittal flexion.

Discussion: By our research we can confirm, that regular participation in physical activities influences flexibility progress in elderly people. Results presents differences between active and inactive elderly in all tests. Average value of difference in sagittal flexion was 6.2 cm; right lateral flexion 0.8 cm; left lateral flexion 3.05 cm; right arm flexibility 1.8 cm; left arm flexibility 1.7 cm. Regular exercises aimed to bending, twisting, and stretching are appropriate to improve spine flexibility. More frequent participation in exercise of active elderly (at least two times per week) would bring more significant differences between groups. We recommend, that each physical activity for elderly people should include exercises for whole body flexibility development. Elderly, even those with disability should participate at least 5 days per week in physical activity or exercise to maintaine or improve their good health and well-being.

INQUIRY EXAMINING THE TRAINING NEEDS OF PHYSICAL EDUCATION TEACHERS FROM THE LOMBARDY REGION

FRATTINI, G., MELICA, S., SALVETTI, C., FRANZINI, D., MARCHETTA, S., VICINI, M., VAGO, P., MONDONI, M., CASOLO, F.

UNIVERSITA' CATTOLICA DI MILANO

Introduction: The aim of this inquiry is to find out the training needs of Physical Education teachers.

The objective of this inquiry is to find out:

- to what extent the PE teachers feel the need for training
- what are the most appealing themes for the training courses
- when to carry out the training courses

Methodology: The inquiry has been carried out via means of a questionnaire. The teachers have expressed their choice by putting a cross on the Likert scale, where 1 means of little importance and 7 of great importance; there were also 2 open questions.

Sample examined

181 teachers were interviewed, 86 Male and 95 Female, 57 teaching in secondary schools with students aged 11-14 years, 124 teaching in secondary schools with students aged 14-19. The interviewees were between 26 and 62 years.

The questions were subdivided into 3 groups

1. Need for training (1)
2. Most relevant areas for training
3. Favoured instruments for the training

Results: From our data we can see that:

1. 74.78% of the interviewed felt a strong need for training

2. The interest for training in sport, dance, expressivity and fitness was 64.27%; 50.58% want training in cross-sectional assessment, disability and coping with adolescent problems(2); 71.19% teachers prefer to have training during the school year, 59.39% want it organized by the state and 59.80% want increased salary after training and near the place of work.(3)

3. 80.66% had attended a training course, 76.8% consulted books or magazines, and 11.51% the internet.

Conclusion

There is a great deal of interest for specific training; it's necessary to divulge computer use; the State and the University should take care of this need.

TEACHER EVALUATIONS OF ICT IMPLEMENTATION IN PHYSICAL EDUCATION

ARNESEN, T.E.

STORD/HAUGESUND UNIVERSITY COLLEGE

Introduction: In the Norwegian national curriculum implemented in -06(Lk06) ICT-competence is described as one of five basic competences in every curriculum subject. In all subjects, there are specific goals intended to improve ICT-competence within the framework of the subject in question. Physical Education(PE) teachers have questioned to what extent ICT can provide efficient learning environments for important aspects of the subject, and whether the requirements in Lk06 are grounded in experience and research.

An important focus has been to investigate the relationship between the use of ICT and important PE characteristics as learning and experiencing bodily movement. This is considered to be crucial for a high quality PE practice.

The aim of this presentation is to present teacher evaluations of the use and effectiveness of ICT in PE. How do teachers evaluate ICT usage with regard to learning outcomes and learning environments in PE?

Methods: The presentation is based on results of a national teacher survey,

"Skolefagundersøkelsen 08" (National School Subject Survey 08). The objective of this survey was to map curriculum teachers' evaluations and usage of ICT in the context of their own lower secondary classroom practices in their respective schools. Of the 991 teachers responding, 89 of them were PE teachers.

Results: Findings from the survey show substantial differences between teachers' evaluations in different curriculum subjects as well as individual differences within one particular subject. PE stands out as the curriculum subject with the highest degree of consensus.

ICT is not practised nor regarded as an important and generic tool for achievement in PE. Attitudes to ICT are more negative in PE than in any other curriculum subject.

While in PE exist a negative consensus view on ICT, this view is also found in other subjects like Arts and Crafts, but teachers in this subject also regard ICT as an efficient tool for learning in certain aspects of the subject, e.g. artistic inspiration and documentation of creative processes. No aspects with the same dimension are found in PE.

Discussion: Less use of ICT and a negative attitude towards ICT is found more among PE teachers than among teachers in other subjects. This reflects PE teachers' views on what are the essential and core subject values and goals for learning. They do not identify learning goals that best and uniquely can be served by ICT usage and express at the same time a fear that ICT intensive activities in PE may direct pupils' foci from essential and core subject values and goals for learning.

With regard to the relationship between ICT and PE, this study tells us that we need future qualitative case studies to see if we can indeed identify parts of PE that best and uniquely can be served by what kind of ICT usage. If we can't, then we must ask ourselves if PE supports the acquisition of ICT competence to a relevant extent or if this could better be accomplished in other subjects.

VOCATIONAL PERSONALITY AND PROFESSIONAL BURNOUT IN PHYSICAL EDUCATION <PE> TEACHERS

BRUDNIK, M.

UNIVERSITY SCHOOL OF PHYSICAL EDUCATION

INTRODUCTION: Professional development of man consists of three strata: objective, constituted by a given contents of the job to be performed, social, or the social environment, and personal, associated with autoperception, a sense of value and life accomplishment. The intertwined spheres form a harmonious entity called by John L. Holland the vocational personality. A profession that does not correspond to the predispositions of an employee may cause chronic stress, a sense of defeat and also convince him of his low value. A mismatch between an employee and his professional environment often contributes to the development of burnout syndrome (Banka 1995).

Using a macro-path of professional burnout in PE teachers plotted in a four-phase typological model (Brudnik 2008), the author analyzed burnout in teachers working in accordance with their vocational personality as well as those not matched to their professional environment.

METHOD: The survey was carried out in May 2006-June 2007 among male PE teachers N=771. The employed tools were: Maslach Burnout Inventory and Holland's Self Direct Search; the statistical methods included data clustering (K-mean method) and U Mann Whitney test.

RESULTS: Of 771 investigated subjects, males characterized by good and lacking match to practice their profession: N=664 (86.1%) and N=107 (13.9%). Burnout of professionally matched and mismatched PE teachers is illustrated using a four-phase typological model.

The macro-path of professional burnout of PE teachers bifurcates at Phase F1 (Brudnik 2008). The results suggest that a decisive factor in the macro-path bifurcation is the degree of match between the investigated teachers and their professional environment.

Matched teachers experience burnout in keeping with path I, reacting to stress with emotional exhaustion (the Maslach's path). In the mismatched group, stress primarily triggers depersonalization of pupils (F1) – the Golembiewski's path, what is indicated by cluster II. (N=31), which illustrates disillusionment with one's work associated with increasing depersonalization of pupils at a low level of emotional exhaustion. The subsequent cluster (IV, N=23), Phase (F2) represents emotionally exhausted teachers, who treat their pupils as objects (IV, N=23).

While undergoing burnout, mismatched teachers (F3) lose the sense of their work ($Z=-5.191$, $p<0.001$) (III, N=11), while matched teachers experience painful emotional exhaustion ($Z= -4.872$, $p<0.001$) (I, N=74).

Derbis (ed.), Measurement and sense of quality of life in the professionally active and unemployed. CECBE, Poznań Lublin 1995, 9-26. Brudnik M. (2008), Professional burnout of female and male physical education teachers: a four-phase typological model, Book of Abstracts, 13thAnnual ECSS Congress, 622.

Key words: PE teacher, burnout, vocational personality.

PRIMARY SCHOOL: THE OPINIONS OF GENERALIST PHYSICAL EDUCATION TEACHER'S TOWARD INCLUSION OF STUDENTS WITH DISABILITIES IN THE REGULAR SCHOOLS AND REGULAR PE CLASSES

CAZZOLI, S., ROSA ROSA, A., SANNICANDRO, I.

UNIVERSITY OF TORINO (ITALY); SSIS PUGLIA (SUPERVISOR SCHOOL OF SECONDARY SCHOOL TEACHER TRAINING)- ITALY; UNIVERSITY OF FOGGIA- ITALY

In the compulsory syllabus of the primary school (students aged 3-11 years), the physical education (PE) subject is included, in Italy. All the students with disabilities are included and integrated in the

regular schools from '80. The teachers in the Italian primary school are generalistic (they are

teaching all the subjects) and they attend semester in Physical Education course in the University curricula. The data about the generalistic PE teachers in the primary school attitude towards disabilities students in the regular Pysical Education setting aren't investigated.

PURPOSE: The survey aims is to investigate the Primary Physical Education Italian teachers' attitude towards inclusion of students with disabilities in regular education settings, after 30 years from the firt law on integration in the Italian schools. It is preliminary study.

METHODS: The Teacher Integration Attitudes Questionnaire (TIAQ)(Sideris&Chandler, 1997) was given to 51 (N1=51) pre-service generalistic Physical Education Teachers primary school. Descriptive statistics were at first derived for the total sample.Cronbach's alpha co-efficient was

used in order to determine internal consistency of the questionnaire. ANOVA was used for the analysis regarding gender, years of experience, training in special pedagogy for support teaching, with 4 subscale of the questionnaire: skill, benefit, acceptance, support. The level of statistical significance was set at $p < 0.05$

RESULTS: The means and the standard deviation of skill, benefit, acceptance, support subscale are respectively 8,4±2,2; 2,4±1; 7±1,5; 8,5±2. T-test data for independent simples didn't give difference between statistical significative means. The ANOVA shows the only statistical significant result is between the acceptance subscale and training in special pedagogy for support teaching ($F= 4,46$ $p<0.04$)

Discussion: The integration and inclusion of all Italian students with disabilities in the regular Primary Schools date back to thirty years in Italy, but the t-test and ANOVA analysis address limitated significative difference and only in the acceptance dimension analysis. The results give idea that Teachers' attitude is not to much oriented towards the other dimension (skill, benefit, support), maybe the causes are the teachers are in traning and they are thinking no up date in the professional training. Further surveys are necessary on great simple for generalization of the results and with teascher in-service for the increase of best quality of integration and inclusion in the present and in the future of the PE regular classes .

FEMALE AND MALE STEREOTYPES OF SCHOOL SPORTS

MARQUES, A.I., BOTELHO-GOMES, P., MIRANDA, L., TAVARES, A., SILVA, P., CARVALHO, J.

1. CIAFEL, 2. CIFI2D, 3. BASIC SCHOOL OF BRANCA

Introduction: Sport is a defining aspect and an essential part in a child's or youths' education. But sport doesn't seem "neutral" when associated with gender: our representations of the sexual identities influence the way we see males and females in sport1.

Available data suggest that school sport can provide participation for approximately 110,000 young people2, which only 24% are girls. Currently, in Portugal, the specific recommendation to promote female participation in school sports is scarce. An understanding of how young/adolescent people perceived certain sports to be masculine, feminine or not culturally associated to one specific sex is important to developers of social and sports policy, as well as to physical education teachers.

Therefore, the aim of this research is to analyse how adolescents of both sexes at 7th, 8th and 9th grades of Portuguese Public Schools perceived gender appropriateness of school sports, as more suitable for girls, for boys or for both equally.

Methods: A sample of 551 students (260 boys and 291 girls) from 7th, 8th and 9th grades completed an online questionnaire including a checklist with 41 sports from the School Sport Programme. Participants were instructed to designate each activity as more suitable "for girls", "for boys" or "for both equally", in the computer classrooms. Descriptive statistics were used in order to characterize de sample. Qui-square test was used to analyze the prevalence of perceived gender appropriateness (p≤0.05).

Results: Some sports were perceived by students as more appropriate for a certain gender. Boys and girls pointed out Basebol, BTT and Rugby as more suitable "for boys". On the other hand, Aerobic Dance was considered "for girls" by both. Rhythmic Gymnastic was mainly perceived as "for both equally" by girls, but boys perceived it as more suitable "for girls". All the other sports were not perceived in a gender-stereotyped way, but as "for both equally".

Statistically significant differences were observed in perceived gender appropriateness of some school sports: Badminton, Korfball, Social Dances, Traditional Dances, Urban Dances, Climbing, Futsal, Group Gymnastic, Adventure Activities, Orienteering, Skating and Rugby.

Discussion: Although the gender perception for the 41 sports is nearly coincident between boys and girls, these results also suggest a slight genderdization3 of certain sports in this context.

COMPARISON BETWEEN SLOVENIAN AND CROATIAN STUDENTS IN THEIR KNOWLEDGE ABOUT HEALTHY FOOD AND THEIR EATING HABITS

ŠTEMBERGER, V., KNJAZ, D., RUPCIC, T.

UNIVERSITY OF LJUBLJANA, FACULTY OF EDUCATION, SLOVENIA (FIRST AUTHOR), UNIVERSITY OF ZAGREB, FACULTY OF KINESIOLOGY, CROATIA (SECOND AND THIRD AUTHORS)

Nowadays great importance is laid on healthy food due to great number of overweighed children and adolescent and diseases caused by being obesity (Conker & Tishler, 1992; Robbins, Powers, Burgess, 2005; Pokorn, 2005; Matković, Knjaz, Cigrovski, 2006; Zupančič, Hoyer, 2006). Primary school teachers and physical education teachers play a big role in the pupils' lives. Therefore it is vital to find out what their eating habits are and what they know about healthy food. For the research purpose two questionnaires were used. Results were analyzed by using descriptive statistics, discriminant analyse and T-test for independent samples.

The results show that students from Slovenia have better eating habits while students from Croatia have better knowledge about healthy food. There should be more education about healthy food in primary and secondary schools and also at higher education. It can't be expected that teachers will teach children about the healthy way of life and proper eating habits, if they do not posses enough knowledge themselves. Nowadays healthy food and proper lifestyle are very important because of peoples' health, their quality of life and expected longer lifetime. Another reason for educating primary school teacher and physical education teacher about healthy food and proper eating habits is that there are too many inappropriate commercials which advertise unhealthy food, in particular sweets and fast food.

ANALYSIS OF THE USE OF FREE TIME BY THE STUDENTS FROM TEACHING PHYSICAL EDUCATION

ZAGALAZ SÁNCHEZ, M.L., CACHÓN ZAGALAZ, J., LARA SÁNCHEZ, A., MARTÍNEZ LÓPEZ, E.J.
UNIVERSITY OF JAEN

Introduction: There is a high demand for students from teaching physical education from University of Jaen to study subjects that prepare them to educate in the proper use of leisure time and specific subjects of physical education and sport. Therefore, this research has been conducted to verify how much time the devoted to physical and recreational activities demand actually.

The aims of this work are: to check if the studied population spends his free time to physical activity and sport; to know the relationship between the choice of those activities and university studies, to examine which other activities occupy their free time.

Methods: 180 students from teaching physical education responded to the questionnaire. It included 25 items to assess the following dimensions:

A) Practice of physical and sports activities during leisure time and its relation to studies.

B) Type of physical and sports activities practiced during leisure time.

C) Justifications about the choice to practice sport during leisure time.

D) Other activities during leisure time

Results: 78% performed between 1 and 2 h of physical activity per day and 71% do so between 3 and 5 days for week. 70% has changed little or nothing of their habits in terms of leisure time physical activity when they enter to university. 61% indicate that the studies that are studying at university with little or no influence on their decision to choose to practice physical activity in their free time. 81% play collective sports always or fairly during their physical activities. 12% do it only sometimos. Also, 12% practiced in their free time individual sports always. The reason that they gave more importance to physical and sport activity during their free time has been associated with positive effects on health. Of the other activities they do during their free time highlights going out with friends with practice sports over other activities

Discussion: The physical and sporting activities occupy much of his free time, there is a relation between physical activity and sport practiced and university Studies elected, and not vice versa; activities like going out with friends or watching television are also part of the time free, but others like reading is done on an occasional or non-existent.

ACTUAL TECHNOLOGIES IN HIGH SCHOOL EDUCATION

ULYANOV, D., KOVALENKO, T., SHKLYARENKO, A.
VOLGOGRAD STATE UNIVERSITY

Introduction. Actual scientific research in the field of physical culture and sport all over the world proves the necessity of use of innovative achievements to develop informatics and qualimetry. Knowledge-consumptive high-tech information concerning process and equipment are used to achieve these goals.

The present research offers the attempt to apply actual technologies based on high-tech information concerning process, equipment and distance education in non-physical education high school students' self-directed learning.

Many researchers share the idea that at the present moment the introduction of new kinds and methods of actual technologies in high school educational process is possible only if a wide range of high-tech information concerning process and equipment are used.

It is a matter of common observation, that the most effective means contributing to the rise in high school modern students learning motivation are computer-aided technologies. They help to form the research activity skills and develop the lifeware.

Research objective is to improve academically physical education with the help of theoretical justification and technological information concerning process and equipment designing during distance education in non-physical education high school students' self-directed learning.

Research methods and management. The following research methods were applied: theoretical study and generalizations of existing scientific sources, of progressive and advanced practical experience, different psychologist and pedagogical techniques, mathematical statistics procedures. To realize this objective we worked out high-tech information concerning process and equipment applied during distance education students' self-directed learning to study the theoretical basis of "Physical culture" educational program in high school, including courseware and computer-based study-guide "Physical culture and sport theory and methods", numerous multi-media teaching programs, computer tests, etc.

Research results and their discussion. The analyze of actual technologies under-utilization in the academic activity showed that the main reasons are low level of students computer skills (36,0 – 43,8%) and lack of possibility to apply them in the physical culture academic activity (22,0-21,3%).

Theoretical physical culture self-directed learning with the use high-tech information concerning process and equipment and new methods of distance education contributed to the rise in students motivation, activeness and interest in the academic process through actual technological distance educational techniques using.

As the result of this innovation, positive changes in students attitude towards the academic subject "Physical culture" were observed: in the experimental group self-motivation increase was 65,3%, in the control group this index corresponded to 57,1 % and was explained only by students desire to pass the exam.

SCHOOL SPORTS IN ELEMENTARY EDUCATION IN CITIES IN SÃO PAULO STATE/BRAZIL

LUGUETTI, C.

PHYSICAL EDUCATION AND SPORT SCHOOL/ UNIVERSITY OF SÃO PAULO

OBJECTIVE: The objective of the current research project is to analyze the elementary school sports conditions in cities of Sao Paulo/Brazil, regarding the following: a) description of the financial and equipment resources; b) the coach's characterization; c) the program planning. METHODOLOGY: The sample was composed of 25 coaches who participated in the Handball Technical School Congress in April 2008. The participants answered a closed questionnaire developed by researchers and validated by specialists. RESULTS: Regarding the financial and equipment resources, it has been noticed that 52% of the coaches considered the equipment to be in good condition, 84% to be genuine, 62.5% to have its maintenance at the appropriate time.; 33.3% of the schools that were evaluated charge some kind of fees from students (weekly, monthly or annual). As regards coach's characterization: their average age is 35,7±8,8; they are mainly male (72%), they had not practiced or played the sports they teach (54.5%), their average experience is of 32.8 months and 68,4% of them work with School Physical Education. The coaches are licensed (43.5%), and 52.2% of them are also Graduates. Over 72% of the coaches have stated they have taken refresher coursers or post graduation ones. As far as planning is concerned, it has been noticed that 68% of the coaches actually do some planning, in an annual basis (37,5%), monthly basis (31,3%) and weekly basis (31,3%). However, they do not follow the policy or program established by the school (68.2%) or its theoretical basis (62.5%); 59.1% of them do not carry out any evaluation and 31.8% have stated that the sport is not linked to the school's Pedagogical Political Project. CONCLUSIONS: It has been concluded that coaches have satisfactory equipment conditions. In spite of the evaluated coaches have stated they worked with School Physical Education, what would immensely help the school's knowledge and consequently the its pedagogical practice, the school Program and its Pedagogical Political Project are not taken into consideration in the School Sporting Practices. Besides that, few coaches carry out evaluation. Something which stands out is the need of other studies that would aim evaluate the study variables in different school origins (private and public), and, the opinion of other participants of the school micro social system, for instance, the coordinator or the director.

INCIDENCE OF INITIATION SPORTS BOOKS IN SPAIN

HERRADOR COLMENERO, M., HUERTAS HERRADOR, J.A., RUIZ VALDERAS, I., LÓPEZ GÓMEZ, S.

UNIVERSITY OF JAÉN

Introduction: The book has a great importance in teaching in Spain, but in PE has a secondary role. The Organic Law on Education introduced a fifth block of content with the launch sports focused on the third cycle of primary education. It is important to know whether the textbooks are adapted to the implementation of this block, and if so, whether it is appropriate to the educational stage.

Methods: We used a sample of 5 editorial impact on our country, focusing on the fifth and sixth courses of primary school. Qualitatively analyzing the initiation of sports through various elements in the publishing and the adequacy of those elements of the age to which they are designed. The factors to consider are: multi-sports, driver availability, cooperation, environment and percentage of pages.

Results: In relation to multi-sports, 5 publishers try 9 different sports. In addition, sports that are working along the publishers are football, basketball, volleyball and handball. If we look at the power plant availability, as well as cooperation, we can show that 4 out of 5 publishers in adapting their content, activities, proposals, etc., Andalusia evolutionary level of the students.

Referring to the sports environment, 1 editorial does not address this issue, and the sport is more work guidance. Finally, the percentage of pages devoted to the sport by launching each book, we see that the sixth books have a higher percentage than the fifth.

Discussion: As can be seen in the results, working a variety of sports in the last cycle of primary education. In addition, four dealt with most sports, are those that are more entrenched in the social culture of the country. All these activities are properly targeted to the age at which they are designed, taking into account the developmental levels of students.

Cooperation will be integrated into the books looking to create a joint work among children, even if a publisher does not provide for this work. Given the sport in the natural environment, sport is more developed and the guidance which allows you to work from an interdisciplinary approach that other sports do not allow the natural environment. We can be seen from the results that most publishers choose to work with this content.

Finally, the percentage of pages devoted to the sport initiation is higher in the sixth because of primary cognitive and motor development of children is greater in this course.

SPORT+ FOR SOCIALLY VULNERABLE YOUTH: A QUALITATIVE ANALYSIS OF COACHING PRACTICES

HAUDENHUYSE, R., THEEBOOM, M.

VRIJE UNIVERSITEIT BRUSSEL

Introduction: From the beginning of the 90's, so called 'neighbourhood sport' has gained popularity in Flanders (Belgium). Most of the initiatives are primarily aimed at socially vulnerable youth in urban deprived areas. The main intention is to reach youth that are by a combination of causes not being reached by the more traditional organized sports services, and include them on a sustained basis in a sports provision. It is in this context that policy makers, practitioners and researchers refer to the social integrating functions and outcomes that are inherent to sport. Recently, this approach has been labelled as 'sport+', because of the proclaimed added value beyond 'mere' participation. However, literature on the social dimensions and guiding principles of coaches working with socially vulnerable youth within a sporting context remain scarce (Seippel, 2008). We will focus our attention on the specific methodological and didactical conditions of coaching practices that are deemed necessary and desirable in facilitating beneficial and sustainable outcomes on the individual, group and community level.

Methods: The leading question throughout this research can be put as followed: How does a coach, within a sport initiative for socially vulnerable youth, develop his/her specific coaching practices in order to facilitate broader social outcomes, and which contextual factors influence these practices? Semi-structured in-depth interviews were held with coaches within initiatives defined as sport+ (N= 30). In order to constitute a conceptual framework, six dimension were distinguished: sport teaching methods, authority, competences, knowledge, functions, and guidance approach.

Discussion & Results: Research in Flanders showed that a difference in approach is perceived by local sport administrators, in how coaching would have to be done in 'neighbourhood sport' initiatives as compared to coaching within a more regular sports organization (Theeboom & De Maesschalk, 2006). Yet not much is know what these differences actually are. Studies on specific coaching and organization modalities for socially vulnerable youth remain limited and are at best beacon lights for further research (Janssens et al. 2004). Results seems to indicate that coaching practices for socially vulnerable youth are closely correlated with the generated motivational climate, the intra-group communication, the function and integration of the coach within the organization, the characteristics and programming of the activities, the locus of authority, and the specific background and competences of the coach.

THE NEW SPORTS INSTRUCTORS IN FINNISH CERTIFICATE SPORTS CLUBS

HAKAMÄKI, M.

LIKES RESEARCH CENTER

Introduction: In Finland there are 500 sports clubs that have a quality certificate (Seal Clubs) granted by Young Finland Association. Essential criteria in quality system is that the sports instructors and coaches have attended some course in instructing sports for children, they are tutored in clubs and are aware of the Young Finland -ideology.

Methods

To find out how this goal is achieved a web-based survey was conducted to all new instructors that had a valid e-mail account. Information was gathered on 186 new sports instructors that had been in the position less than a year. Their background, motives and future plans as instructors were asked. Also amount and forms of tutoring in the clubs are reported. In addition the needs of the new instructors are examined.

Results: There were more girls than boys as young new instructors. Their main motive was that sports or coaching was a hobby for them. Adult instructors were usually fathers, whose children were in the club. Half of the instructors said they had been given tutoring, some material or a course. the respondents opinion on courses and tutoring was that they are important.

Discussion: Although the respondents represented the quality certified sports clubs in Finland and there are many courses and training available, many of them thought that tutoring practises in clubs are still insufficent and support is needed.

NON-WESTERN ETHNIC BACKGROUND, GENDER AND SPORT PARTICIPATION AMONG NORWEGIAN ADOLESCENTS

SAND, T.S., SISJORD, M.K., FASTING, K., OMMUNDSEN, Y., ROBERTS, G., SØRENSEN, M.

NORWEGIAN SCHOOL OF SPORT SCIENCES

Introduction: Both Norwegian and international studies have revealed that adolescents with a non-western ethnic background have a weaker tie to organized sport (e.g., through higher drop-out rates (Strandbu & Bakken, 2007). Research has also uncovered larger gender differences among adolescents with a non-western ethnic background, where girls are less involved than boys. However, little is known to what characterizes adolescents with a non-western ethnic background who are involved in organized sport. This paper therefore, explores whether there are gender differences between adolescent athletes with a non-western ethnic background and majority adolescent athletes in terms of frequency of how much they participate in their sport, involvement in other sports, exercise outside of organized sport, and anticipation of withdrawal from their sport.

Methods

The sample consisted of 1514 athletes aged 12-16 involved in eight different sports. The method of data gathering was the use of a questionnaire. Non-western ethnic background was measured through two questions about mother's and father's birthplace respectively. Both parents born in a non-western country implied categorization as non-western ethnic background, while the remaining were categorized as majority adolescents.

Results: Significantly fewer athletes with a non-western ethnic background than majority adolescents were involved in other organized sports, and/or were doing other kind(s) of exercise in addition to their sport. Additionally, more adolescents with a non-western ethnic background anticipated they would withdraw from their sport the following season. There was also a tendency for athletes with a non-western ethnic background to take part in fewer practices a week in their sport. These differences are due to the boys' sport participation. Boys with a non-western ethnic background participated in fewer other organized sports, did less other kind(s) of exercise in addition to their sport, and more anticipated they would withdraw from their sport the following season, compared to majority boys. There were no significant differences between girls with a non-western ethnic background and girls from the majority.

Discussion: The findings will be discussed in relation to gender theory and Strandbu's (2006) four main explanations for under-representation of athletes with non-western ethnic background in sport; (1) religion, (2) culture, (3) resources, and (4) discrimination.

SPORT PARTICIPATION, SOCIAL CLASS AND GENDER. A STUDY OF NORWEGIAN ADOLESCENTS.

SISJORD, M.K., FASTING, K., SAND, T.S., OMMUNDSEN, Y., ROBERTS, G., SØRENSEN, M.

THE NORWEGIAN SCHOOL OF SPORT SCIENCES

Introduction: The relationship between sport and social class has been extensively examined. Research on adult populations give strong empirical support for the view that sport preference and social class are closely related (e.g. Sudgen & Tomlinson, 2000), however, studies on youths (in Norway) are less convincing (Grue, 1985; Krange & Strandbu, 2004). This paper, which is part of a larger study exploring socio-cultural and psycho-social dimensions in youth sport, addresses the relationship between social class, gender, and participation in organized sport, both in general terms and looking at a sample of sport disciplines.

Theoretically, the paper draws on Bourdieu's conceptualization of social class, emphasizing economic and cultural capital as vital predictors for lifestyle choices and social distinction (Bourdieu, 1984).

Methods: The sample consists of 1514 athletes aged 12-16 years (41% females and 59% males) from eight different sports; fotball, track and field, handball, basketball, volleyball, floor-ball, cross country skiing, and alpine skiing. Data collection was made by means of questionnaire conducted in connection with team practice. To measure social class we used 'number of books at home' as indicator of cultural capital (similar measurement is used in national investigations). The variable consists of three values: 1) less than 100 books, 2) 101-500 books, and 3) more than 501 books.

Results and Discussion: The results show a strong relationship between sport participation and social class, with 26% in category 1, 33% in category 2, and 41% in category 3. In relation to gender, the results reveal evidence for a stronger class component for females (18%, 35%, 47%) than for males (31%, 31%, 38%).

When divided by sport discipline, the results show relationships on each sport except for floor-ball which shows the opposite pattern (highest percentage in category 1 and lowest in category 3). When divided on gender, female participants follow the positive class-relationship for all sports except for volleyball; whereas males diverge on the following sports: Track and field, handball, and basketball. The findings will be discussed in relation to previous research and Bourdieu's conceptualization of social class and cultural capital.

MAIN RESULTS OF THE FINNISH PROGRAM FOR CHILDREN'S AND YOUNG PEOPLE'S SPORT

HAKAMÄKI, M., LAAKSO, N., LAINE, K., LEHTONEN, K., SAARI, A.

LIKES RESEARCH CENTER

Finland has a program for children's and young people's sport comprising various supportive and development measures to encourage young Finns to engage in sports daily. The aim is to increase young people's physical activity.

Among others, the program supports after-school sports development projects, sports clubs which arrange physical activities for children, and inclusive practises in sport. Special focus is on physically inactive children and teenagers.

The program has been evaluated continuously by LIKES Research Center. The evaluation is based on interviews, observations, surveys and analyses of the documents produced during the program.

In this presentation the key results are summarised.

POPULARITY AND ASSERTIVENESS OF ATHLETIC ADOLESCENT PUPILS IN THE CLASSROOM

HOTTER, B., KORNEXL, E., RÖSER, D.

UNIVERSITY OF INNSBRUCK

Introduction: Popularity and social acceptance are important values for youth. Research shows a close connection between sport performance, self-esteem and social status of adolescents (1,2). Sport participation in adolescents is positively associated with indices of

adjustment such as self-esteem. The aim of this study was to compare popularity and assertiveness of athletic pupils with non-athletic pupils.

Method: To determine which pupils were most liked and qualified to act as class representative a sociometric questionnaire was used. Sociometry is a quantitative method for measuring social relationships developed by Moreno (3). He developed methods to analyse interpersonal emotional relationships within a group. His methods can be used to identify informal leaders and social rankings. Pupils ranked their favourite classmates in the following: neighbour in class, leisure companion, and spokesperson in conflict situations. The five best and worst athletes in each class were ranked by the respective physical education teachers. The nominations for best or worst athletes were tabulated (3 points for first ranking, 2 points for second, and so on). The study was conducted in January 2007 in two schools (one girls' school, one boys' school) in western Austria. Data from a sample of 174 adolescents (93 male, 81 female), aged between 12 and 17 in seven different classes were examined.

Results: There was a significant preference of athletic pupils as neighbours ($p<0.05$) and as leisure companions ($p<0.01$). Trends were evident that athletic pupils were favoured as spokespersons. Athletic pupils achieved higher ranks in all categories.

Discussion: Humans often believe that behaviour is influenced by stable personality traits rather than by situational influencing factors (4). The present study shows a good correlation between athleticism and popularity but less correlation between athleticism and assertiveness.

It is evident in this sample that adolescents positively associated athleticism with social acceptance. Research shows a link between sport participation and better behaviour in school. Sport can teach children social skills such as how to communicate, commit and collaborate.

EVOLUTION OF COEDUCATION IN PHYSICAL EDUCATION IN SPAIN: SCHOOLS WITH THE PLAN OF COEDUCATION.

HUERTAS, J.A., HERRADOR, M., LARA, A.J., PEINADO, O.

UNIVERSITY OF JAÉN

Introduction: In this study, we show the relationship that has existed throughout history between women and Physical Education. We analyze the most influential in this regard, referring to the spatial distribution, language, effort and discrimination, found after a historical review, which followed focused on the historical development of Physical Education, they are watching relationships that the woman had with her. Finally, we sought to compare the centres that have the Plan of Co-education and those who do not possess.

Methods: To obtain an update on these four elements, a semi-structured interview of 15 questions for teachers in service, about the impact of these agents in the classrooms.

Results: The results of the study are:

- Spatial distribution: the 42.85% of respondents indicated that boys and girls sharing the space in the classroom, while 57.15% say that they do not. Among those indicating that if they share the space, we can state that in these school is Coeducation Plan implemented.
- Language: 28.57% of the teachers accept the use of sexist language on occasion. On the other hand, 71.43% do not use it, being inside all the teachers who are in a school with the Plan of Coeducation.
- Effort: The 42.85% of teachers surveyed say that there are differences in the assessment effort, using different scales for boys and girls. By contrast, 57.15%, not making distinctions.
- Discrimination: the 85.71% of teachers observed discrimination between boys and girls, while 14.29% did not observe.

Discussion: When comparing the data obtained with the historical suffering, we can see many similarities and developments that have occurred in these 4 areas of study:

- Spatial distribution: until the introduction of mixed schools, boys and girls doing physical education in various space environments. When these spaces are shared, problems occur sometimes by the occupation of the city, not going with the Plan of Coeducation.
- Language: This type of discrimination has been used throughout history, especially recently, but is now being eradicated. This problem does not occur in places with the Plan of Coeducation.
- Effort: in general, the evaluation effort is the same mode for both sexes, which has school in both Plan and non Coeducation.
- Discrimination: throughout history, discrimination has always been in benefit of males, and now can be seen in high percentages, which are both in the school of Coeducation Plan as in those who do not possess.

SOCIAL-DEMOGRAPHIC DETERMINATS OF SPORT PRACTICE FOR THE POPULATION OF THE METROPOLITAN AREA OF MADRID

GARRIDO-MUÑOZ, M., RODRÍGUEZ-ROMO, G., FERNÁNDEZ DEL VALLE, M., MERINO, A., LÓPEZ-DÍAZ, A.

EUROPEAN UNIVERSITY OF MADRID (UEM)

Introduction: Numerous studies have analyzed the influence of different social-demographic variables on the levels of sports participation (García, 2006; Sports England, 2004). In the region of Madrid, the only recent study which analyzed the sports habits of its population was Rodríguez-Romo et al. (2005, 2006). In the present work we analyze the possible relationships amongst some sociodemographic characteristics of the population (gender, age and social status) and certain indicators of sporting interest and behaviour.

Methods: A descriptive study with cross sectional design was used for data collection, utilizing a questionnaire administered through personal interview. Residents of the metropolitan area of Madrid aged from 15 to 69 years comprised the study population. 625 people was selected, with a margin of error of the + 4% and a confidence interval of 95.5% for the whole population. Multistage sampling was used with an ad hoc questionnaire and a descriptive analysis and a non-parametric Chi-Square test was performed on the data.

Results: The results obtained showed that the perception of the population of Madrid regarding the need to practice physical activity and/or sport was related to the social status of those polled [X2 (2) = 9.764; p<.01]. Also significant differences were found in the global rate of sports practice according to the gender [X2 (1) = 17.345; p<.001], the age [X2 (4) = 32.798; p<.001] and the social status [X2 (2) = 16.335; p<.001] of the participants. On the other hand, the frequency of sports practice only seemed to be related to the age [X2 (4) = 11.671; p<.05].

Discussion: The majority of the population of Madrid is conscious of the benefits of the regular practice of physical activity and/or sport. However differences can be observed with the social status. The rate of sports practice is 55.7%, this is 15.7% more than that of the Spanish population (Garcia, 2006). This rate of practice is greater in men than in women; in the youngest participants (from 15 to 34 years) than in those of more advanced age (from 55 to 69 years) and in the people of middle and upper class than in those of lower social status. Approximately 90% of sport participants carry out physical activity and/or sport at least once a week. These figures barely differ according to the gender, although this is not so with age.

PUBLIC HEALTH THROUGH PHYSICAL ACTIVITY AND HEALTHY NUTRITION IN NORWEGIAN SCHOOL

SKOGVANG, B., STORBERGET, A., NORHEIM, T., SALSTEN, C.

HEDMARK UNIVERSITY COLLEGE

A lot of focus has been put on public health and the need for daily physical activity and healthy nutrition for children both in Norway and in other European countries. The Norwegian Government has published research, strategies and policy documents (Departementene, 2005, Departementene 2007, Helsedepartementet 2003). Several research projects are done in this field in Norway like for instance Andersen et. al. (2004), Andersen, L. B. (2006), and Kjønniksen (2008). This poster discuss if and how daily physical activity and focus on healthy nutrition among school children effect public health, exemplified through the on-going project "Daily physical activity and nutrition in primary school" in Norway (Skogvang, et.al.2008, Storberget et.al. 2008).

Methods used in the research project are; surveys, observations and in-depth interviews. A survey is done among PE-students at Hedmark University College (HUC). Observations are done in PE-classes and also through watching the children's physical activity when they play in the breaks. In-depth interviews are done among employers at the primary school (PE teachers, headmaster etc.), and in-depth interviews with pupils and parents are going on now.

Results from the survey with the students show that PE-students state that daily physical activity is positive for the pupil's future health. Also the employers at the primary school state that daily physical activity and more focus on healthy nutrition among school children is crucial for the public health. Data from the observations and in-depth interviews with the parents and pupils will be presented at the congress poster, but they are not analysed yet.

THE <RE>CONSTRUCTION OF NATIONAL IDENTITY THROUGH ENTERTAINMENT IN CASE OF THE EUROPEAN FOOTBALL CHAMPIONSHIP <EURO> 2008: THE ONLINE OPTION

DIMITRIOU, M., SATTLECKER, G., HOFFMANN, F., MÜLLER, E.

UNIVERSITY OF SALZBURG

New technologies, in particular their applications in the field of Internet, digital television and mobile telephony, are also producing new distribution platforms and services for the delivery of sports content. Online media have grabbed the attention of communication researchers in the second half of the 1990s, but the focus to date has been primarily on media audiences and their use of these new forms. Regarding the penetration of nationality in the media sport coverage a number of studies illustrated the impact of representation of national identity in newspaper and TV-coverage of sport events (Blain et al. 1993, Billings/Eastman 2002).

The purpose of this study was to analyse the relationship between content of the online sport portals and national or international orientation during the European Football Championship (EURO) in June 2008. More specifically the research will seek to identify the contribution of the new information technologies in the reconstruction of the national identity.

The survey employed content analysis of six online sport portals – Kicker.de and Sport1.de (GER), Nzz.ch/sport and Sport1.ch (SWI), Laola1.at and Sport.orf.at (AUT) – during the EURO. In order to select the sport sites to be coded, the Nielsen/NetRatings top 20 sport news list (GER), the Austrian Web Analysis (AUT) and the Netreport.net-metrix.ch (SWI) were consulted to determine the most prominent sport news sites. The analysis focused on the first three navigation levels of the homepages. To explore this more systematically, the contents of the websites were coded by two principle dimensions (communication interactivity and information transparency). The communication interactivity included four categories: social interaction, integration, research and multimedia. On the other side, the content transparency

was evaluated by measuring the appearance of sports reporting, the presence or absence of the types of sports reporting and the focus on the national or international coverage regarding topics and personalities.

Concerning the communication interactivity the analysis illustrated that all online sport portals have adopted interactive innovations to produce spectacular entertainment. In concrete, the study found that the commercial portals Kicker.de, Sport1.de, Sport1.ch and Laola1.at have used more integration and multimedia elements than the Nzz.ch/sport and Sport.orf.at. In view of the national or international orientation of the sport coverage, the analysis showed that all online portals focused on the national topics and athletes. Further, national media representation was often characterised by stereotyping of other nations - for example Germany at Laola1.at (AUT). The main result of this study was that the construction of national identity can find expression in online sport coverage.

YOUTH SPORT IN NORWAY: THE FINDINGS FROM STATISTICS NORWAY

VAAGE, O.F.

STATISTICS NORWAY

Interview surveys of Norwegians' living condition made by Statistics Norway did in 2004 and 2007 contain questions about sports activities. The data cover persons from 6 to 79 years. The surveys cover a wide range of activities, but a general question of physical activities in people's leasure time is included.

In the paper we shall most of all look at young people's sports activities, covering persons from 13 to 19 years: What kinds of activities do they prefer and what do they not prefer? Are there differences between boys and girls? Do the young teenagers prefer other activities than the older teenagers? How does their general physical activity differ? We shall also look at young persons' activities compared to activities of children and adult persons.

SPECULATING ON THE RELATIONSHIP BETWEEN PHYSICAL EDUCATION, YOUTH SPORT AND LIFELONG PARTICIPATION

GREEN, K.

UNIVERSITY OF CHESTER & NORWEGIAN SCHOOL OF SPORT SCIENCES

The central concern of this paper is the long-standing issue of whether it is possible to identify a 'causal' link between school PE and youth sport that might implicate PE in promoting increased engagement with sport and active recreation among young people.

There is a body of research – exploring among other things the so-called 'determinants' and 'correlates' of participation in sport over the life course – which purports to show that active participation in sport during childhood and youth is an important prerequisite for involvement in later life. However, the findings from such studies typically leave the question 'What specifically does PE contribute to any "carry-over" effect?' unanswered.

It is entirely plausible that for some young people, the effects of PE on their leisure-sport participation are causal in a necessary sense; that is, without the impact of PE they simply would not take part in any sport in their spare time. PE may, therefore, be important for those youngsters for whom it provides the only opportunity to engage with sport and active recreation or particular activities. It is equally feasible that without the intervention of PE, some youngsters would not take part in particular sports in their leisure to which they are introduced by their PE teachers via curricular or extra-curricular PE. In such cases, PE may be sufficient in itself to result in the desired effect. The evidence for a 'PE effect' on youth and adult sports participation more generally, however, is indirect at best. All-in-all, it seems that school interventions (via PE) appear likely only to impact upon youth sport around the margins; that is to say, they may only be effective within what Birchwood, Roberts and Pollock (2008) refer to as a 'mini.-max. range' to which young people are already predisposed by virtue of their socialization (in the family setting in particular) into or away from sport.

Ongoing attempts to identify conditions in which PE may have an effect, however slight, on participation in sport and active recreation among young people in the here and now (as well as adults in the future) stand to benefit from studies which add a qualitative dimension to the growing list of quantitative studies. That said if research into the sporting careers of those locked into sport as adults provides a barometer of the impact of PE, then improvements in participation levels are more likely among those already engaging with in sport and active recreation in their leisure. Even where interventions such as PE do boost levels of sports participation during school time these levels are likely to be unsustainable beyond school in so far as they exceed the proportions of young people genuinely motivated to take part.

PHYSICAL EDUCATION AND YOUTH SPORT IN SCANDINAVIA

ANNERSTEDT, C.

NORWEGIAN SCHOOL OF SPORT SCIENCES

The purpose of this session is to give an overview of physical education and youth sport in Scandinavia: The focus is on Sweden.

A comparative analysis reveals many similarities between the school systems as well as between PE in the Scandinavian countries. It even seems possible to talk about a Scandinavian model for PE, characterized by a broad content area, where pupils choose from a kind of smorgasbord of physical activities. Although these take the form of multi-activity programs in practice ballgames, gymnastics, fitness training and track and field dominate the subject. On the other hand, typical activities for Scandinavian culture like skiing, skating, orienteering and outdoor education also form part of a PE program. Further, health is a central proficiency area in PE in especially Sweden and Finland. However, what a health perspective means in practice is seldom discussed and the teachers have difficulty defining the concept.

In the Scandinavian countries sports are also offered either as specific programmes or as available options. Schools in Sweden can have either an elite approach, developing talents in different sports, or a sports-for-all approach, where the focus of sporting activities is on the health benefits. In 2007, 17% of elementary schools (grade 1-6) and 34% of secondary compulsory schools (grades 7-9) in Sweden offered a certain sports profile at their school. In upper secondary the figures were much higher; 51% of the Swedish state schools and 45% of the independent schools (private schools) stated that they had a sports profile. These sporting profiles are probably the most surprising changes regarding PE in Sweden in recent years.

There used to be a tradition of school teams and competitive sport in Scandinavian schools. Nowadays, there seems to be a resistance due to two reasons: a general negative attitude towards competitiveness at school and the tradition of having all sorts of sport activities easily accessible during leisure time. This has led to a decreasing interest in school sport, even though there are still extra-curricular school sports available.

However, organized sport is highly valued in Scandinavia during leisure time and attract major parts of its citizens in one way or another. In Sweden about two thirds of all children and youth are members of some of the 22.000 sports clubs all over the country and almost 80% of their parents are, in some way, voluntary involved in the daily work in the clubs. The Swedish government has during the last years also introduced a big program called the Handshake in order to stimulate physical activity and sport. This is a huge investment of 50 million Euros per year during 8 years and includes cooperation between the sport federations and the schools.

OP-PP02 Physical Education and Pedagogics 2

BODY CULTURE WITHIN THE EU'S COMPETENCE SYSTEM

HAMAR, P., SZILVA, Z.S., SOÓS, I.

1. SEMMELWEIS UNIVERSITY, 2. BUDAPEST AMERICAN INTERNATIONAL SCHOOL OF BUDAPEST, 3. UNIVERSITY OF SUNDERLAND, UK

Introduction: Proficiency and customs in body culture are essential in drawing the picture of 21st century education and civilization; it is even more important when sketching key knowledge competencies and life in schools. Despite the significance of body culture, it was not included in EU's framework of key competencies. This paper addresses reasons for the necessity of the key competency that represents the values of body culture.

Competence

The word "competence" originates from the Latin "competentia", which means skilfulness. It is mostly embedded in cognitive features but motivation elements, abilities and emotional factors also have important parts in it. Another interpretation implies that competencies comprise basic knowledge that reveals the individual's competitive abilities in life. In competencies-based education, competence means possession of knowledge of something. Curricula based on competencies emphasize abilities that need to be developed as opposed to curricula based on content that emphasise arranging syllabuses.

Competence systems of Hungarian curricula

Recent political changes in Hungary have brought changes in preferences of values, but the former approach of a nation only having a future that is healthy and physically active has remained; this persisting approach retains the value of health and physical active. Thus, the following aim was emphasized: "Development of understanding of the importance of health as a value throughout all areas in social and economic life is our highest common interest" (Program of National Revival, 1990). All-round improvement of physical and mental abilities was, in the outlined future perspective, a task to be completed in order to meet requirements that were set by the environment in the fields of health, lifestyle and behaviour. The common standards of teaching different cultural domains, so-called key competencies, were established in this spirit in the 1995 National Curriculum.

Necessity of key competencies in body culture

The key competence that involves all kinds of values of body culture should not be omitted from the EU's framework of key competencies and from basic pedagogical and educational goals. "Body cultural" should be employed as a terminus technicus. Development of the key competencies of body culture can happen in early childhood, in elementary, in high school, in university and in adult education. Different levels of education can only achieve the required life long development effect together with conscious practice of sport activities. Collectively family, school and sport institutions can provide the educational spheres of developing the competencies of body culture.

PEDAGOGICAL REPRESENTATIONS AND PRACTICES OF PHYSICAL EDUCATION UNIVERSITY PROFESSORS

STADNIK, A., CAMILO-CUNHA, A., PEREIRA, B.

UNIVERSIDADE TECNOLÓGICA FEDERAL DO PARANÁ; UNIVERSIDADE DO MINHO

Introduction: Within this study about university professors of Physical Education and their reality we have taken two paths: on the one hand, a more cognitive one based on the professors' thoughts (representations); and on the other, their actual practice which is based on

their actions. The approach we have opted for relates straightly to the significance the professors themselves give to their daily professional lives.

Methods: We have chosen a qualitative approach. The rationale behind this study underlies an interpretative nature whose focus of interest and methodological analysis lay on observation and interviews. It is based on diagnosing observed facts: we have collected, described, interpreted, and presented a given reality data without interfering in it (Gil, 1994). The sample for accomplishing this research is: two men and two women professors who have been teaching for more than ten years, who have either a master or a doctor degree, and are considered competent within their working environment – considering the importance of good models for students, specially because of modeling learning. As learned from Ferraroti (1979), we have pondered that a small and deliberate chosen sample, when deeply dealt with, could meet our goal needs, after all, "if each individual represents a single re-appropriation of the social historical universe surrounding us we can come to know its social aspect from the irreducible specificity of an individual praxis" (p. 51).

Results: Their lives history illustrate the plurality of meanings each professor attributes to their life, which somehow brings, by means of integrating their thoughts and action, what their professional life is like in that given moment.

Discussion: The reflection upon the lives history led the study to present a possible profile of "the good Physical Education university professor", by means of disclosing and reflecting on their personal characteristics as well as scientific and social features, which we believe can be entailed within their attitude, their thoughts and curricular action towards the Physical Education teachers-to-be. We came to find, among other facts, that the professors we have analyzed show a great coherence between their speech and their actions and we have concluded that those are constantly diligent professors and that despite being deemed to be good professionals within their social environment and being self-confident, they go through numberless difficulties in several aspects of their lives, particularly when it concerns applying, transforming and innovating their pedagogical actions. Notwithstanding, they are tenacious and resilient. And finally we can state that those professors love what they do and they try to do their best.

"SENSITIVITY TOWARDS STRANGENESS": MEASUREMENT AND PRACTICAL IMPLICATIONS WITHIN THE FIELD OF PHYSICAL EDUCATION

ESSER-NOETHLICHS, M.

OSLO UNIVERSITY COLLEGE

Introduction: The objective of this paper is to present a conceptualization of "sensitivity towards strangeness", its measurement, and practical implications within the field of physical education. Long term goals are intended to develop training programs which will develop and/or improve sensitivity towards strangeness - in particular through the medium of sport and physical activity. The evaluation of the intended training program, however, requires measuring instruments. As a result, the sensitivity towards strangeness questionnaire (STSQ) is developed in order to measure effects of intervention activities in a quasi-experimental design.

Strangeness appears to be a central construct within the field of intercultural education (Auernheimer 2005; Erdmann 1999; Gieß-Stüber 2005). In this context, strangeness is basically understood as a social construction (Simmel 1994; Hahn 2000). Terms such as "xenophobia" and "hatred against strangers" illustrate problematic consequences related to this phenomenon.

However, sensitivity towards strangeness also means learning to deal with perceived differences and strangeness constructively. The insight that strangeness is not an attribute of a person or social group but a socially constructed perception is a crucial element when intending to improve mutual understanding. In addition, knowledge about the structures and mechanisms leading to strangeness is compulsory in order to meet these situations with a certain degree of open-mindedness and being capable of dealing with implicit uncertainty as well.

Method and Results: As a result, sensitivity towards strangeness questionnaire (STSQ) is developed theory-based and with a number of related field studies and quasi-experimental design.

In addition, practical situations were experienced within P.E. school classes and on-the-job-training with teachers and P.E. students in order to examine the options of improving a STS through the medium of sport and various types of physical activities.

Conclusion and outlook: Thus, these practical experiences seem to be fruitful in terms of the theoretical assumed direction, but further research is required in order to examine the effects of such interventions under more scientifically controlled circumstances. The STSQ is consequently supposed to be one central indicator in order to evaluate training programs with respect to increasing sensitivity towards strangeness.

ASSESSMENT IN PE - DIFFICULTIES AND CONSEQUENCES OF A CRITERION-REFERENCED SYSTEM.

ANNERSTEDT, C., LARSSON, S.

NORWEGIAN SCHOOL OF SPORT SCIENCES AND UNIVERSITY OF GOTHENBURG

Background: A new national assessment system was introduced in Sweden in 1994 – a criterion-referenced system instead of the former norm-referenced system – which meant other ways of assessing and that teachers at every school were to discuss, develop and formulate local criteria for assessment.

Purpose: The study is about how PE teachers' experience the criterion-referenced grading system and what consequences one can see. It aims specifically at investigating which aspects teachers discern in grading students in PE.

Method: The study is divided in two parts; one quantitative looking at the development of grades in PE over a seven years period and comparing grades given in the municipal schools with those given in the independent schools, and one qualitative in which we conducted semi-structured interviews with 20 PE teachers about which aspects they discern in assessing students.

Findings: The study shows significant changes towards giving higher grades in PE. However, this slide towards higher grades can also be seen in other subjects and it seems as if assessment in PE is not significantly different from assessment in other subjects. Furthermore, grades given in the independent schools are significantly higher than those given in the municipal schools.

There is also considerable discrepancy between schools. This can partly be explained by differences in socio-cultural capital, but there are also great differences between teachers in the same school that can only be explained by different approaches to grading and to what and how they assess their students.

The teachers mean that they were not properly informed about why they should formulate assessment criteria and how to do it and they were given very little in-service training regarding assessment. They also claim that guidance given from the national authorities were indistinct, unclear and somewhat difficult to understand.

Due to the lack of guidance and support, other ways of assessing have been developed locally, sometimes concealed and contrary to the national directions. Furthermore, there seems to be combinations of norm-referenced and criterion-referenced principles in use. Even personal criteria, or what can be labelled as "gut-feeling", sometimes determine the outcome of assessment in PE. The data also indicate that the teachers make judgements about students´ level of achievement without explicit reference to the national criteria in PE or even to the schools´ "local work plans" and "local grading criteria". The following is assessed in PE: presence, effort, social capability, leadership skills, skill in physical activities and sport as well as knowledge about PE.

Many years after the change in grading systems, assessment of students does not seem to occur in line with the intentions of the reform. The criteria are not always openly stated by the teachers and therefore not accessible to the students. Thus, there still seems to be many problems in reaching fair and equivalent grading of students in Swedish PE.

PHYSICAL EDUCATION TEACHERS ATTITUDES TOWARDS STUDENTS WITH DISABILITIES

HERNÁNDEZ VÁZQUEZ, J., BOFILL RÓDENAS, A., NIORT, J.

INSTITUT NACIONAL D'EDUCACIÓ FÍSICA DE CATALUNYA

Introduction: The political model of educative inclusion in Spain emphasizes the external resources and ignores the training of the ordinary teaching staff dealing with special educative needs students, being the teaching staff formation an aspect that needs improvement.

Methods: The final purpose of this study is to develop the degree formation and lifelong learning of the teaching staff in physical education dealing with attention to the diversity by having the physical education teachers (n=59) at secondary school, in Barcelona, to answer and complete a questionnaire as regards the intervention of the teaching staff in the classroom with this kind of students. Concretely, the self-perception of the teachers with special educative needs students regarding their performance as professors.

Results: The results show a complex situation among the teaching staff, perceiving a lack of resources to optimize their competence with the pupils with special educational needs. Also an improvement of the formation and the attitudes of the teaching staff of physical education is required in order to take care of the attention at the diversity.

Discussion: The study describes a social and educational profile as regards the situation of the teaching staff related to the pupils with special educational needs. It is necessary to stand out that one of the objectives of the current educative legislation is the attention to the students with special educational needs. More resources and a training of the teaching staff working at the ordinary educative schools focused a initial formation but also a longlife learning to take care of the diversity is needed. From the knowledge and the data obtained we can improve the programs of degree formation and longlife learning.

OP-SO03 Sociology 3

SPORTS PARTICIPATION FROM ADOLESCENCE TO MIDDLE AGE - A 38-YEAR FOLLOW-UP STUDY

ENGSTRÖM, L.M.

STOCKHOLM UNIVERSITY

Many studies have found that there is a low to moderate association between exercise during adolescence and exercise habits in adulthood. A question that arises from these earlier studies, with a follow-up period of about 5 to 20 years, is how children's and adolescents' physical activity affects their inclination to exercise later in life, after the age of 50, e.g. after a follow-up period of almost 40 years.

The main objective of this study is to illustrate whether, and in that case how, differences in sports experiences during childhood and adolescence and differences in cultural capital are reflected in exercise habits in middle age. The specific research questions are: (i) How does sport habitus formed during childhood, in physical education lessons at school and through leisure time sports during leisure time, relate to exercise habits in middle age? (ii) How does the cultural capital acquired during childhood relate to exercise habits in middle? The analysis takes its starting point in Pierre Bourdieu's conceptual framework.
The individuals included in this follow-up study were first contacted in 1968 when they were 15 years old. Follow-up contact and information gathering has been conducted on six additional occasions, primarily via questionnaires sent by post. In 2007 the highest possible number of responses was 1,979. A total of 1,518 responses were received, which corresponds to 77 per cent of the total reachable group.

Neither membership of a sports club nor the amount of time spent on sports activities at the age of 15 had any significant association with the exercise habits displayed in middle age when the individual's breadth of sport experience was used as a simultaneous control. As indicators of sport habitus both the breadth of sport experience during leisure time and grades in Physical Education had a significant association with later exercise habits. There was also an almost five times greater chance that an individual with a very high cultural capital at the age of 15, as defined by their social background and grades in theoretical subjects, was still an active exerciser 38 years later in comparison to an individual with a very low culture capital.
Conclusions: A middle-aged individual's level of exercise is closely linked to that person's social position and, accordingly, to his or her educational capital. The children and adolescents with the greatest chance of achieving this middle-class position were those coming from backgrounds with a relatively high social positions and/or high grades in school. If they had a strong sport habitus as well, their inclination to exercise was strengthened.

PHYSICAL ACTIVITY AND OLDER ADULTS. A CHARACTERIZATION OF THE NORTH INTERIOR OF PORTUGAL

PEREIRA, A., SANTIAGO, L., PINHEIRO, C., MOREIRA, M.
POLYTECHNIC INSTITUTE OF VISEU; MAIA INSTITUTE OF HIGHER EDUCATION; UNIVERSITY OF TRÁS-OS-MONTES AND ALTO DOURO

Introduction: Scientific research has highlighted the effects of regular physical activity for the health and well-being of older adults (Buckly, 2007). Among various benefits, it reduces the risk of various chronic situations namely coronary heart disease, hypertension and it has a high positive impact on decreasing illnesses and possibly mortality (Mota et al., 2006). On the other hand, it promotes psychological well-being and it has a positive causal effect on the older adults' self esteem (Stathi, Fox, & McKenna, 2002).
In spite of the benefits that physical activity has on the older adults' autonomy, in Portugal only 3% of this population does physical activity and it is mostly women (Marivoet, 2001; INE, 2003). We therefore consider it important to know the representations that the elderly population in the north interior of Portugal has in relation to physical activity, to enquire about their practices and to know their aspirations at this level.
Methods: This study was carried out on 75 older adults (45 women and 30 men), physically and mentally autonomous and residing in Douro Sul. Semi-structured interviews were carried out (Ghiglione & Matalon, 2001).The technique used for data analysis was content analysis (Bardin, 1977). The elaboration of the categories had been defined à priori and à posteriori. The computer programme of qualitative data analysis QSR NVivo 7 was used in coding the transcripts of the interviews.
Results and Discussion: The majority of the older adults interviewed state that they do not do any physical activity because of health problems, low income, little time available and the fact that they find no pleasure in doing physical activities. The most popular leisure activities are watching television, walking, being with friends and reading. If possible they would like to do dancing and swimming in the future.
The older adults that are physically active prefer walking, gymnastics and swimming / hydro-gymnastics; they do these activities for health reasons, for fun, to socialise, to be with their friends, to occupy their free time and to become physically fit.

'EVIDENCE. WHAT EVIDENCE?': A STUDY OF SCHOOL SPORT PARTNERSHIPS IN NORTH-WEST ENGLAND

LEECH, R., SMITH, A.
UNIVERSITY OF CHESTER

Introduction: Since the late 1990s, increasing political and policy emphasis has come to be placed on the alleged role that physical education and school sport (PESS) can play in the achievement of government's (non-)sports objectives. This increasing government support for PESS has been accompanied by a potential threat – evidence-based policy. In Britain, the focus on outcomes and effectiveness was further enhanced by the emphasis that New Labour has placed on the need to provide evidence of policy effectiveness and base policy and practice on robust evidence to ensure the delivery of government's policy goals. However, despite this alleged concern with basing policy and practice on outcomes and effectiveness, the systematic monitoring and evaluation of sports programmes are in their infancy.
Methods: The central objective of this paper is to examine aspects of the monitoring and evaluation of the School Sport Partnership (SSP) programme, a school-based initiative that was launched in England in 2006 as part of the Physical Education, School Sport and Club Links (PESSCL) strategy. The SSP programme is expected to help contribute towards the achievement of non-sports objectives related,

among other things, to young people's health, behaviour, attainment and attendance. This paper reports on data generated by semi-structured interviews conducted in June and July 2008 with 14 Partnership workers from a SSP in north-west England.

Results: The findings of the study reveal that while there is some evidence of the effectiveness of the programme in relation to the achievement of some sporting objectives, evidence of the extent to which those who deliver the programme are successful in achieving other policy outcomes is considerably more variable and limited. In particular, although those working within SSPs made a range of claims about their ability to use PESS as a tool for achieving a range of desired social outcomes, the presumed benefits of the SSP programme were often accepted uncritically and perceived as almost inevitable outcomes of participation in the programme. Few attempts were also made to systematically monitor and evaluate (beyond the generation of basic quantitative outcome data) SSPs for their desired impacts. This was not especially surprising because monitoring observed changes in pupil behaviour and attainment, for example, is further compounded by the difficulties of identifying the presumed impacts on these complex aspects of young people's educational experiences.

Discussion: Despite the rhetoric that surrounds the need for Partnership workers to provide evidence of the effectiveness of the SSP programme, there are few signs that the programme is being monitored and evaluated effectively, if at all. Like many other areas of policy, the programme appears to be indicative of wider government concern with encouraging the 'take offs' of new PESS strategies than ensuring the 'safe landing' and enhancing the effectiveness of existing ones.

INCLUSION AND NATIONAL CURRICULUM PHYSICAL EDUCATION IN ENGLAND: A STUDY OF UNPLANNED OUTCOMES

HAYCOCK, D., SMITH, A.

UNIVERSITY OF CHESTER

Introduction: Since the mid-1990s, physical education (PE) has been seen as an important vehicle of social policy targeted at promoting the inclusion of young disabled people in mainstream schools. But to what extent has government been able to achieve its stated objective of greater inclusion in schools? Has the inclusion of disabled pupils in NCPE helped enhance the educational experiences of these pupils? Or have these policies also resulted in consequences that are the very reverse of what was intended?

Methods: This paper sets out to examine these issues by drawing upon data from focus groups conducted with 12 PE teachers from five secondary schools in north-west England during July 2008. The focus groups were designed to generate data on teachers' experiences of inclusion and were concerned with examining the extent to which government have been able to bring about desired change in pupils' experiences of National Curriculum Physical Education (NCPE).

Results: While government has increasingly constrained teachers to include disabled pupils in PE, the outcomes of the increasingly complex interweaving of the actions of the many different groups have made it more difficult for teachers to achieve the government's goals in relation to enhancing pupils' experiences, an outcome which it is fair to assume was neither intended nor desired by government. Teachers suggested that the process of inclusion has created the opportunity for experiences of PE to become more unequal. When disabled pupils are educated in the same class as their age-peers, there is a tendency for them to be taught separately from one another in what amounts to de facto integration. The existence of integration in PE has meant these pupils' often receive a narrowly focused PE curriculum comprising more individualized physical activities and adapted versions of team sports. Pupils are also often not assessed in the same manner and according to the same criteria as other pupils and for some, perhaps even a majority, both these things impact negatively on self-esteem and confidence, isolate them from other members of the class, and reinforce, rather than break down, barriers between them and other pupils.

Discussion: The growing complexity of the networks of relations involved in PE has had unplanned outcomes that are indicative of the inability of any one group – even a group as powerful as central government – to retain control over the policy process so that they are able, within closely defined limits, to pursue effectively their inclusion policy goals. This has had the effect of undermining the extent to which government are able to achieve its other priorities related to the subject. It also reveals that whilst government has a greater capacity to make crucial decisions over policy priorities, the nature and complexity of the relationships in which they are involved means that the extent to which they are able to achieve their objectives is very dependent on the actions of other, seemingly less powerful, groups like teachers.

SPORT AND SOCIAL CAPITAL AMONG ETHNIC MINORITIES IN FLANDERS (BELGIUM)

THEEBOOM, M., DE KNOP, P.

VRIJE UNIVERSITEIT BRUSSEL

Introduction: It is often assumed that organized sport involvement can contribute to the development of social capital. This assumption is based on a number of specific characteristics of the organized sport context, namely the creation and maintenance of social relations and cohesion between members as a result of a regularity in membership, voluntary work, etc.. It is also indicated that members of sport associations have systematically more exogenous friendships in comparison with non-members and that they are more trustworthy. It is even stated that sport participation enhances more feelings of trust and civic engagement in comparison with other leisure activities. Moreover, membership in sport associations is believed to encourage group cohesion and that sport organizations can contribute to the (re)construction of social cohesion in today's individualized societies.

In light of the assumed social integrative potential of organized sport, there is a tendency among policy makers in Flanders (Belgium), to advocate mixed organized sport involvement as one of the answers in dealing with tensions among different ethnic groups in today's Flemish multicultural society. The present study, using Putnam's theory on bridging and bonding social capital, attempts to analyze this potential of organized sport involvement among ethnic minorities in Flanders by looking at experiences of members actively involved in either 'separate' or 'mixed' sport organizations.

Methods: A face-to-face survey was conducted among 262 adult ethnic minority members (171 males - 91 females) from 20 sport organizations (7 separate - 13 mixed sport context)(10 sport clubs, 1 fitness club, 9 specific youth initiatives). Also, 35 in-depth interviews were conducted (26 females - 9 males) (18 separate - 17 mixed). Questions related, among other things, to social interactions, mutual support, inter-ethnic relations, trust and racism.

Results: Specific differences were reported with regard to age, gender and organizational context. For example, mixed members indicated more that they have learned to make contact with others, become more self-confident and learn more about other ethnic groups. However, separate members appeared to have more in-depth conversations with other members and consulted each other more often for advice outside the sporting context.

Discussion: This study provides some evidence that a number of variables exist that can alter the experience of organized sport involvement. However, findings of the present study cannot support the general notion that a mixed organized sport context offers more opportunities for increased social capital among its members compared to a separate sport context. Moreover, the results do neither provide evidence for the assumed social integrative potential of an organized sport context as the direction of this causal relation is still to be firmly determined.

ORGANIZATIONAL REQUIREMENTS FOR INCLUDING LOW-ACTIVE GROUPS IN WORKPLACE EXERCISE PROGRAMS

BJØRNSTAD, T.

NORWEGIAN SCHOOL OF SPORT SCIENCE

Project description: Organizational requirements for including low-active groups in workplace exercise programs

Thor Christian Bjørnstad, PhD student at the Norwegian School of Sport Sciences, thor.bjornstad@nih.com

In resent years we have witnessed an increasing concern regarding workplace health issues. A driving contextual force is the consensual political ambitions aimed at stopping the ongoing trend of more and more people leaving the workforce. In this regard the political initiative put forward by the Minister of Government Administration and Reform, in collaboration with the Confederation of Norwegian Enterprise (NHO) and the Norwegian Confederation of Trade Unions (LO), has intensified the focus on health related to the workplace environment . The economically motivated concerns have increased funding to research , besides having reintroduced and revitalized exercise as a preventive measure at work. Although the traditional gymnastics is abandoned for more sophisticated exercise, like aerobics, golf or yoga, the overall intention still is to include the majority of the workforce. However, exercise as a preventive measure is first and foremost targeted at the inactive part of the population.

Within this context, my project focuses on the work carried out by the Norwegian Federation for Company Sports (Norges Bedriftsidrettsforbund: NBF), as I follow their intervention in three different organizations. The NBF is part of The Norwegian Olympic Committee and Confederation of Sports (NIF) and has 310,000 members divided into 4,691 teams. As their primary goal is to motivate people to exercise in a work place context they provide workplace exercise programs to companies in both private and public sectors. These programs aim at getting people who do not normally exercise to get in physical shape in accordance with their own preferences. The programs are developed in close cooperation with each company, assisting the company, drawing up action plans, implementing and evaluating initiatives through project groups where representatives from the NBF is working together with company representatives.

The central research question will address: What kind of organizational prerequisites influence on the implementation process of a workplace exercise program for including low-active employees?

The intention is to observe and analyze the processes these kinds of interventions generate, identifying the possible consequences for including low-active groups in a work place exercise program. The research question addresses various potential influential organizational levels: as individual preferences to health and exercise, socioeconomic background, the implementation as a working process and possible prerequisites external to the organization. The ambition is to locate the required conditions for getting inactive people to get fit, beyond mere individual factors, but also including the social environment at their workplace.

FUNCTIONAL WEAK LINK TESTING AND ITS RELATIONSHIP WITH LOWER EXTREMITY INJURY HISTORY: A STUDY ON FEMALE TEENAGE ATHLETES

JOHNSEN, M., JOHANSEN, K., SEILER, S.

UNIVERSITY OF AGDER

Introduction: The lumbo-pelvic (core) muscles are important for optimal energy transfer through the kinetic chain. It is hypothesized that core stability plays a major role in musculoskeletal injury prevention. The aim of this study was to determine the prevalence of diminished core muscle capacity in young female athletes, and to quantify the relationship between results from 3 rotational "weak link tests" and lower extremity injury history.

Methods: Female athletes (n= 90, 17.3 ± 1.0 yrs), participating in a variety of competitive sports (football, team handball, martial arts, running, etc.) performed three weak link tests and completed a questionnaire regarding their lower extremity and lower back injury history. Weak links were defined as 1) >6mm depression of the navicular bone from seated to standing, 2) > 2.5 degree pelvic rotation during 30 deg abduction from a supine bridge position (performed in slings, with instrumented visual feedback), and 3) clinically visible inward rotation and/or adduction of the femur, and/or failure to achieve 90 degree knee angle during a one legged squat.

Results: Navicular drop was not an independent predictor for lower extremity injury risk. Only 5 of 90 subjects had >6mm depression in either foot. While 41% failed the supine abduction test (one or both sides), test failure was not significantly related to injury history. Only 7 of 41 subjects who passed the one- legged squat test on both legs (1LS PASS) reported previous acute knee injury compared to 24 of 48 subjects (RR 2.92, $p<0.01$) who failed on one or both legs (1LS FAIL). Both knee (1.0 ± 1.3 vs 0.24 ± 0.6, $p=0.001$) and ankle injuries (2.8 ± 3.3 vs. 1.6 ± 2, $p=0.04$) were more frequently reported in 1LS FAIL, while previous back problems also tended to be more prevalent (44% vs 27%, $p=0.09$).

Conclusions: Excessive navicular drop (inward foot/ankle rotation) was infrequent and not associated with increased lower extremity injury history. The supine abduction test revealed a high prevalence of poor pelvic rotational stability, but this was not directly associated with higher lower extremity injury prevalence. In contrast, past knee injuries were nearly 3 times more frequently reported among female athletes who failed the one legged squat test on one or both legs. These results suggest that the one legged squat is strongly predictive of lower extremity injury risk. The one legged squat test may be a simple, useful screening tool for targeting female athletes for intensive knee injury prevention programs designed to strengthen hip and pelvic musculature.

HOW SHOULD CORE STABILITY BE EVALUATED? A COMPARISON OF INTEGRATED AND ISOLATED METHODS

JOHANSEN, K., JOHNSEN, M., SEILER, S.

UNIVERSITY OF AGDER

Purpose

Lumbo-pelvic (core) stability and strength is determined by the integrated function of multiple deep and global muscles working in three dimensions. In contrast, the most popular quantitative tests of core function are one dimensional and isolated in nature. The purpose of this study was to compare the results of several common isolated muscle tests for the core region with results from two integrated, 3-dimensional "weak link" tests.

Methods: 30 sports active females (18 ± 1 yrs, 167±7 cm, 60 ± 5 kg) who trained regularly (13 ± 5 hrs/wk) participating in the study. About 75% reported performing specific training for improved core stability. Between day test-retest reliability was evaluated for the one legged squat (pass-fail based on 90 degree hip angle and absence of inward knee rotation and/or adduction, 3 attempts) and a 30 degree leg abduction test from a supine bridge performed with one leg in an unstable sling hanging from the ceiling (pass-fail based on ability to maintain less than 2.5 degrees pelvic rotation with instrumented visual feedback). Subjects also performed a side bridge test to failure (holding time in s), a 60 degree isometric sit-up to failure (holding time), the Biering-Sørensen back extension test (holding time), and a 10 degree isometric hip abduction test (maximal force in N).

Results: Combined right and left leg test-retest agreement for the one legged squat was 93%. Agreement for the supine 30 degree abduction test was 84%. 50% of the subjects failed the one legged squat test on one or both legs. 12 of 30 (40%) subjects failed the supine abduction test on one or both sides. Performance on the 4 isolated muscle tests was compared in 8 females who passed both left and right sides of the 2 integrated tests and 7 subjects who failed on at least 3 out of 4 side-specific tests. Biering-Sørensen (117 ± 47 vs 104 ±26 s, p=0.5), 60 degree flexion (206 ± 122 vs 215 ± 111 s, p= 0.89), side bridge (101 ± 27 vs 97 ±39, p= 0.82), and 10 degree abduction force (212 ± 32 vs 195 ± 49 N, p= 0.42) were all similar in the two groups.

Conclusions: The 1-legged squat and 30 degree supine bridge abduction test both showed good test-retest agreement However, when clinical findings from these two functional tests were compared with results from 4 established muscle performance tests, we observed no relationship. Given the one-dimensional nature of the isolated muscle tests, we question their validity as integrated measures of lumbo-pelvic stability. We also observed that females who reported a combination of strength training exercises on stabile and unstable surfaces had fewer "weak links" based on functional testing.

EFFECT OF KINESIO TAPING ON QUADRICEPS MUSCLE STRENGTH IN HEALTHY, NON–ATHLETES ADULTS. A PILOT STUDY.

ZERVAKAKI, E., ALIGEORGA, A., DASKALAKI, CHR., METALLINOU, E.P., EXERTZOGLOU, E., PAPANDREOU, M.

FACULTY OF HEALTH SCIENCES, TECHNOLOGICAL EDUCATION INSTITUTE (T.E.I), ATHENS.

Introduction: In recent years, the use of Kinesio Tape (KT) has become increasingly popular. One of the proposed benefits (2) is the alignment of the fascia tissue and therefore improvement of muscle activity. However, only few studies have measured its effectiveness in quadriceps strength and these studies have obtained inconsistent results (1,4,5). The purpose of this RCT double blind pilot study is to investigate the effect of Kinesio taping on quadriceps muscle strength compared to sham taping in healthy non-athletes adults.

Methods: 20 healthy adults, (age: mean=22.65y±2.39, weight: 68.6 Kg±13.4, height: 1.71m±0.08), were enrolled in this study. The isokinetic dynamometer (Human Norm CSMI 770) was adopted to assess concentric and eccentric exercise in the quadriceps muscle strength while contracting at a speed of 60 ◦/s, (peak torque, five repetitions). Subjects were randomly allocated in two groups. In the experimental group a Y-shaped Kinesio tape was applied parallel to quadriceps fibers which placed in a stretched position (KT) (according to Kenzo Kase) (3). In the control group an I-shaped Kinesio tape was applied perpendicular to quadriceps fibers in their normal length (sham taping-ST). The subjects were measured under two conditions 1. without tape, 2. immediately after taping.

Results: ANOVA repeated measures were shown that there was no statistical significant effect of Kinesio-tape on quadriceps concentric and eccentric strength at both legs. Statistical significant result was revealed on quadriceps concentric contraction at right leg, F (1,18)=6.634, p=0.019, p<0,05, but no difference was shown between the experimental (KT) and the control (ST) group, F (1,18)=0,044, p=0,836 >0,05.

Discussion: These findings suggest that Kinesio taping does not enhance quadriceps muscle strength of healthy non-athletes individuals. The limitation of this pilot study was that the measurements of quadriceps strength were done immediately after the application of the tape, when the propose literature suggest that the optimal effect of KT is shown 12h after taping (3). These results can not been generalized in an injured population and therefore the need of future research in this area is imperative.

EFFECT OF TAPING ON FUNCTIONAL ANKLE INSTABILITY IN FEMALE ELITE HANDBALL PLAYERS

SØRENSEN, H., SØGAARD, L., KNUDSEN, I.Y., ANDREASEN, C.B.

DEPARTMENT OF SPORT SCIENCE, UNIVERSITY OF AARHUS, DENMARK; PHYSIOTHERAPY, VIA UNIVERSITY COLLEGE, ÅRHUS, DENMARK

Introduction: 20% of all sports injuries are related to the ankle joint (Bahr, 2002); in handball the ankle is involved in 40% of all injuries, and females are considerably more injury prone than males (Lindblad et al., 1992). Self reported functional ankle instability (FAI) has been linked to increased injury risk (Ross & Guskiewicz, 2004). Likewise, FAI has been linked to reduced postural stability (PS) quantified from force plate data (Noronha et al., 2006). Taping is frequently used to prevent ankle injuries. The effect has not been investigated directly, but the effect on PS has been tested with equivocal results in studies using static, one legged stance (Bennel & Goldie, 1994; Leanderson

et al., 1996). Recently, more functional methods for testing dynamic PS has been developed and validated (Ross & Guskiewicz., 2004), but hitherto not employed to study the effect of taping in players with FAI. Thus, the purpose of this study is to assess the effect of taping on dynamic PS in elite female handball players, and to detect a possible relation between the effect of taping and the severity of FAI.

Methods: Fourteen female elite handball players with FAI performed standardised horizontal jumps with and without tape in randomised order. The subjects were required to stabilize as fast as possible after a one legged landing on a force plate. Time to stabilization (TTS) was calculated and used as a quantitative measure of dynamic PS. The jump, data acquisition and TTS calculation were slightly modified from Ross & Guskiewicz (2004).

Results: We found no significant (p=0.075) difference in TTS values obtained with and without tape. The values were actually (non-significantly) higher (i.e. less stability) with tape, in agreement with Ross et al. (personal communication). Further, we found no correlation (r=0.008, p=0.979) between the effect of tape (TTS difference with and without tape) and severity of FAI (TTS value without tape).

Discussion: Without prospective studies directly investigating taping's effect on injury risk, we only have studies linking PS to injury risk and studies like the present investigating taping's effect on PS. Since we found no reduction in TTS, the widespread use of taping among athletes might not be warranted. A possible stability reduction might even suggest that taping interferes negatively with sensori-motor functions necessary for stability.

THE ADAPTATIVE COMPORTMENT OF ADOLESCENT IDIOPATHIC SCOLIOSIS ON THE DYNAMICAL BEHAVIOUR.

MESURE, S., BRUYNEEL, V., CHAVET, P.

INSTITUT DES SCIENCES DU MOUVEMENT

Introduction: Adolescent Idiopathic Scoliosis (AIS) is characterized by morphological trunk modifications acting on the body masse distribution. Consequently, specific biomechanical strategies during the postural regulation are reported (Allard et al, 2004). Considering that the deformation is three-dimensional, the analysis of strategies resulting from different stepping directions may lead to a better understanding of the behavioural dynamical adaptation. The scoliosis deformation induced dynamical postural perturbations that enlarge asymmetry between lower limbs in terms of ground reaction forces during different normal gait phases.

Methods: Twenty-five adolescent girls participated in this study (13.18 years). The average Cobb angle was 33.4±18° for right thoracic or thoraco-lumbar without compensatory curve. The control group consisted in 15 able-bodied adolescent girls. Two forceplates at the floor level provided the GRF. The set up experimental paradigm consist to do an initiation step in two directions. Specific Fx, Fy and Fz GRF parameters (magnitude and occurrence) were extracted to characterize step dynamics. Impulse of GRF components was computed.

Results: Our results showed differences inter-groups and inter-limbs for both movements. The Anterior step was characterized by a dominant initiation side with CPx and Cpy increased amplitudes for AIS group compared to control group. For the Lateral step, only AIS group had asymmetry with a CPx and Cpy amplitudes significantly increased for non dominant side compared to dominant side. The analysed correlations highlight an inverse dynamic behaviour in the 2 groups only in the Lateral step. The asymmetry Index comparison between groups, whatever the direction was, revealed increased variability of the overall parameters computed for scoliotic patients.

Discussion: This study demonstrates the interest to focus on movement initiation following orthogonal directions for a pathological population presenting a three dimensional trunk deformity. Whatever the stepping direction was, GRF are asymmetrical to control balance for AIS patients. Forward stepping is associated with a permanent learning that results in a systematic adaptative strategy by a daily use. This contrasts with lateral stepping which allows analysing short-term strategy adaptation (Bruyneel et al. 2009). The originality of our study resides in the kind of used movement paradigm which is not posture neither gait but stepping as the transition between both. This suggests that lateral step better proves the scoliosis adaptive strategies associated to the three dimensional deformity and to the neurophysiological asymmetry. To understand the dynamics of an adaptive behaviour, a dynamical movement must be analyzed in the different planes to consider the mechanical modification and the influence of the training.

INTER-RATER RELIABILITY OF THE VISUAL ESTIMATION OF SHOULDER ABDUCTION ANGLES AND THE AGREEMENT OF MEASUREMENTS WITH AN ACELEROMETER

BECKERT, J., SILVA, F., PALMA, S.

INSTITUTO DO DESPORTO DE PORTUGAL, I.P.

INTRODUCTION: In clinical context, the evaluation of joint angular amplitudes is usually done by visual estimation (VE).

METHODS: In this study, six independent observers made, simultaneously, the VE of the shoulder position on the frontal plane for a set of 140 repetitions. The angles of the arm were monitored by a Biodex electro-goniometer.

At the same time, the arm acceleration measurements were recorded using a tridimensional xyzPlux accelerometer. The accelerometer was fixed with a Velcro tape to the anterior face of the subject's forearm. The 3D components of the acceleration signal were transmitted via Bluetooth to the processing unit which computed the abduction angle of the shoulder. The accelerometer data was taken as reference to validate the agreement analysis.

The VE error was determined by analysis of the variance of the six observers' VEs. The interclass correlation coefficient was determined with formula 2.1 from [1] after the verification of the statistic model's assumptions.

The correlation between VE from observers and xyzPlux measurements was established using Pearson's Coefficients (0.01 significance level; 2 tailed). The limits of agreement between both measurements was estimated using the standard error of the differences (SDdiff) [2].

RESULTS: The correlation obtained between the observers VE's is high (0.92), although the standard error of the method is 6.4°. The minimum detectable difference (MDD) (95% confidence level) is 17.6°. The correlation between the data from the observers and from xyzPlux is also high (0.986 to 0.996) and SDdiff is between 4.98° and 7.92°.

DISCUSSION: The high level of agreement between the VE of the six independent observers assures that the clinical evaluation of the shoulder joint angular amplitudes can be done by any of the six observers without a clinically significant increase of the measurement error.

We may accept that the VE method is appropriate if we assume that the identification of a difference of around 20° between the two measurements is acceptable and does not introduce problems in clinical interpretation.

If a MDD of 20° (more precisely, 17.6°) is not adequate but we still want to use the VE method, we have to lower the confidence levels.

For a higher precision of the measurements the VE method is not adequate and it is necessary to the use more sophisticated instruments like the xyzPlux used in this study.

The data from xyzPlux and the electrogoniometer obtained in this study showed a very good level of agreement (0,757° Typical error ; SDdiff = 1,069 determined according to [3]; MDD of 2.10°).

HUMAN ACTION, TACIT KNOWLEDGE AND EMBODIED SKILLS

BRUEMMER, K.

UNIVERSITY OF OLDENBURG

Skillful performance in sports requires the ability to master uncertain situations by means of body techniques often under time constraints. It appears obvious that this kind of competence does not only owe to time-consuming planning processes and knowledge-based rationalizations governed by the conscious mind, but also involves the 'intelligence' of an experienced body. Yet, many hegemonic approaches to human action or movement provided in the field of sport sciences focus almost exclusively on those underlying mental processes. Especially in the last couple of years, however, these theories have come under criticism for their intellectualistic stance and reductionist understanding of human action and being. Against the background of this critique, several frameworks have been formulated, claiming that the faculty to react to uncertain situations in a quick and flexible manner constitutively depends on incorporated knowledge and subjective sensations, which are largely tacit and hence difficult to objectify.

In the course of a paradigm shift labeled 'practice turn' [1], in the field of social sciences as well, concepts of tacit knowledge and embodied skills have started to enjoy an increasing popularity with regard to the explanation of dexterous practice. Sociological practice theories maintain that versed action is not only to be attributed to cognitive processes, but draws on incorporated dispositions, too, which had been acquired in collective practices during socialization. Under certain conditions, these dispositions function as a 'practical sense' [2], an intuitive feeling and tacit knowledge for what is to be done, allowing for an immediate, i.e. pre-reflective understanding and flexible coping with a situation. According to the premises of practice theory, this sort of intelligence is not stored in an individual's mind as a subjective possession, but is rather to be regarded as a relational and situational phenomenon emerging in between different (human and non-human) 'actants' [3].

So far, attempts to establish interdisciplinary linkages between the different approaches from sport and social sciences have been rare. Thus, I intend to correlate them in order not only to identify parallels but also to uncover blind spots and shortcomings in the particular concepts and to correct them mutually. It is my prior concern to integrate insights from social practice theory into concepts of motor control and vice versa in order to achieve a more adequate understanding of human activity, which accounts for both sports and everyday situations.

CONSCIOUSNESS IN SPORT

BIRCH, J.

NORWEGIAN SCHOOL OF SPORT SCIENCES

The talk argues there is an explanatory gap between theories in neuroscience and our conscious experience. Theories in neuroscience are reductions to events at the neuronal level. Our conscious experiences are subjective mental states of qualia. Neuroscience may explain how the visual system works, how memory is possible and which parts of the brain are necessary to perform motor actions. Although parts of conscious experience, the explanatory gap is between what the brain does (psychological consciousness) and how an experience feels (phenomenal consciousness) (Chalmers). How an experience feels is usually described as what it is like (Nagel). The problem then, is to account for how non-conscious matter like neurons can give rise to conscious experience.

Identity theories try to do this by reducing conscious states to brain states by claiming they are identical. Brain states do not produce, realize or correlate with conscious states, there is only one state. Even if this seems counterintuitive, we just have to accept this is so, and these days it is the neurosciences that are going to convince us. If identity theories are right, there is no explanatory gap, and phenomenal consciousness is no more mysterious than how neurotransmission is done in synaptic clefts. Could it be that reductive sciences like

chemistry, biology, mechanics and (neuro)physiology are able to give a full blown account of sport? If so, they must also account for some problems of reductive physicalism, like The Knowledge Argument (Jackson).

The knowledge argument asks: suppose I know all that physical science could possibly teach me about football, would we say I know what it is like to play the game even though I have never done so? The intuitive response is "no". If this is correct, what's left out is phenomenal consciousness. If you were to say "yes", the answer must go something like: brain state F is identical to conscious state C. If I have all the knowledge there is about brain state F, I could obtain brain state F. Since F is identical to C, I must know what C is like.

If you can obtain any knowledge there is about football by knowing all the physical descriptions of football, you are also saying knowing how is completely reducible to knowing that (Perry). That is: not only would you get an experience by knowing the perfect physical description, you also obtain the skill involved. If you are an identity theorist then, you must conclude that simply by knowing armchair science, you could become the next Maradona. The talk denies this and suggests sport provides good examples of why reduction by identity is not promising when it comes to phenomenal consciousness and skill.

WHAT IT IS ALIKE TO LEARN A MOTOR ACTION

KROMER, M.

ELLY-HEUSS-KNAPP-SCHULE

Experts and novices organize and experience their motor actions very differently. Merleau-Ponty's (1945, 1964) theory of body and human movement helps to better understand the learning processes and offers as well chances to integrate different approaches to motor organization (self-organization and representation).

According to Merleau-Ponty implicit and explicit ways of motor organization work together interdependently. Learning leads to important changes in the way a motor action is organized. The implicit way of motor organization is prereflective and based on a "motor intentionality" that structures the perception of a situation. There is a stable and flexible "intentional arc" between the skilled person and the situation. This sort of knowledge is largely tacit and embodied. The implicit way of organizing motor actions is typical for experts acting in complex situations and under time restraints. In early stages of a learning process however there is no reliable "intentional arc". The person has to organize the motor action using explicit planning processes and explicit internal representations. Simondon's theory of individuation (1995) helps to understand the development of "Gestalten". They are developed in a repetitive and sudden transductional process in the system of a human and the world. This point of view may explain why the learning process is not linear but consists in alternating periods of rapid progression and of apparent stagnation or even regression.

A pilot interview-study (Kromer, 2007) focuses the early stages in learning in unicycling. The participants start first with a static view on keeping the balance, but then change to a dynamic view, which is necessary for further learning. The study shows the importance of specific feelings in motor organization. A specific feeling appears suddenly and with it the change from explicit to implicit organizing has taken place. Therefore beginners can't tell much about unicycling, because they don't go the straight way to organize it, but make a detour. After the decisive transduction the now advanced learners or experts take the straight way, but they do it in an implicit way. It is as if the situation tells them what is to be done and how it is to be done. They can't report much about the motor oganization as well. The findings of the study seem to support the theoretical approaches by Merleau-Ponty and Simondon.

SKILLED BEHAVIOR IN SPORT AND THE PHENOMENOLOGY OF MOTOR INTENTIONALITY

MOE, V.F.

SOGN OG FJORDANE UNIVERSITY COLLEGE

Introduction: Skilled motor behavior has been widely discussed in sport science from the information processing, expertise and ecological/dynamical systems approach (Williams and Hodges, 2004). Even though phenomenological approaches to skilled behavior are underrepresented, they are beginning to emerge more frequently. This paper takes a phenomenological turn on skilled behavior. Its aim is to reveal the role of motor intentionality in skilled behavior in sport.

Research on novice-expert differences provides a clear approach to the varieties of skilled motor behavior. Normally, a novice tends to perform in a slow, rigid and reflective way, whereas the expert performs fast, flexible and unreflective. To account for these behavioral characteristics, this paper applies the concept of intentionality. It means that consciousness and our mental and bodily attitudes are object-directed, that is, meaningfully directed at objects and states of affairs in the environment.

Method: Conceptual analysis (e.g., Searle, 1983) and phenomenological description (e.g., Merleau-Ponty, 1962) is used to account for the intentionality of skilled motor behavior (Moe, 2007).

Analysis/Discussion: Kelly (2002) has distinguished between cognitive and motor intentionality. Cognitive intentionality is characterized by its representational or propositional content, whereas motor intentionality, a term coined by Merleau-Ponty (1962), is characterized by its non-representational nature (i.e., the body's holistic and direct understanding of tasks).

The paper begins to discuss the cognitive-motor intentionality distinction in relation to skilled behavior performed by novices and experts. Arguably, the representational content of cognitive intentionality fits the reflective attitude towards problem solving often experienced by novices, whereas the non-representational nature of motor intentionality illuminates the unreflective and immediate way experts are normally coping with their environment.

Furthermore, it is argued that the non-representational character of motor intentionality is often overlooked in sport research, and that it marks a bodily competence that is tacit and thus difficult to account for. Hence, a phenomenological description of skilled behavior in sport is established in order to provide an accurate description of several essential characteristics of motor intentionality.

The paper closes with some remarks on how this understanding of cognitive and motor intentionality can be used by practitioners to facilitate skill learning in sport.

IS-SS11 How can we change the exercise behaviour in the population? (ECSS Position Statement Symposium)

PHYSICAL ACTIVITY BEHAVIOUR CHANGE FOR OLDER ADULTS (60+ AND 75+)

HOPMAN-ROCK, M.

TNO QUALITY OF LIFE AND BODY@WORK RESEARCHCENTER TNO VU UNIVERSITY MEDICAL CENTER

It is known from European figures that physical activity (PA) decreases with higher age. Also sedentary behaviour is relatively higher in older adults. Sufficient PA (including exercise and sports) as given in standards from the ACSM and in national European standards is important to enhance the health of the ageing population and to decrease care demands. Evidence based intervention components to stimulate the PA of the old age and the old-old age group will be briefly reviewed. Attention will also be paid to the relationship between PA and falling, as it is relevant in the aged population. Also, existing European networks and projects on ageing, falling and PA will be reviewed. First steps will be made to come to a European position statement in the area of physical activity stimulation, resulting in behavioural change. Perspectives in this presentation are from individual factors as well as from social and environmental factors.

PHYSICAL ACTIVITY BEHAVIOUR CHANGE FOR ADULTS (20 – 60+)

BREHM, W.

UNIVERSITÄT BAYREUTH

PHYSICAL ACTIVITY BEHAVIOUR CHANGE FOR ADULTS (20 – 60+)

Brehm, W.

Institute of Sport-Science, University Bayreuth, Germany

Introduction: According to recommendations of the ACSM or the WHO-Europe, adults should accumulate structured physical activities and sports of at least two hours a week (in 2 – 4 units), stimulating all relevant fitness factors (endurance, strength, flexibility, coordination). "Everyday physical activities" (e.g. walking around, stair climbing, household, gardening) should be added. At least two third of the European population is not undertaking sufficient activity to meet such recommendations. But over 90% of the adults in Europe believe that physical activity has numerous health benefits. For enhancing physical activity in the adult population intervention components and concepts meanwhile concentrate on changing the individual behaviour as well as changing social and environmental factors.

Method

System of intervention factors

Systematic study review

Results & Discussion: This presentation will (a) give a short overview of the recommendations for physical activities for adults and the extent of sedentary behaviour in adulthood, (b) summarise evidence of intervention factors and strategies during the process of behaviour change to an active lifestyle. This summary will feed into an ECSS Position Statement concerning physical activity behaviour change.

PHYSICAL ACTIVITY BEHAVIOUR CHANGE FOR CHILDREN AND ADOLESCENTS

BIDDLE, S.J.H.

LOUGHBOROUGH UNIVERSITY

Introduction: Much has been written about young people and physical activity, with extensive research concerning the correlates of activity, and more recent evidence concerning intervention efficacy. International data, including Europe, shows that physical activity (PA) in this population is the highest for any age group, but declines particularly across the teenage years. Also, new sedentary behaviours are attractive to many and can take up large amounts of time.

Method

Review-level data summary

Results & Discussion: This presentation will summarise review-level evidence on a). socio-demographic, psychological, behavioural, social, and environmental correlates of PA and sedentary behaviour, and b). how successful interventions have been to change PA and sedentary behaviours in young people. This summary will feed into a ECSS Position Statement concerning physical activity behaviour change.

IS-BC02 Molecular mechanism controlling mitochondrial biogenesis and function

MITOCHONDRIAL SUBSTRATE OXIDATION: EFFECT OF TRAINING AND TYPE 2 DIABETES.

SAHLIN, K.

GIH, THE SWEDISH SCHOOL OF SPORT AND HEALTH SCIENCES

There is a reciprocal dependency between carbohydrate (CHO) and lipid oxidation and the relative fuel utilization is influenced by a number of factors including exercise intensity, training status and substrate availability. Control of lipid oxidation occurs at several sites with mitochondria being one of the most important. A high rate of CHO catabolism may interfere with both the transport of long-chain fatty acids (LCFA) into mitochondria and with β-oxidation. The supply of lipids is increased in Type 2 diabetes (T2D) due to elevated blood fatty acid levels and increased intramyocellular contents of triglycerides. Combined with a reduced capacity to oxidize lipids this leads to accumulation of lipid intermediates, which has been suggested to cause insulin resistance. This presentation will discuss the interaction between carbohydrate and lipid oxidation at the mitochondrial level, the effect of training and the implication in T2D.

MECHANISMS OF MITOCHONDRIAL BIOGENESIS IN HUMAN SKELETAL MUSCLE

PILEGAARD, H.

UNIVERSITY OF COPENHAGEN

Introduction: Peroxisome proliferator activated receptor gamma (PGC)-1alpha is a transcriptional co-activator regulating the expression of proteins in many cellular processes including mitochondrial biogenesis and the anti-oxidant defence (Lin et al. 2005). Exercise-induced regulation of PGC-1alpha expression and activity is suggested to be a key event in training-induced mitochondrial biogenesis.

PGC-1alpha gene regulation

PGC-1alpha transcription and mRNA is increased in human skeletal muscle in response to both short, high-intensity and prolonged low-intensity exercise, and PGC-1alpha mRNA is markedly induced in both the glycolytic triceps muscle and the more oxidative vastus lateralis muscle. The exercise-induced PGC-1alpha mRNA increase in human skeletal muscle is determined by the relative rather than the absolute exercise intensity. The PGC-1alpha mRNA response to a single exercise bout does not seem to be influenced by muscle glycogen levels prior to exercise, but to be modulated by the metabolic status in recovery from exercise.

Cell culture studies indicate that calcium signalling through both CAMK and calcineurin as well as ROS-induced signalling may play a major role in regulating the expression of PGC-1alpha in skeletal muscle.

PGC-1alpha protein

PGC-1alpha protein is in western blotting detected at a molecular weight of about 115 kD. But analyses of endogenous PGC-1alpha protein should be done with utmost caution, as the amount of endogenous PGC-1a in skeletal muscle is very low.

PGC-1alpha mediated regulation of mitochondrial proteins

The late mRNA responses to exercise for genes encoding mitochondrial proteins in human skeletal muscle are in accordance with the suggestion that exercise-induced regulation of PGC-1alpa expression and/or activity may mediate the induction of genes encoding mitochondrial proteins.

In mice skeletal muscle, PGC-1alpha is required for the beneficial effect of exercise in preventing an age-associated decline in cytochrome c and superoxide dismutase 2 protein expression. In addition, findings in mice suggest that although AMPK is not needed for exercise-induced PGC-1alpha gene regulation, AMPK mediated regulation of PGC-1alpha seems to play an important role in regulating the expression of mitochondrial proteins.

MECHANISMS OF MITOCHONDRIAL BIOGENESIS IN AGING MUSCLE

HOOD, D.

YORK UNIVERSITY

It is well known that mitochondrial biogenesis in muscle can occur as a result of regular exercise. However, the mechanisms underlying organelle biogenesis are not fully established. In addition, whether similar mechanisms exist in aging muscle remains controversial. Evidence suggests that the initial signals generated by exercising muscle which provoke gene expression leading to mitochondrial biogenesis are related to changes in intracellular calcium, reactive oxygen species, and AMP kinase activity. Activation of AMP kinase leads to the transcription of PGC-1α, an important regulator of the expression of many nuclear genes encoding mitochondrial proteins. In addition, chronic exercise increases the import of proteins into the organelle. This is a result of an increased expression of protein import machinery components. During the aging process, mitochondrial content in muscle declines, and this is reflected in a reduced endurance performance. The decrease in mitochondrial content is due in part to a reduced transcriptional drive, since PGC-1α levels are markedly reduced, particularly in slow-twitch muscle fibers. In addition, in response to a standardized acute contractile activity paradigm, signaling kinase activation is increased to a lesser degree than in muscle from young animals. This contributes to the reduced adaptation of aged muscle to regular exercise, consisting of attenuated increases in the expression of biogenesis regulatory proteins of transcription and protein import, reduced increases in mitochondrial enzymes, and lesser improvements in endurance performance. These data suggest that activation of the mitochondrial biogenesis pathway by exercise is down-regulated with age. Despite this, adaptive responses to exercise can still occur in aging muscle, leading to reduced fatiguability and improved quality of life. Further studies are required to determine the underlying basis for the attenuated adaptive response of aging muscle to exercise.

IS-NU02 Nutritional strategies to increase muscle mass

NUTRITIONAL STRATEGIES TO AUGMENT MUSCLE MASS AND FUNCTION IN THE ELDERLY

VAN LOON, L.

MAASTRICHT UNIVERSITY

Aging is accompanied by a progressive loss of skeletal muscle mass and strength, leading to the loss of functional capacity and an increased risk of developing chronic metabolic disease. The age-related loss of skeletal muscle mass is attributed to a disruption in the regulation of skeletal muscle protein turnover, resulting in an imbalance between muscle protein synthesis and degradation. As basal (fasting) muscle protein synthesis rates do not seem to differ substantially between the young and elderly, many research groups have started to focus on the muscle protein synthetic response to the main anabolic stimuli, i.e. food intake and physical activity. Recent studies suggest that the muscle protein synthetic response to food intake is blunted in the elderly. The latter is now believed to represent a key factor responsible for the age-related decline in skeletal muscle mass. Physical activity and/or exercise stimulate post-exercise muscle protein accretion in both the young and elderly. However, the latter largely depends on the timed administration of amino acids and/or protein prior to, during, and/or after exercise. Prolonged resistance type exercise training represents an effective therapeutic strategy to augment skeletal muscle mass and improve functional performance in the elderly. The latter shows that the ability of the muscle protein synthetic machinery to respond to anabolic stimuli is preserved up to very old age. Research is warranted to elucidate the interaction between nutrition, exercise and the skeletal muscle adaptive response. The latter is needed to define more effective strategies that will maximize the therapeutic benefits of lifestyle intervention in the elderly.

NUTRITIONAL STRATEGIES TO INCREASE MUSCLE MASS AND FUNCTION IN ATHLETES

TIPTON, K.

UNIV OF BIRMINGHAM

Appropriate muscle mass and function are critical for athletes. Nutrition influences the impact of training on muscle mass and function. In particular, protein intake is often considered to be the most important nutritional factor. The metabolic basis for changes in muscle mass is the balance between protein synthesis and breakdown of muscle contractile proteins. The net balance (NBAL) between synthesis and breakdown over any given time determines changes in muscle mass. Accretion of muscle proteins occurs during periods of positive balance, i.e. when synthesis exceeds breakdown, and muscle proteins are lost during periods of negative balance. Exercise and nutrition influence muscle mass through changes in muscle protein synthesis and breakdown that will increase (or decrease) NBAL. On a daily, or even hourly, basis NBAL can be either positive or negative, depending on feeding and exercise situations. The length and duration of these periods of positive and negative balance determine the net loss or gain of muscle mass. Nutritional influences on muscle mass have received a great deal of attention lately. It is clear that protein ingestion is critical for increased muscle mass. Muscle protein balance can be improved by exercise alone, but without a source of amino acid NBAL does not reach positive levels. Thus, protein and amino acids in various forms are generally thought to be the most important nutrient for muscle building. However, the optimal amount of dietary protein for optimization of muscle mass remains unclear. Furthermore, it is clear that factors other than the total amount of protein in the diet influence muscle mass and function. The latter include energy intake, intake of other nutrients, timing of nutrient intake and the interaction of these factors. In particular, energy balance seems crucial for gains in muscle mass. Carbohydrate intake is often overlooked by those desiring increased muscle mass. However, carbohydrate intake must be sufficient to support appropriate training. Recent evidence suggests that glycogen levels may help determine the response of muscle to exercise. Whereas most of the attention on muscle mass has been given to gaining muscle, athletes in many situations may want to maintain or even lose muscle mass. Nutritional interventions may help to influence the adaptations to particular situations. Furthermore, muscles that are immobilized due to injury will atrophy. Minimizing the atrophy during forced disuse and optimizing regain of muscle during recovery are crucial for returning an athlete to competition as quickly as possible. Metabolic changes during disuse atrophy may influence the nutritional strategy to optimize recovery. Protein is important, but energy intake must be carefully considered. Finally, use of particular amino acids, such as leucine may be a method to help reduce muscle loss during immobilization.

THE IMPACT OF NUTRITION AND EXERCISE ON THE SYNTHESIS OF MYOFIBRILLAR AND SARCOPLASMIC PROTEINS

PHILLIPS, S.

MCMASTER UNIVERSITY

Day-to-day regulation of muscle protein mass is accomplished by the ingestion of complete sources of protein. The subsequent hyperaminoacidemia stimulates muscle protein synthesis (MPS) and also, along with insulin, suppresses muscle protein breakdown (MPB). Eating throughout the day thus provides periods of feeding and fasting during which muscle protein balance (MPS minus MPB) is positive and negative, respectively. We are now beginning to understand how different protein sources (animal versus plant) can affect MPS and MPB to differentially affect protein balance. We also know that resistive exercise can markedly, and independent of feeding, stimulate MPS. Thus when feeding and resistance exercise are combined a synergistic stimulation of MPS occurs, MPB is inhibited and muscle protein balance becomes even more positive. Such small periods of positive protein balance summate to yield hypertrophy. We now know that proteins such as whey, casein, and soy are hierarchically effective in their ability to stimulate MPS both at rest and post resistance exercise. Thus, it should be evident that training studies in which whey is used as a supplement might yield greater hypertrophy; this appears to be the case. We have also begun to define contractile intensities and their effects of protein balance. These data will be discussed and inferences for optimal models of training to promote hypertrophy will also be discussed.

MUSCLE METABOLIC DEMAND IN ELECTRICALLY EVOKED MAXIMAL ISOMETRIC CONTRACTIONS OF THE ELBOW FLEXORS INVESTIGATED BY NEAR-INFRARED SPECTROSCOPY

MUTHALIB, M., JUBEAU, M., MILLET, G.Y., MAFFIULETTI, N.A., NOSAKA, K.

EDITH COWAN UNIVERSITY

INTRODUCTION: Previous studies (1,2) reported that muscle oxidative metabolic demand in isometric contractions induced by electrical muscle stimulation (EMS) was greater than voluntary isometric contractions (VOL) at the same force level. Our previous study (ECSS-2008) showed that the metabolic demand of the biceps brachii assessed by near-infrared spectroscopy (NIRS) during EMS (30 Hz) was similar to VOL, when repeated isometric contractions (1-s contraction, 1-s relaxation) were performed at maximal intensity for VOL and at maximally tolerable current intensity for EMS. Since higher stimulation frequency (>50 Hz) and contraction duration (>4 s) are often used to improve strength in EMS training, this study compared EMS (75 Hz) and VOL for changes in biceps brachii muscle oxidative metabolism during intermittent 4-s maximal isometric contractions.

METHODS: Ten men (23-39 yrs) performed EMS with one arm and VOL with the other arm separated by 2-3 weeks in a counterbalanced order. EMS and VOL consisted of 50 maximal isometric contractions (4-s contraction, 15-s relaxation) of the elbow flexors at an elbow joint angle of 160°. For EMS, the biceps brachii and brachioradialis muscles were stimulated at maximal tolerated current (36-64 mA) via surface electrodes (frequency: 75 Hz, pulse duration: 0.2 ms). Maximal voluntary isometric contraction (MVC) torque was measured before and after exercise, and torque produced during exercise was recorded. A NIRS probe was placed on the mid-biceps brachii of the exercise arm and NIRS signals were sampled at 6 Hz using a NIRO200-NIRS system. Changes in muscle oxygenation (TOI), oxygen extraction (HHb) and blood volume (cHb) over 50 contractions (contraction and relaxation phases) were compared between EMS and VOL by a two-way repeated measures ANOVA with Bonferoni post-hoc test. Significance was set at $P<0.05$.

RESULTS: MVC decreased ~30% immediately after both protocols with no significant difference. The average peak torque produced during VOL (33 ± 3 Nm) was significantly greater than EMS (17 ± 2 Nm). All NIRS variables showed significant changes, and the changes in TOI and HHb during contraction and relaxation phases were not significantly different between EMS and VOL. However, cHb was significantly greater during both contraction and relaxation phases for VOL compared with EMS.

DISCUSSION: These results confirmed our previous study showing no significant difference between EMS and VOL at maximal intensity for changes in TOI and HHb of the biceps brachii. The greater increases in cHb for VOL than EMS were also found in the previous study, but the difference in cHb may not necessarily represent a difference in metabolic demand (3). It is concluded that muscle oxidative metabolic demand in EMS is similar to VOL at the respective maximal intensity.

TISSUE OXYGENATION DURING EXERCISE MEASURED WITH NIRS: A QUALITY CONTROL STUDY

PLATEN, P., GERZ, E., GERASKIN, D., NEARY, P., FRANKE, J., KOHL-BAREIS, M.

1. INSTITUTE OF SPORTS MEDICINE AND SPORTS NUTRITION, RUHR-UNIVERSITY BOCHUM, GERMANY; 2. UNIVERSITY OF APPLIED SCIENCES KOBLENZ, GERMANY; 3. FACULTY OF KINESIOLOGY, UNIVERSITY OF REGINA, CANADA

Introduction: Near infrared spectroscopy (NIRS) is widely used to observe muscle metabolism, however, some of the most basic questions regarding errors, reproducibility and data quality have not been answered or asked. The purpose here is to shed some light on: 1. Reproducibility and 2. Comparison of Modified-Lambert Beer (MLB) and Spatially Resolved Spectroscopy (SRS).

Methods: Nine volunteers (5 females; age: 29.4 ± 7.6 years; body mass = 69.0 ± 9.5 kg; height: 178 ± 13 cm) performed an incremental cycling exercise increasing the exercise power stepwise every 3 minutes by 40 W. A 10 minute cycling recovery period at 30 W followed the maximal step. This protocol was repeated three times separated by rest periods of 60 min. Optical fibres were kept in place during the whole period. The exercise protocol (one of the three repetitions) was repeated at a second day 27 ± 18 days after D1. The spectroscopy system is based on a Peltier-cooled slow-scan Charged Coupled Device-camera in combination with a spectrometer. From the slope of attenuation with respect to tissue absorption spectra and subsequently haemoglobin concentrations (oxyHb, deoxyHb) and oxygen saturation values (SO2 = oxyHb/(oxyHb + deoxyHb)) were calculated.

Results and Discussion: When comparing the SO2 vs. power traces for the different exercises, there were variations smaller than 2 %. OxyHb was markedly different for the two days and with differences much larger than for deoxyHb. Absolute SO2 values revealed a large inter-subject variability but similarities in the slope with exercise power output. Likely explanations for this are the heterogeneity of the muscle tissue and the influence of the subcutaneous lipid (adipose tissue thickness). Analysis of inter-subject variability and reproducibility (R) for all parameters can be summarized as follows: 1. R of SO2 is around 1.5 % both for same-day and different-day trials; 2. R of deoxyHb and oxyHb is somewhat poorer (R < 3 % and < 8 % for same-day and different-day comparison); 3. When changes with respect to the lowest exercise power are considered, the reproducibility of SO2 is about 0.4 % and 0.9 % for same-day and different testing; 4. There is no indication for fatigue for the three same-day tests; and 5. R based on SRS-method is considerably better than for MLB-method. The likely explanation is the larger depth penetration of SRS limiting the influences of haemoglobin in the skin and the adipose tissue thickness. A vindication for this is the correlation of the adipose tissue thickness as measured by ultrasound with the haemoglobin parameters.

Conclusion

The reproducibility of the haemoglobin parameters is high. The finding of large differences between MLB- and SRS-analysis is surprising and needs to be taken into account when comparing data acquired with different instrumentation.

OXYGEN KINETICS IS NOT DETERMINANT FOR DELAYING FATIGUE IN SEVERE EXERCISE: ATHLETIC WALKING VERSUS

MILLE-HAMARD, L., GARCIN, M., BILLAT, V.L.

INSERM U 902

Introduction: Previous studies have showed that the type and intensity of exercise as well as the physical fitness of subjects influences the slow component of oxygen uptake (VO2) during severe exercise. As athletic walking elicits less strength at each step than running, we hypothesized that the lowered strength could reduce the slow component of VO2. Therefore the purpose of the present study was to compare the kinetics of VO2 during severe walking and runs performed at the same relative intensity, until exhaustion.

Methods: In subjects of the same physical fitness, VO2 was measured breath by breath using a portable gas analyser (K4b2, Cosmed) during severe exhaustive exercise performed on a running track, in the severe intensity domain The VO2 response was fit with mathematical models to determine the slow component of VO2.

Results: Results on athletic walking demonstrated the absence of a slow component of VO2. Furthermore, there was no association between the time to exhaustion and the slow component phenomena given that the delaying of fatigue was not different (769 ±241 vs. 769 ± 510 s, p = 0.858) in contrast with the slow component.

Discussion: These results confirmed that the slow component is not responsible for fatigue. However the nature of the link between Time to exhaustion and the slow component of VO2 remains unclear (Zoladz et al., 2008, Malek et al. 2008). Furthermore, the slow component of VO2 seems to be related with force production during severe exercise, and percentage of type I fibres recruited (Garland et al., 2004, Pringle et al. 2003, Saunders et al. 2000). Thus, the recruitment of lower proportion of type II muscles fibers during walking, a consequence of the lower force requirement compared with running, could contribute to the lack of a slow component of VO2. Furthermore, as fatigue occurs, running but not walking has been associated with alterations in pace (Borrani et al. 2003, Derrick et al. 2002, Brisswalter et al., 1998) that increase the energy expenditure during the run. It is may therefore be possible that this lack of alteration with fatigue also explain to the absence of the slow component during athletic walking.

THE EFFECT OF PHYSICAL STATUS ON PHOSPHOCREATINE AND PULMONARY OXYGEN CONSUMPTION KINETICS DURING EXERCISE: A COMBINED PULMONARY GAS EXCHANGE AND 31P-MRS STUDY

LAYEC, G., BRINGARD, A., YASHIRO, K., VILMEN, C., LE FUR, Y., MICALLEF, J.P., PERREY, S., COZZONE, P.J., BENDAHAN, D.

UMR CNRS 6612

Introduction: A number of models have been proposed to explain the control of O2p which can be schematically classified into parallel activation mechanism by calcium or feed-back mechanisms through numerous factors e.g. PCr, ADP, Pi and pH. The model proposed by Meyer et al. (Meyer, 1988), which postulates that creatine kinase reaction plays a key role in the regulation of O2 has recently received considerable attention. Although animal and in vitro studies provided support for this model, data relating PCr and O2p kinetics in human are sparse. Recently, Francescato et al. (2008) reported that the time constant (τ) of PCr kinetics was linearly related to the PCr concentration measured at rest (Francescato et al., 2008). Given that a lower resting [PCr] concentration has been reported in endurance trained subjects (Bernus et al., 1993), one could wonder whether the kinetics of O2p and [PCr] are correspondingly modulated. The purpose of the present study was to compare the kinetics of O2p and [PCr] during moderate (MOD) and heavy (HEAV) exercises between sedentary and endurance-trained subjects.

Method: Six sedentary (SED) and seven endurance trained (TRA) subjects performed a dynamic standardized rest-exercise-recovery protocol at an exercise intensity corresponding to either 25 or 35% of maximal voluntary contraction while 31P-MRS, and breath-by-breath measurements of pulmonary oxygen uptake were obtained simultaneously.

Results and Discussion: Endurance trained subjects exhibited a faster O2p (τ = 26 ± 10 for TRA vs. 51 ± 17 s for SED; $P < 0.01$) and PCr kinetics (22 ± 5 for TRA and 45 ± 16 s for SED; $P < 0.01$) during moderate exercise. In contrast, O2p (31 ± 3 for TRA and 38 ± 9 s for SED) and PCr kinetics (29 ± 14 for TRA and 41 ± 9 s for SED) were similar in both groups during the heavy-intensity exercise. For both exercises, neither O2p nor PCr time-constants were related to the PCr concentration at rest. However, both time constants recorded during the moderate exercise were linked through a linear relationship ($r = 0.59$; $P < 0.05$).We failed to observe this relationship during the heavy-intensity exercise. Overall, our results illustrate a complex relationship between [PCr] and VO2 which is not consistent with a linear control model (Meyer, 1988) but rather suggest that other factors (O2, phosphate potential, pH and [ADP]) would be involved in the control of oxidative phosphorylation.

ELECTROMYOGRAPHIC ALTERATIONS ARE EVIDENT DURING HEAVY INTENSITY TREADMILL RUNNING

PATRAS, K., ZIOGAS, G., RISTANIS, S., TSEPIS, E., STERGIOU, N., GEORGOULIS, A.D.

ORTHOPAEDIC SPORTS MEDICINE CENTER, UNIVERSITY OF IOANNINA

BACKGROUND: The development of an "additional" slow component on the oxygen cost of submaximal exercise performed above the lactate threshold may be attributable to altered motor unit recruitment patterns, that is, the recruitment of lower efficiency fast-twitch fibers [1, 2]. Enhanced fast-twitch fiber recruitment may result in increased EMG amplitude and shift of the power spectrum to higher frequencies [3].

PURPOSE: To examine the effect of heavy intensity exercise on VO2 and electromyographic variables response over time during treadmill running.

METHODS: Fourteen soccer players underwent an incremental test to volitional exhaustion and two 10-min bouts, one at a moderate (80%LT) and one at a heavy intensity (40%D). During the bouts electromyographic activity was recorded at minutes 3, 5, 7 and 10 for muscles vastus lateralis and biceps femoris bilaterally. Blood lactate was measured before the bouts and at end-exercise. The dependent variables were mean peak EMG amplitude and the total energy of the high frequency components (>90Hz, HE) of the power spectrum [4].

RESULTS: There was a significant time x intensity interaction for VO2 ($F=29.6$, $p<0.001$). VO2 values for heavy exercise were increasing until the 8th minute of exercise. The magnitude of the VO2 slow component averaged 0.4 (0.12) lt/min. End-exercise blood lactate values averaged 7.9 (1.6) mM and 2.5 (0.6) mM for heavy and moderate exercise respectively. There was a significant time x intensity interaction for EMG amplitude of the vastus lateralis muscle ($F=5.85$, $p=0.002$). EMG amplitude did not change for biceps femoris muscle ($F=1.99$, $p=0.131$). There was a significant time x intensity interaction for the HE of the vastus lateralis ($F=5.632$, $p=0.003$) and biceps femoris ($F=7.493$, $p<0.001$) muscle. However there was no correlation between the relative increase of the VO2 and the relative increases in any of the electromyographic variables.

CONCLUSION: Heavy intensity treadmill running results in a significant VO2 slow component and also in significant electromyographic alterations in both vastus lateralis and biceps femoris muscles. These results may indicate that the slow component is at least partly attributed to additional recruitment of motor units and/or recruitment of type II muscle fibers.

EFFECTS OF PROLONGED EXERCISE WITH VOLUNTARY HYPOVENTILATION ON MUSCLE OXYGENATION AND BLOOD LACTATE CONCENTRATION

WOORONS, X., BOURDILLON, N., VANDEWALLE, H., LAMBERTO, C., MOLLARD, P., RICHALET, J.P., PICHON, A.

LABORATOIRE

Intro

It has recently been reported that training with voluntary hypoventilation (VH) may induce muscular adaptations that could delay metabolic acidosis (Woorons et al., 2008). This study aimed first to determine whether a prolonged exercise with VH could decrease muscle oxygenation and raise blood lactate concentration and second to evaluate the respective effects of hypoxia and hypercapnia.

Methods: Eight healthy active men (VO2max = 53.2 ± 3.7 ml/min/kg) performed three series of 5-min exercise on a cycle ergometer at 65% of normoxic VO2max under the following conditions: 1) Voluntary hypoventilation in normoxia (VHnx) 2) Voluntary hypoventilation in hyperoxia (VHhpr) (inspired oxygen fraction [FIO2] = 0.29) 3) Normal breathing (NB) in hypoxia (NBhpo) (FIO2=0.15) 4) NB in normoxia (NBnx). Between series, subjects kept on cycling for one minute at the same exercise intensity in NBnx. Using near infrared spectroscopy (NIRS), concentration changes of oxy- and deoxyhemoglobin (Δ[O2Hb], Δ[HHb]) were measured in the left vastus lateralis muscle. Δ[O2Hb -HHb] and change in total Hb (Δ[THb]= Δ[O2Hb + HHb] were calculated and used as oxygenation index and change in regional blood volume respectively. All NIRS values were averaged and compared over the last 15 sec of each series. Blood gases were taken at the end of 1st (S1) and 3rd (S3) series, and at two-minute recovery (R2).

Results: In the four tests, Δ[O2Hb], Δ[HHb] and Δ[THb] increased from the beginning to the end of exercise. However, while there was no difference in Δ[THb] between testing conditions, Δ[O2Hb - HHb] was lower and Δ[HHb] higher at the end of each series in VHnx than both NBnx and VHhpr. Δ[O2Hb] in VHnx was lower than in NBnx and was not different from VHhpr. We did not find any difference in all NIRS values between VHnx and NBhpo.

In VHnx, arterial oxygen saturation (SaO2) at S1 (87.0 ± 2.7%) and S3 (86.9 ± 3.1%) were lower than in NBnx and VHhpr, whereas there was no difference with NBhpo. During series, P50 and arterial CO2 pressure (PaCO2) in VHnx were higher than in NBnx and NBhx and not different (P50) or lower (PaCO2) than VHhpr. From S1 to R2, lactate concentration in VHnx was higher than both NBnx and VHhpr but not different from NBhpo.

Discussion: These results show that a prolonged exercise with VH increases blood lactate concentration, as a consequence of a hypoxic effect, and therefore probably leads to a greater contribution of anaerobic glycolysis. The lower muscle oxygenation during VH is probably due to the drop of SaO2 as well as a rightshift of the oxyhemoglobin dissociation curve under the effect of both metabolic and respiratory acidosis. A greater O2 extraction may also occur during exercise with VH. These acute responses could lead to interesting adaptations at the muscular level after VH training.

THE EFFECT OF TERRAIN TYPE AND TIME OF YEAR ON MUSCULAR, CARDIAC AND ENERGETIC STRAIN: TERRAIN FACTOR

OKSA, J., RINTAMÄKI, H., MÄKINEN, T.

FINNISH INSTITUTE OF OCCUPATIONAL HEALTH, OULU

Introduction: Terrain type and time of year modifies muscular, cardiac and energetic responses to a given exercise. This study was conducted to evaluate the effect of six different terrain types (road, footpath, easy and rough going forest, hilly terrain and swamp) and three different walking velocities (2, 4 and 6 km/h) on muscular, cardiac and energetic strain during summer (no snow) and winter condition (snow).

Methods

Nine healthy male subjects participated in the study. During walking their oxygen consumption (energetic strain, Metamax 3 B, Cortex Gmbh, Germany), heart rate (cardiac strain, Actiheart, Cambridge Neurotechnology Ltd, UK) and EMG activity from m. tibialis anterior, m. gastrocnemius medialis, m. rectus femoris and m. biceps femoris (muscular strain, ME6000, Mega Electronics Ltd, Finland) was measured continuously. They also performed maximal oxygen consumption test (maxVO2) and maximal voluntary contraction (MVC) for each muscle studied in order to define the percentual level of strain. Based on the results a terrain factor was formulated indicating the level of strain in different functions.

Results: Depending on the walking velocity and time of year the muscular strain varied between 2-44 %MVC, cardiac strain between 51-73 %maxHR and energetic strain between 21-58 %maxVO2. In relation to strain during summer condition winter increased the strain by 2-12%, 3-14% and 3-10% in muscular, cardiac and energetic functions, respectively.

Taking the walking velocity of 2 km/h in summer condition as baseline (terrain factor = 1), terrain factor for muscular strain varied between 1.2-2.4 and 1.5-3.6 during summer and winter condition, respectively. For cardiac strain the values were 1.1-1.4 in both conditions and for energetic strain 1.1-2.8 and 1.3-2.6 during summer and winter condition, respectively.

Discussion: The terrain factor for muscular and energetic strain seems to be more sensitive than terrain factor for cardiac strain. The results of the study can be utilised when predicting the changes in physical strain during summer and winter conditions, especially in military context.

EFFECTS OF LOW INTENSITY ENDURANCE TRAINING ON SMALL AIRWAYS OF MDX MICE

CHIMENTI, L., SANTAGATA, R., MACALUSO, F., BENIGNO, A., LICCIARDI, A., MORICI, G.

UNIVERSITY OF PALERMO; ITALIAN NATIONAL RESEARCH COUNCIL (CNR)

Introduction: Duchenne muscular dystrophy (DMD) is characterized by a progressive weakness of skeletal muscles including respiratory muscles which lead to respiratory failure. Dystrophin-deficient (mdx) mice have been used to investigate the effect of exercise in DMD patients. However, whether exercise is beneficial or detrimental in mdx mice it is not currently clear. In small airways of wild-type (WT) exercised mice we previously showed increased bronchiolar epithelium thickness induced by low intensity endurance training (Chimenti et al, 2007). No study to date has examined whether bronchiolar epithelium of mdx mice show any structural differences compared to WT mice and whether low intensity endurance training affect small airways of mdx mice.

Methods: 31 male mdx adult (C57BL/10ScSn-Dmdmdx/J; 10wk old) and 35 male adult WT mice (C57BL/10ScSn; 14wk old) were used and randomly assigned to sedentary or trained groups. Training was performed 5 days/wk for 6 wks at progressively increasing loads. Mice were also observed after 2 wks of cessation of training (Recovery, R). Formalin-fixed, paraffin-embedded lung sections were obtained from all mice groups and bronchiolar epithelium thickness was examined by measuring the Epithelial Area/Basement Membrane (EA/BM) ratio (BM length <1mm).

Results: In sedentary control animal, both WT and mdx, no significant difference was found between wk 0 and subsequent time points (6 wks, R), and pooled data were used for comparisons vs trained mice. At 6 wks EA/BM increased in exercised WT compared to sedentary WT (WT-EX: 20.5±3.9μm, WT-SD: 17.2±2.3μm, respectively; p<0.0001), while there was no significant difference between exercised and sedentary mdx (MDX-EX: 20.7±3.5μm, MDX-SD: 21.0±2.7μm, respectively). At R, EA/BM in WT-EX reverted to baseline values (WT-EX R: 17.4±1.8μm; p<0.005 vs WT-EX), while in mdx EA/BM did not differ significantly among all groups. Irrespective of the effect of training EA/BM was greater in mdx than in WT (MDX: 21.1±3.8μm, WT: 18.6±3.4μm; p<0.0001).

Discussion: Bronchioles of mdx mice showed structural differences compared to WT mice at all time points irrespectively of the effect of training. We previously demonstrated that cellular proliferation and cell death of bronchiolar epithelium might partially explain the structural changes observed in WT trained mice. To evaluate whether proliferation and apoptosis of bronchiolar epithelial cells may also contribute to the thickened epithelium observed in mdx mice further studies are needed. However, the novel finding of this work was that interruption of training reverted the increased epithelial thickeness observed in exercised WT mice, suggesting that this may represent a physiological response to increased ventilation during exercise.

THE MELATONIN RESPONSES TO EXERCISE ARE MODERATED BY TIME OF DAY

MARRIN, K.., DRUST, B., GREGSON, W., MORRIS, C., CHESTER, N., ATKINSON, G.

1. EDGE HILL UNIVERSITY, 2. LIVERPOOL JOHN MOORES UNIVERSITY

Introduction: Melatonin (MEL) is important for the human circadian system, via its soporific and hypothermic actions (Atkinson et al., 2005). The circadian rhythm of MEL is believed to be mainly endogenous, peaking at 03:00-04:00 h. (Atkinson et al., 2003). Exercise may be a synchronizer of circadian rhythms, possibly via direct thermoregulatory, or MEL-mediated, pathways. The responses of MEL to exercise have, therefore, been examined, but there are conflicting findings possibly because participants have exercised at different times of day (Atkinson et al., 2003). Thus, the aims of the present study were to compare salivary MEL levels during, and after, steady state exercise between the morning and afternoon, and explore relations between exercise-mediated changes in MEL and body temperatures.

Methods: At two times of day (08:00 h and 17:00 h), 7 male subjects (mean±SD age: 27±5 y) completed 30 min of cycling at 70% peak oxygen uptake followed by 30 min of rest. Salivary MEL levels were measured (ELISA immunoassay) at baseline, 15 min during exercise, immediately post-exercise and following 30 min recovery. Oesophageal (Tes), rectal (Trec), intestinal (Tint), and skin (Tskin) temperatures were also measured. Data were analysed using factorial within-subjects general linear models. Within-subjects correlation coefficients were calculated (Bland and Altman, 1995) to explore relations between MEL and body temperatures. Data are described as mean±SD.

Results: Averaged over all 4 time-points, MEL was 15.6±17.7 pg/ml higher at 08:00 than at 17:00 h (P=0.059). Exercise generally increased (P=0.006) MEL during (14.8±5.1 pg/ml), and after, exercise (18.7±5.9 pg/ml) compared with baseline (10.7±3.8 pg/ml). The change from baseline to post-exercise was 11.1±8.7 pg/ml in the morning compared with 5.1±5.7 pg/ml in the afternoon (P=0.024). All core temperatures were lower in the morning, with diurnal variation being greatest for Tint (P=0.019). Tskin was not different between morning (33.71±1.09°C) and afternoon (33.62±1.26°C). At 08:00 h, changes in MEL were positively correlated with Tes (P=0.001), but not Tint, Trec or Tskin. At 17:00 h, MEL correlated positively with changes in all body temperature measurements (P<0.01).

Conclusions

These findings indicate that 30 min of moderate-intensity exercise mediates an increase in MEL that is greatest in the morning when resting MEL is higher and core temperature is lower. Relations between MEL and body temperature changes during exercise are positive and appear more robust in the afternoon than in the morning, irrespective of whether core or skin temperature was considered, supporting the notion that MEL may have both central and peripheral influences during exercise (Aoki et al., 2006).

EFFECT OF VOLUNTARY WHEEL RUNNING ON LIPID PEROXIDATION IN <I>SNARK</I>-DEFICIENT MICE

ICHINOSEKI-SEKINE, N., UMETSU, Y., KAKIGI, R., NAITO, H.

JUNTENDO UNIVERSITY

This study investigated the effect of voluntary wheel running on lipid peroxidation in Snark-deficient (Snark^{+/–}) mice. Snark^{+/–} mice exhibit mature-onset obesity and related metabolic disorders under sedentary conditions, although they show no significant differences in body weight according to genotype at the time of weaning. Sedentary Snark^{+/–} mice consume less oxygen than their wild-type counterparts, but Snark^{+/–} mice exposed to an environment that allows for voluntary exercise will run greater distances than their wild-type counterparts. It is hypothesized that Snark deficiency may alter antioxidant capacity and that this may contribute to increased running distance.

Two-month-old Snark^{+/–} mice (n = 10) and their wild-type counterparts (Snark^{+/+}; n = 10) were assigned to sedentary or exercise (4-month voluntary wheel running) groups. The mice were maintained under a 12-h light/dark cycle at 23 ± 1°C and 55 ± 5% humidity; water and standard chow were provided ad libitum. After a 1-week acclimation period, the running distance was recorded every 6 s for each animal, throughout the duration of the exercise period. Food intake was also determined and recorded weekly. Mice in the exercise group were euthanized after the last exercise period. Sedentary control mice of the same age were also euthanized. The heart, liver, kidney, and white adipose tissue (WAT; gonadal fat) as well as the extensor digitorum longus, tibialis anterior, soleus, gastrocnemius, and plantaris muscles on the left side were dissected and weighed. Tissue samples were frozen in liquid nitrogen and stored at –85°C until analysis. Liver thiobarbituric reactive substances (TBARS) were measured using a TBARS assay kit (Cayman Chemical, Ann Arbor, MI).

Consistent with our previous study, exercised Snark^{+/–} mice ran 1.4-fold the distance run by their wild-type counterparts. Sedentary Snark^{+/–} mice exhibited heavy fat deposition; body and WAT weights were significantly lower in the exercised group ($P < 0.01$). In particular, WAT weight was decreased by more than 50% in the exercised group compared with the sedentary group. In addition, exercise resulted in lower muscle and liver weights in the mice. The liver TBARS value was significantly lower in the exercise group compared with the sedentary group ($P < 0.01$); however, no significant differences were found between the genotypes. Liver TBARS negatively correlated significantly with running distance ($P < 0.01$). These findings suggest that SNARK may not be involved in changes of oxidative stress and lipid peroxidation in the liver.

EFFECTS OF THE GENETIC VARIATION ON MUSCULOSKELETAL, CARDIAC TRAITS AND ADAPTATION TO ENDURANCE TRAINING IN MICE

VENCKUNAS, T., KILIKEVICIUS, A., ZELNIENE, R., RATKEVICIUS, A., LIONIKAS, A.

LITHUANIAN ACADEMY OF PHYSICAL EDUCATION

Identifying the genetic factors modulating the adaptation to exercise training can contribute to the insight into the prevention and treatment of many chronic diseases, since exercise training is generally a well-known powerful tool to improve health-related fitness. Genetic factors also do play a substantial role in musculoskeletal and cardiac size and function and their adaptability to chronic exercise training among individuals (Bray et al., 2009). However, the specific genes underlying these effects and the mechanisms of this variation are not well understood. We have chosen a mouse model to explore how the genetic variation influences morphological musculoskeletal and cardiac characteristics, endurance capacity and their adaptation to training. The goal of this study is to identify a suitable model capable

to elucidate the genetic factors relevant to variation in several phenotypes important for health and physical performance. It is an important first step in selection of research tools for further elucidation of the genetic mechanisms underlying variation in relevant traits.

Methods. To investigate effect of endurance swimming training on morphological parameters and endurance capacity (as a time of swimming to exhaustion) depending on genetic background, 11-14 week old male mice from six inbred strains (A/J, BALB/cByJ, DBA/2J, C3H/HeJ, C57BL/6J, and PWD/PhJ) were studied. Littermates were allocated into sedentary and trained groups (n=92 each) balanced by strain, age and body weight. Skeletal muscle, cardiac ventricular mass, femur length, and the endurance capacity were measured at the end of the five-week progressive endurance swimming training programme.

Results. Significant variation among inbred strains was observed in all tested phenotypes.

In conclusion, we identified a mouse model, which can be successfully used to shed light on the genetic mechanisms underlying variation in musculoskeletal and cardiac characteristics and adaptation to endurance training.

PERCUTANEOUS ELECTRICAL MUSCLE STIMULATION ATTENUATES POSTPRANDIAL HYPERGLYCEMIA IN OBESE MEN

KIMURA, T., MATSUMOTO, K., KAMEDA, N., HAYASHI, T., TANAKA, S., MORITANI, T.

KYOTO UNIVERSITY

Introduction: The patients with type 2 diabetes are encouraged to exercise after a meal to attenuate postprandial hyperglycemia in order to reduce the risk of myocardial infraction. However, we know that there are diabetic patients who have a difficulty in performing physical exercise as a consequence of excessive obesity and/or orthopedic problems. Now, we tried to develop percutaneous electrical muscle stimulation (EMS), as an alternative to voluntary exercise, to treat postprandial hyperglycemia.

Methods: Eleven middle-aged obese men [age 43.7 (10.9) years, body mass 81.5 (9.2) kg, body mass index 27.4 (2.7) kg/m2, mean (SD)] served as subjects. Each subject participated in two experimental sessions, i.e., one was a 20-min EMS after a breakfast (EMS trial) and the other was a complete rest after a breakfast (Control trial). In EMS trial, quadriceps, biceps femoris, and gluteus maximus muscles were simultaneously stimulated at 4 Hz. In each experimental session, blood sample was taken before and 30, 60, 90, and 120 minute after the meal. Respiratory gas exchange and blood lactate concentration were measured during EMS and complete rest after a meal in EMS and Control trials, respectively.

Results: The elevation of blood glucose after the meal observed in Control trial was significantly attenuated in EMS trial ($P < 0.05$). In addition, the postprandial increase of blood insulin was significantly lowered in EMS trial ($P < 0.05$). It was also found that respiratory quotient and blood lactate concentration were significantly increased during EMS ($P < 0.05$).

Discussion: The novel finding of this study was that postprandial hyperglycemia was significantly attenuated by a 20-min EMS after a meal. In addition, the elevation of respiratory quotient and the increase in blood lactate concentration during EMS suggest that the attenuation of postprandial hyperglycemia was mainly attributed to the enhanced anaerobic glycolysis in contracting muscle and subsequent elevation of glucose uptake.

IS-BM03 Adaptation in tendons and connective tissues in response to loading

REGULATORY FACTORS IN CONNECTIVE TISSUE ADAPTATION TO EXERCISE

HEINEMEIER, K.M.

BISPEBJERG HOSPITAL

Tendon tissue and the extracellular matrix of skeletal muscle are collagen rich tissues that are important for muscle function. Mechanical loading via exercise/training induces collagen synthesis in both tendon and muscle. This indicates an adaptive response in the connective tissue of the muscle-tendon unit. However, the precise mechanisms that lead from physical loading to changes in collagen production are yet unknown. Several in vitro studies on connective tissue cells indicate that stress-responsive growth factors, such as transforming growth factor-b-1 (TGF-b-1), insulin like growth factor-I (IGF-I) and connective tissue growth factor (CTGF) could be involved in this process. These growth factors are expressed in response to mechanical stimuli and at the same time they induce expression of collagen in connective tissue cells.

In support of this hypothesis, short-term strength training in rats leads to increased levels of TGF-b-1 and IGF-I expression in a pattern closely resembling the increase in collagen expression in both tendon and muscle tissue. CTGF on the other hand does not seem influenced by mechanical loading of tendon but does respond to loading of skeletal muscle.

Especially IGF-I may be an important player in connective tissue growth/maintenance. Recent findings show that increased systemic levels of growth hormone (GH) elevates IGF-I systemically (as expected), but also locally in tendon and muscle tissue. Simultaneously collagen mRNA expression and synthesis is increased in good correlation with local IGF-I expression. This suggests involvement of the GH-IGF-I axis in the regulation of collagen synthesis in connective tissue.

GENDER DIFFERENCES IN CONNECTIVE TISSUE RESPONSES TO EXERCISE – DO WOMEN ADAPT SLOWER THAN MEN?

HANSEN, M.

BISPEBJERG HOSPITAL

The incidence of several diseases linked to collagen-rich tissues seems to be biased by gender. Furthermore, women are at a greater risk than men of sustaining certain kinds of sports-injuries. Part of the gender difference may be caused by sex hormonal differences. Estrogen receptors have been localized in fibroblasts in ligaments, tendons and skeletal muscle. Animal studies have shown conflicting data concerning the effect of estrogen on tendon and ligament collagen protein turnover, and the knowledge is difficult to transfer to human caused by differences in the ovarian system. Human data in this field is very space, but this presentation will focus on recently results showing effects of gender, oral contraceptives and estrogen replacement therapy on tendon collagen protein synthesis, fibrillar structure and tendon biomechanical properties at rest and in response to exercise. Data suggests that tendon collagen synthesis is slower in women compared to men, and in oral contraceptive users compared to non-users both at rest and in response to exercise. Furthermore, estrogen replacement therapy seems to stimulate tendon collagen synthesis in postmenopausal women and thereby reduce the relative stiffness (young modulus) of the patellar tendon. In conclusion, the effect of female hormone estrogen seems to be dependent on the situation, age, and the direct and/or indirect effects of different types of estrogen. Taken together, these results may suggest a pivotal role for estradiol in maintaining homeostasis of female connective tissue.

MORPHOLOGICAL AND BIOMECHANICAL ADAPTATIONS OF HUMAN CONNECTIVE TISSUE TO EXERCISE TRAINING - FROM HEALTHY TO OVERLOADED TENDONS

KONGSGAARD, M.

INSTITUTE OF SPORTS MEDICINE

Tendons play a key-role in human movement and proper tendon function is a requirement for optimal locomotion. Tendons have previously been regarded as somewhat inert structures unable to adapt structurally and functionally to changes in loading conditions. However, recent studies have clearly shown that tendons are quite capable of both structural and functional adaptations. Despite these adaptive capabilities, tendon overload injuries are highly frequent, disableing and resistant to treatment. To optimize functional performance, and to prevent and treat tendon overload injuries, it is necessary to understand the adaptations of healthy and injured tendons to mechanical loading. Subsequently, this presentation will focus on data concerning structural and functional adaptations, as well as clinical improvements, in response to various modes of loading in healthy and injured tendons.

An increasing number of recent studies have shown that tendons are capable of hypertrophy and increases in mechanical properties in response to loading. However, the magnitude of loading seems to be crucial, and therefore the role of high vs. low force loading with regards to specific functional and structural tendon adaptations will be discussed. Also, data suggest that regional variations in tendon structural and mechanical properties could be related to the development of tendon injuries. In this context, the possible tendon injury preventive effect of various loading regimes will be evaluated.

Loading based therapies, especially eccentric contractions, have been reported to be effective in the management of tendon overload injuries (tendinopathies). However, the clinical effectiveness of these therapies needs optimization, and the underlying mechanisms need to be established. This presentation will discuss recent data showing promising clinical effects of heavy slow resistance training in tendinopathy management. Additionally, data associating these promising clinical improvements with changes in fibril morphology, collagen crosslink properties and tendon mechanical properties will be presented. Last, a discussion on optimal load, volume and training frequency in loading based tendinopathy therapies will be put forward.

OP-PI01 Philosophy and Ethics

MINDLESS COPING IN COMPETITIVE SPORT: SOME IMPLICATIONS AND CONSEQUENCES

ERIKSEN, J.

THE NORWEGIAN SCHOOL OF SPORT SCIENCES

Recent discussion in sport science has focused on to what extent one uses different kinds of cognitive capacities during skilled behavior and what role they play in the execution of skills in competitive sport. Do high-level athletes rely on mindful activity such as deliberate decision making, use of memory-based recognition and conscious controlled movements during skill execution or is it really the case that the action is done "without thinking" in an automatic or intuitive style? One of the more scientific approaches to this topic has been concerned with to what extent we make use of mental representations during experienced skill execution in sport. An obvious reason for this

discussion is the limited access we still have to observe, measure and to monitor the internal processes involved in our skilled behavior, and especially those processes that are inaccessible to our conscious mind.

The aim of this paper is to elaborate the phenomenological approach to skilful behavior proposed by Dreyfus and Dreyfus and to give an account of to what degree their approach may be considered a useful framework for a better understanding of how athletes use their cognitive capacities during skilful activity. According to Dreyfus and Dreyfus, it seems that beginners make judgments using strict rules and features, but that with talent and a great deal of involved experience the beginner develops into an expert who sees intuitively what to do without applying rules and making deliberate judgments at all. Their description of expertise is based on a non-representational view of the underlying cognitive structures for human behavior. The paper will subsequently examine if Dreyfus and Dreyfus' approach is capable of resisting the different attacks that have been made against their view, and in particular regarding the practical application of their approach to the skill domain of competitive sport. This paper also aims to explore the possible limitations of their description of highly skilled behavior leading to mastery.

OPERATIVE METHODOLOGY TO USE OF PHYSIOLOGIC FACTORS IN SPORT TRAINING: A PROPOSAL IN COMPLEXITY PARADIGM

ESTEVES, D., BRÁS, R., O'HARA, K., PINHEIRO, P.

UNIVERSIDADE DA BEIRA INTERIOR

Current research in coaching development infers that coaching is predominantly a decision-making process (Abraham et al., 2006). Nevertheless, there is a general perception that research in sports science does not meet the needs of coaches (Goldsmith, 2000; Williams & Kendall, 2007), since is not helping the coaching process, in order to make the best decisions. Consequently, there is a need for a model of coaching (Abraham et al., 2006). This model should consider the "real world" problems of the training process, taking in account the complexity of the sport performance phenomena, since in literature on coaching, several authors refer that exist a "gap" between sports science research and coaching practice (Spinks, 1997; Goldsmith, 2000; Williams & Kendall, 2007 and Midgley et al., 2007).

Under the scope of contributing to minimise that "gap" between research and coaching practice, specially referring to physiologic factors that impair sport performance, this work proposes an operative methodology that considers (1) the epistemological and methodological aspects of complexity; (2) the change in understanding the physiologic factors that influence sport performance, required by the complex approach and (3) a paradigm rupture in training methodology, that allow coaches to use physiologic factors in decision-making process of the sport training.

SPORT MEDICINE AND THE ETHICS OF BOXING IN THE AREA OF GENOMICS –

MÜLLER, A.

MAASTRICHT UNIVERSITY

Among others the British Medical Association demands a ban on boxing for several years now (BMA, 1993, 2007). However, such a request on the basis of the potential health risk for boxers is falling short for ethical and societal reasons (Cowie et al., 2000; Leclerc & Herrera, 1999). It overlooks other forms of health risks in society in general (e.g. traffic, suicide) and health risk in other sport disciplines in particular, namely high risk sports such as mountain climbing (Müller, 2008). Furthermore the argument against boxing from a medical professional's perspective, such as the duty to heal can not 'automatically' override the respect for the athletes' autonomy which is used as an argument against the ban of boxing (Beauchamp & Childress, 2001). Thus a sound ethical approach needs to balance the stakeholder's views and (ethical) arguments. However, a general ban of boxing is no option for boxers, the reduction of risks is. E.g. the reduction of the number of rounds, usage of protective head gear, improvement of pre-participation examinations seems desirable form both sides, i.e. physicians and athletes (Loosemore et al., 2007; McCrory, 2007). But how far can/should preventive measures go? Should genetic testing (e.g. APOE e4) be part of those risks reduction strategies? (Jordan et al., 1997; Savulescu, 2005; Spriggs, 2004). If such a test is feasible should it be offered to athletes as a screening, i.e. to asymptomatic boxers or as a test, that means to athletes that already have a certain family history? What view do stakeholders (such as athletes, coaches, physicians, etc.) hold on this issue? In this paper I would like address these questions supported by qualitative empirical data (results of interviews and focus groups) of a two-years research project.

SPORT AND ITS PHILOSOPHICAL SIGNIFICANCE

HOGENOVA, A.

CZECH OLYMPIC COMMITTEE

Sport and its philosophical significance

Prof. PhDr. Anna Hogenová, PhD.

e-mail: Hogen@volny.cz

Sport as a conflict phenomenon. Conflict is something fundamentally different to battle in the sense of war. Sporting conflict shows us something which is otherwise inaccessible both to the athletes themselves and the spectators watching them. Hence sport involves something other than triumph. Questioning is a commitment to thought, it is the utmost in man's spiritual life. Sport is hence a space for substantive questioning, which manifests itself right in the midst of competition. The spectator is drawn into the fundamental nature of questioning during the contest. The spectator experiences this questioning quite perceptibly. Sport is a place in which the truth can be unmistakably, indisputably and instantaneously experienced. The spectator and the athlete both know who will be first past the finish line. Such a testament of truth is not often experienced in everyday life; sport is an exception in this regard. The spectator experiences the uncovering of the essence of truth by watching the conflict unfold and is the so-called target witness of the truth of this conflict. This harbors within it the sense of ethics, pedagogy and humanities. Truth cannot be so easily confirmed during the course of everyday life. This can lead to turmoil and confusion which cannot often be completely explained even after thorough analysis. Sport is also a space for encountering genuine greatness. Sport as dialogue par excellence. Questioning, the path to truth and accomplishment – everything becomes feasible, comprehensible and unequivocal. The experience of encountering the truth occurs in the present, this is very important for the nature of man's thoughts even in other walks of life.

Sport is not only entertainment and a means to human health. It is something much more important than it seems at first glance. Hence, sporting events are important and the most important of all are the Olympic Games. The Olympic Games are not only entertainment, they are not only a space for the appreciation of advertising revenue, they are not only for the manifestation of peace on earth. The Olympic Games are a space in which athletes and spectators all over the world can experience truth as the foundation of being. It is also important to care for the philosophical sense of sport. This is often forgotten about!

THE FAIR PLAY PRINCIPLE AND OTHER VALUES IN SPORT

KOSIEWICZ, J.

UNIVERSITY OF PHYSICAL EDUCATION

In the text is assumed that man constitutes the highest value in sport and all other values are secondary in their relation to this principal value. They serve its strengthening. It refers, of course, to the principle of fair play and to all other moral values influencing behaviour and life of societies and persons connected with sport, since man – using Kant's terminology contained in "Groundwork of the Metaphysics of Morals" – is in sport a non-relative value. All others have a relative character.

The essence of sport, that is: the essence of a particular sport discipline, is constituted by its rules, regulations. They define its identity, character, qualities and principles of rivalry. They are its fullest and the most coherent definition. If they didn't exist, a given sport would cease to exist too. They constitute for it the second – next to man – value of a fundamental character and the principle of fair play can be applied only in its relation towards the rules regulating the course of sport rivalry.

However, in order to enable this rivalry to arise, it is necessary to meet, inter alia, one extremely important condition connected with proper training and preparing for competition. Only a suitable level of physical fitness and skills, a high degree of professional competence – not counting the whole sport infrastructure - enables sport rivalry to take place and makes it possible to achieve success as a social and individual value. Thus, fitness and skills of a luger, a bobsleigh rider or a tennis player are not enough to take part e.g. in ski jumping or car racing.

The preparations for competitions and the course of rivalry are highly positively influenced by the principles of fair play. They supplement the rules and humanise sport competitions saturating them with moral good.

CAN PHYSICAL ACTIVITY INCREASE MENTAL HEALTH? NO WAY

BIRCH, J.

NORWEGIAN SCHOOL OF SPORT SCIENCES

Physical activity is apparently beneficial for almost everything these days. Even minds benefit from exercise we are told. At least, that is what is claimed in studies regarding physical activity to increase mental-, as well as physical health. From a philosophical perspective, how are we to interpret such claims? The suggestion in this talk is that we are confronting cases of mental causation. The two interesting ways such causation might happen is: 1) a mental state causes a physical state, and 2) a physical state causes a mental state. The first way might be psychosomatics, the latter is what I suppose is meant when claims about physical activity and mental health are made, so I will concentrate on this case, but the argument will also undermine the possibility of psychosomatics.

There are three standard ways to understand the relationship between mind and body in philosophy:

a) Substance dualism is the view that there are two substances in the world: the material body and the immaterial mind. These stand in a causal relation, but how the interaction works remains a mystery. Such a view of the world is not going to explain how physical activity makes a difference in the non-physical realm of the mind. It is a difficult scientific position to hold, since one of the most basic laws of physics is the closure principle.

b) Epiphenomenalism is the view that mind does not make a difference in the physical world, it is just an epiphenomenon. Since the view denies there is causation between the physical and the mental, it is certainly not the view you want to hold if you're claiming that physical activity benefits mental health.

c) So we are left with physicalism. Physicalism is the view that there is nothing but physical matter in the world. So what we call mental must be realized by, be identical with or supervene on the physical.

From a physicalist perspective, it is impossible to have mental or physical change without a physical cause. For physical activity to benefit mental health then, the activity must alter a physical state, say at the level of neurotransmitters, because if there isn't a change at the physical level, there isn't going to be any change at all: the mental is physical. If you claim there is a genuine mental change, you must defend the view called substance dualism. When it comes to mental causation, it's not a good option.

I believe these considerations are important because our concepts describe the goings on in the world. If what I have claimed above is justifiable, health workers should stop telling patients they are mentally ill (which some feel ashamed of, or believe is not really an illness at all), because they are physical ill. In the same way, physical activity cannot increase mental health, only physical health. But that is just as well.

The talk is based upon the work of Jaegwon Kim (2005).

TOWARDS AN INCLUSIVE INTEGRITY POLICY IN SPORT? A DECADE OF PREVENTION POLICY OF SEXUAL HARASSMENT IN SPORT IN THE NETHERLANDS

VERTOMMEN, T., MOGET, P., WEBER, M., VAN VELDHOVEN, N.

*NOC*NSF*

Integrity policies become more and more accepted in public governance, police and other social sectors. In sport however, there seems to be a lack of interest to install a set of protection measurements concerning integrity. We notice some examples of good practice in local and national sport federations or clubs. Unfortunately there are not enough coordinated, coherent and subsidized initiatives to install a toolbox of integrity instruments (Maesschalck & Vanden Auweele, 2008).

The prevention policy of the Dutch Olympic Committee against sexual abuse and harassment in sports has been crucial for the social safety for a decade now (Moget & Weber, 2008). Rules of conduct were formulated for coaches and other sport leaders and the NOC*NSF hotline was formed. Victims and perpetrators of sexual harassment but also other (indirect involved)athletes, parents, coaches, board members of clubs and federations can reach this emergency telephone 24/7 for questions, support, first relief and report on incidents. More support and advice, when necessary, is given by councilors and advisors.

Every year, several incidents (approximately 100 a year) are reported to NOC*NSF. Cases of sexual harassment and abuse, violence, unwanted intimacies, abuse of power, handled by the councilors and advisors of NOC*NSF produce crucial information on the nature and number of complaints concerning harassment and abuse in sport.

The registration forms of the councilors and advisors contain valuable information about the age, sex and position of victim and accused. Types of harassment, point in time and duration of the incident and sport discipline can also be found in these documents.

With this information we can check theories and models, f.e. the grooming process as described by Brackenridge (2001) and possible correlation between soft and serious types of harassment.

The research will also take a close look to the process of treating the complaints, so that this can be evaluated.

The ongoing research, of which the first results will be presented during the conference, is the first worldwide to evaluate a prevention policy in sport based on real incidents.

SOCIAL INEQUALITIES AND OBESOGENIC ENVIRONMENT – WHAT ARE THE LINKS?

BRANDL-BREDENBECK, H.P.

UNIVERSITY OF PADERBORN

Introduction: Overweight and obesity have become an epidemic problem in most countries of the western world (Brettschneider & Naul, 2007). Despite a lot of programs fighting the increasing number of overweight people the success of these programs, which are directed to the indiviual's behaviour, is rather limited. The own research has two main goals. On the one hand we look at the lifestyles of ten year old children from Cologne by examining their nutritional patterns, their media consumption as well as their level of physical activities in order to identify life-style patterns which might be strong predictors for the prevalence of overweight in children. On the other hand living conditions and social inequalities in an urban setting are analysed in order to identify the importance of these factors (Hoffmeyer-Zlotnik, 2005; Keller, 2007).

Methods: Nearly 1200 ten year old children from Cologne (Germany) have filled in a questionnaire in a classroom setting.Validated instruments to assess nutritonal patterns, media consumption and physical activity have been applied. In addition the fourth graders were measured and weight in order to assess the BMI for each kid.

Results: The analysis of the structural level reveals that their is a strong negative relationship between the housing conditions, the SES and the prevalence of overweight and obesity. Children growing up in suburbs are less active, watch more TV and show a higher BMI.

Discussion: These results show that children with low socio-economic background suffer from several negative impacts of an obesogenic environment (Richter et al., 2008; World Vision, 2007). These results have to be taken into consideration when new programs for the prevention of overweight and obesity are designed.

'WE ONLY SMOKE WEED, DRINK BEER AND PLAY SPORT WHEN WE NEED TO': SPORT AND DRUG USE IN THE LEISURE LIVES OF YOUNG PEOPLE

SMITH, A.

UNIVERSITY OF CHESTER

Introduction: It is widely assumed that the promotion of young people's participation in sport and physical activity may be a particularly effective way of enhancing participants' health and preventing them from engaging in the use of legal and illegal drugs. However, such a view is premised on a one-sided and uncritically accepted perception of sport as an unambiguously wholesome and healthy activity in both a physical and a moral sense. Of course, such a perception is not wholly inaccurate, but it is one-sided and an appreciation of the other side of sporting culture might help us to develop a more realistic view of the likely effectiveness of those schemes in which sports of various kinds are used to promote health and social inclusion.

Methods: Set in this context, drawing upon questionnaire and interview data from a broader study that investigated the place of sport and physical activity in the lives of 1,010 15-16 year-olds attending schools in north-west England and north-east Wales, the central objective of this paper is to examine the independence between young people's participation in sport and their use of legal (e.g. alcohol and tobacco) and illegal drugs (e.g. marijuana) during their leisure time.

Results: The findings of the paper reveal that while participation in leisure-sport and physical activity was part of young people's quest for generating sociability and excitement in the company of friends and because it enabled them to do what they wanted, when they wanted and with whom they wanted, for many of them, and particularly the more frequent participants, playing sport and doing physical activity was just one component in their generally busy and wide-ranging leisure lives. It is also suggested that the consumption of drugs of various kinds did not prevent young people in the sample from engaging simultaneously in the consumption of legal and illegal drugs.

Discussion: In this regard, the paper argues that it is only possible to understand adequately where sport and physical activity fit into the multi-dimensional lives of 15-16 year-olds by examining those lives 'in the round', and by locating young people within the various networks of relationships to which they have belonged in the past, and which they continue to form in the present. The paper concludes by reflecting upon the relevance of the findings for understanding some of the policy issues surrounding the use of sporting schemes as vehicles of social policy in which the intention is to contribute to the promotion of health and social inclusion by reducing levels of legal and illegal drug use among young people.

THE ROLE OF PHYSICAL ACTIVITY AND SPORTS IN PREVENTIVE ACTIONS AGAINST DRUG ADDICTION IN RUSSIAN FEDERATION

BARYAEV, A., SHELKOV, O., EVSEEV, S.

ST PETERSBURG RESEARCH INSTITUTE OF PHYSICAL CULTURE

Introduction. The drug addiction is considered today as a social pathology and one of global problems. A problem of additive behaviour represents the complex problem consists of some aspects: medical, psychological, social, etc. Proceeding growth of a drug addiction in Russia by the end of 2019 will lead to serious demographic 'failure' in several age categories of the Russian population that threatens preservation of the nation*.

Methods. As popular wisdom says, it is better to struggle for something good, than against something bad, so the question of preventive actions is put more widely, about integration of sports methods. This integration is carried out in several directions: [1]the sports world is

considered, how intuitively clear model for teenagers of a social reality with its situations of competitive struggle, victories and defeats; [2]physical activity and sports means find wide application in actions by means of carried out pedagogical and psychological support of socialization; [3]traditional methods of socialization adapt for interests and inquiries of the teenagers who are professionally going in for sports.

Results. During realisation of preventive actions programs, developed by employees of the St.-Petersburg research institute of physical culture, following results are reached: [1]we prepared methodical literature on use of means of physical activity and sports; [2]in system of teaching and educational process introduced the component directed on preventive actions against drug addiction; [3]there are constantly worked qualification improvement courses of sports-pedagogical employees at schools of Russia; [4]since 2005 we carried out annual all-Russian mass sports actions «against drugs». Constant regional sociological monitoring proves efficiency of the developed actions directed on preventive actions against drug addiction by means and methods of physical activity and sports. At all persons captured by preventive actions, in relation to psychoactive substances the quantity of children and the teenagers carried to group of risk has decreased for 20-25 % as compared took place prior to the beginning of the given actions.

Discussion. The physical activity and sports potential is very essential in researched problem. First, such employments are capable to satisfy the majority of those requirements that induce to try drugs. Also here both bright emotions, and intensive dialogue, and an eventful life, self-test and risk. Secondly, sports are the most powerful «social lift», allowing young men sharply to raise the status, on to leave qualitative other level of ability to live. Thirdly, it is activity which for the objective reason is not compatible to drugs and promotes the statement of healthy way of life.

SPORT PRACTICE AND RESILIENCE: POWER TO OVERCOME.

SANCHES, S., RUBIO, K.

SAO PAULO UNIVERSITY

The educational sport psychology can be an important tool for the prevention and solution of a large number of social problems. One of the concepts related to it is the resilience, which is the capacity of some people that, even living in a hostile environment, can overcome the adversities and present adapted patterns of normality. People can be considered resilient when they present internal resources and abilities to avoid adversity determining negative directions for their lives. (Luthar, Cichetti and Becker, 2000). To investigate the resilience, we have to look at the risk factors, which can be defined as the negative events that can increase the probability of physical, social or emotional stress, and at the protective factors, that help dealing with these difficulties. The objective of the present study is to investigate how the sport practice can contribute to the development of the resilience, and what are the benefits from the acquisition of copings strategies to deal with stressful situations in different contexts of life. The method includes the investigation of the "life stories" (Rubio, 2006) of 10 elite athletes and the application of an adapted version of the "Five Fields Map" (Sanches, 2004). The results indicate many contributions of the sport practice: the sport as a profession that helps to overcome poverty; the opportunity to study with an athlete scholarship; the chance of not having to work at young age; the growth of their social and affective support net and the strengthening of significant bonds with good role models; the experience of positive emotions; increased health and body care, self-esteem, self-confidence and the development of future plans; the distance of drugs and criminality; the boost of social and group work abilities, autonomy and initiative to fight for wishes and dreams; better levels of self-control, empathy, and others. The conclusion of the study is that sport practice can decrease a large number of risk factors and increase other protective factors, contributing to the development of the resilience. This capacity of coping with adversities can help people that practice sports as a free time activity or with an educational or social finality, as well as the elite athletes that will cope better with the adversities (like losing or getting injured) and will have more chances to succeed in their sport career.

NOT HEALTH PROMOTON BUT HEALTHY ACTIVITY

SKILLE, E.Å.

HEDMARK UNIVERSITY COLLEGE

In order to bring the analysis of research into policy related to health and physical activity down to earth, this paper scrutinizes the views of the representatives of the implementers: the sport clubs. Based on document analysis and observation in board meetings, the role of sport clubs was identified to be, first, a facilitator for sport development which was associated with a competitive attitude, achievement orientation and development of athletes. However, during interviews, sport was, secondly, expressed to play a role in the development of social goods, such as upbringing and health. Regarding upbringing, one informant held: '[The sport club] shall be a place where children can get good values, attitudes, something more than just knowing the technical skills of football. We will take a societal responsibility. That is, we shall develop the human being, be in interaction with others and care for others. And not at least, we will give the children a positive experience for life'.

Paraphrasing Hillary Clinton, he noted that: 'it takes a whole village to raise a child'. There seemed to be competing ideals between the logic of sport as achievement oriented on the one hand, and sport as a social institution for well being and upbringing on the other. But for many sport club representatives, the provision of sport needs no further legislation; sport is good, period. The instrumental values of sport, as for example health, take a slightly different form in the discourse. Sport club representatives are not concerned with health in relation to somatic illness, but they believe in the value of sport because they see sport as a healthy way of spending leisure time, of growing up, and of personal and social development. With the application of neo institutionalism and the translation perspective, the perspective of the local organizations is underscored. In conclusion, it is suggested that sport policy is as much influenced by local sport policy, as vice versa. Aiming at identifying elements of government's sport policy in local and voluntary sport clubs, the analysis has to take the sport club representatives as the point of departure. The limited focus on health during the case studies of sport clubs may have several, but not necessarily mutual exclusive, reasons. First, it could be that health is simply not a focus for a sport club. Second, health is

implicit in the representatives' understanding of sport; it is so taken for granted that it is not considered to speak about. Third, and closest to reality for most informants, health is not mentioned explicitly because it is part of larger packages of societal goods.

OP-RE04 Rehabilitation 4

RESISTANCE TRAINING IMPROVES MUSCLE STRENGTH AND FUNCTIONAL CAPACITY IN RELAPSING-REMITTING MULTIPLE SCLEROSIS - A RANDOMISED CONTROLLED TRIAL

DALGAS, U., STENAGER, E., JAKOBSEN, J., PETERSEN, T., HANSEN, H.J., KNUDSEN, C., OVERGAARD, K., INGEMANN-HANSEN, T.

UNIVERSITY OF AARHUS; SOENDERBORG HOSPITAL; AARHUS UNIVERSITY HOSPITAL

Introduction: Patients suffering from multiple sclerosis (MS) are characterized by reduced muscle strength(1) and functional capacity(2). For MS patients, improvements in muscle strength and thereby functional capacity could make daily living easier and extend independent living. Progressive resistance training (PRT) has proven to be effective in increasing muscle strength and functional capacity during daily activities in healthy older people. However, the effects of PRT have only been sparsely investigated in randomised controlled trials in MS patients(3). We therefore tested the hypothesis that lower body progressive resistance training (PRT) can improve muscle strength and functional capacity in MS patients, and that possible improvements are maintained 12 weeks after the trial.

Methods:

The present study was a two-arm, 12 week randomised controlled trial (RCT) including a post study follow-up period of 12 weeks. 38 MS patients (EDSS;3-5.5) were randomised to a progressive resistance training group (Exercise, n = 19) or a control group (Control, n=19). The Exercise group completed a biweekly 12 week lower body PRT program and was afterwards encouraged to continue training, on their own. The Control group continued their usual daily activity level during the trial period. After the trial the Control group completed the PRT intervention. Both groups were tested before (Pre) and after 12 weeks of trial (Post) and at 24 weeks (Follow up) where isometric muscle strength of the knee extensors (KE MVC) and functional capacity (FS; score calculated from four functional tests) were evaluated.

Results: KE MVC and FS improved significantly after 12 weeks of resistance training in the Exercise group (KE:15.7±20.5%; FS:21.5±8.3%, $p<0.05$) and the improvements were significantly better than seen in the Control group ($p<0.05$). The improvements of KE and FS in the Exercise group persisted at Follow up after 24 weeks. The exercise effects were reproduced in the Control group during the 12 weeks PRT period after the trial.

Discussion: The present study gives support to use of resistance training in MS patients. Twelve weeks of intense PRT of the lower extremities leads to improvements of muscle strength and functional capacity in moderately impaired MS patients the effects persisting after 12 weeks of self guided physical activity.

INFLUENCE OF THREE DIFFERENT BALANCE SHOES ON EMG-ACTIVITY DURING WALKING

TURBANSKI, S., LOHRER, H., NAUCK, T., FAULSTICH, M., SCHMIDTBLEICHER, D.

1. INSTITUTE OF SPORT SCIENCES, UNIVERSITY OF FRANKFURT/MAIN, GERMANY, 2. INSTITUTE OF SPORTS MEDICINE, FRANKFURT/MAIN, GERMANY

Introduction: In numerous studies it was shown that sensorimotor training on balance boards and on unstable surfaces leads to improved neuromuscular control. Injury prevention or rehabilitation is aimed by appropriate exercises. Recently, manufacturers advertise specific shoe and unstable sole constructions to induce neuromuscular training stimuli. Therefore, the purpose of this study was to compare muscle activity during walking using three different balance shoes.

Methods

Twelve healthy male subjects, all physical education students, participated in this study (age: 25.3+/-1.4 years; height: 180.9+/- 5.5cm; weight: 78.6 +/- 8.3kg). On two days subjects were adapted to the test shoes.

Muscle activity of the lower leg was analysed during treadmill walking using surface EMG. In every testing condition subjects walked four minutes at 4.5 km/h (1.25m/s) and the last 30 seconds of each trial were recorded. The treadmill was equipped with two force plates to detect ground reaction forces on both sides (left and right leg). First, each person performed an unshod trial (control condition). Then, MBT® shoe (MBT), Finnamic-Rollenschuh® (FIN), and Reflex Control® shoe (RC) were applied and tested in a randomized order. EMG-activity was recorded of the following muscles: m. tibialis anterior (TIB), m. gastrocnemius lateralis (GAS), and m. peroneus longus (PER). We calculated iEMG for each ground contact phase and the mean values of at least 20 steps were used for statistical analyses. The four testing conditions (barefoot and three therapy shoes) were compared by using ANOVA for repeated measures.

Results: In comparison to control condition (barefoot - BF) we found in all muscles a tendency to increased EMG-activity when subjects wore MBT and RC and decreased EMG-activity when subjects wore FIN. But the level of significance (p≤0.05) was not reached in muscles TIB and PER. In GAS and in summarized muscle activity we found significant differences between RC and the conditions FIN and

BF (p=0.000 – p=0.031). There were no significant differences between RC and MBT but a tendency to higher activity in RC in muscles GAS and PER.

Discussion: Our data indicate that the different therapy shoes show varying demands during walking on a treadmill. Similar effects were found in a study comparing these unstable shoes during postural control in one-leg stance (Lohrer et al. 2008).

In conclusion, we suggest that balance shoes with unstable sole constructions (e. g. MBT and RC) increase sensorimotor training stimuli during walking. One can speculate about positive influences on injury prevention and rehabilitation in athletes and in elderly people. The shoe FIN seems not to be adequate to achieve such effects.

CARDIOVASCULAR RESPONSES DURING INCREMENTAL ENDURANCE AND RESISTANCE EXERCISES IN SUBJECTS WITH AND WITHOUT CARDIOVASCULAR DISEASE

HAUTALA, A., KARJALAINEN, J., KIVINIEMI, A., MÄKIKALLIO, T., HUIKURI, H., TULPPO, M.

VERVE RESEARCH

Introduction: Both endurance (EE) and resistance (RE) exercises have been recommended to include in exercise training programs in subjects with and without cardiovascular disease (1). Blood pressure increases linearly during incremental EE, but blood pressure response during incremental RE is not well established. We compared cardiovascular responses during acute RE and EE. We hypothesized that RE results in higher blood pressure responses than EE at the same relative exercise intensities in subjects with and without coronary artery disease (CAD).

Methods

Ten healthy male subjects (age 46±5 yr, BMI 27±4 kg/m2, VO2peak 45±8 ml/kg/min, mean±SD) and ten male CAD patients (age 56±3 yr, BMI 26±2 kg/m2, VO2peak 29±5 ml/kg/min) performed a graded RE and EE protocols. RE was performed by knee extension device (HUR Oy, Kokkola, Finland) without Valsalva maneuver including sets of 15 double-knee extensions (45 s work, 75 s recovery) starting at 0 kg and followed by an increase of 4 kg every 2 minute until voluntary exhaustion. EE was performed by bicycle ergometer starting at 0 W and followed by an increase of 25 W every 2 minute until voluntary exhaustion. ECG, respiration and beat-to-beat blood pressure (Finapres, USA) were recorded during the protocols. Peak heart rate (HR) and peak systolic (SBP) and diastolic blood (DPB) pressures were analyzed from three successive beats at the end of the each work load. Rate pressure product (RPP), an index of myocardial work, was calculated as SBP multiplied by HR.

Results: HR was higher during EE compared to RE at the levels of 50 – 100% of peak exercise capacity (p=0.011 – 0.0001) in healthy subjects, as well as in CAD patients at the intensity level of 40 – 100% (p=0.044 – 0.0001). No significant differences were found in SBP or DBP between the exercises at the same relative work loads. However, in healthy subjects RPP was higher during EE than RE at the intensity levels of higher than 60 % of peak exercise capacity ($p<0.050$), and similarly in CAD patients at the intensity levels of higher than 70% of peak exercise capacity ($p<0.050$).

Discussion: Surprisingly, cardiovascular responses did not differ between EE and RE at low or moderate relative intensity levels of exercise. Peak cardiac work was even higher during EE compared to RE at the high intensity levels of exercise both in healthy subjects and in CAD patients. It appears that resistance training can be incorporated safely into rehabilitation programs for patients with cardiovascular disease.

ADOLESCENT CONCERNS, PERSPECTIVES AND EXPERIENCES IN RETURNING TO SPORT FROM INJURY

PODLOG, L., SMITH, C.

TEXAS TECH UNIVERSITY

The purpose of this investigation was to examine injured adolescent athlete concerns, perceptions and experiences prior to a return to competition as well as during the initial come-back season. A total of 27 interviews with eleven Australian adolescents (aged 13-17) who had incurred a range of severe injuries (e.g., anterior cruciate ligament tears) were analyzed using Maykut and Morehouse's (1994) constant comparative method. Prior to their first competition, adolescents reported concerns about the potential effects of diminished fitness and skill levels, "falling behind" competitors, and anxiety over re-injury. At the same time, participants, particularly those with an extended competitive absence, commented that they "couldn't wait" to get back into competition, to achieve personal bests, and to compete alongside their teammates. For some (n=5), the eagerness to return to competition was tempered by the recognition of the need to take sufficient time in recovering to ensure optimal post-injury performances. Along these line, participants (n=4) indicated that coaches and parents reinforced the necessity of taking adequate time to recover and to avoid rushing a pre-mature return. These participants commented that it would likely take time to return to the same level of "sharpness", skill and fitness as before their injury. Following resumption of competitive play, adolescents articulated a range of positive and negative experiences. Adolescents (n=8) expressed feelings of satisfaction in making an expedient return to pre-injury levels and in receiving positive performance feedback from coaches and teammates. Others however (n=3), indicated that they put too much pressure on themselves to perform well in their first competition which in turn led to feelings of frustration and diminished confidence. In some cases, participants were extremely disheartened after experiencing re-injury or another traumatic injury shortly after their return to competition. In addition, frustrations over a lack of competitive fitness, and an inability to execute skills were persistent issues for some during the first several months of the come-back season. These challenges notwithstanding, adolescents typically indicated, that they "enjoyed being back on the team", they were "happy" to once again "do something that was fun", and to be part of the team. The results highlight the ways in which issues of competence (e.g., performance concerns), autonomy (e.g., self-induced pressures, an absence of coach/parental pressure), and relatedness (e.g., the importance of team affiliation) highlighted within self-determination theory may be relevant in examining the psychosocial processes associated with adolescent athletes' return to sport from injury. Further research utilizing an SDT conceptual framework is warranted.

STANDARDIZED REHABILITATION PROGRAM MEETS PERSONAL STORIES OF MOVEMENT. A CHALLENGING DUET.

SCHRIVER, N., ENGELSRUD, G.

NORWEGIAN SCHOOL OF SPORT SCIENCE AND MOVEMENTUM APS

Introduction: Persons with an ACL ligament injury have different functional abilities following a rehabilitation program, even if the program is meant to be standardized in its activities. The reasons for this are discussed within medical research as being a problem with knee stabilization, differences in movement strategies or differences in muscular activity. The differences in functional outcome are, moreover, difficult to explain. Our perspective is that to be injured and to be in a rehabilitation process is a personal issue imbedded in an institutional context, and it might affect the patients' ability to move, after rehabilitation as well. Therefore the aim of this study was to investigate how the patients participate in the rehabilitation program and what their experience entail.

Method and material

The study consists of 46 interviews and observations with 28 patients with an ACL rupture. The interview was based on the understanding that the patients' language in the interviews contained both an institutional level and a personal level (Søndergård 2002).The interviews were tape-recorded and fully transcribed. The analyses are based on the informants' statements, and our observations, and reveal the different approaches the participants employ.

Results: Four themes were typical in the material: 1) "Exercise to just get it done"; 2) "Exercising what the body is familiar with"; 3) "Following the programme closely; 4) "Being indifferent to the program" The different approaches seem to be closely related to the patients´ prior experience with movement and their approaches towards the training.

Discussion: To talk about standardized training program holds a high value within research and so do demands for ensuring evidence and effect. Our results illustrate that it might be possible to talk about a standardized description of a program, but very difficult to ensure standardized performance. Herbert and Bø (2005) state that it is difficult to assess the quality of the intervention before it is known whether it is effective. Our results raise an important discussion and questions about how the patient's own understanding and interpretation plays a central part in the researcher's understanding of effect.

Participating in a rehabilitation program is realized in a multifaceted and complex way that is integrated into the lives and prior experience with movement of persons with an ACL injury.

FUNCTIONAL LEVEL DURING SUB-ACUTE REHABILITATION AFTER TRAUMATIC BRAIN INJURY: COURSE AND PREDICTORS .

SANDHAUG, M., ANDELIC, N., VATNE, A., SEILER, S., MYGLAND, A.

AGDER UNIVERSITY

Objectives: To describe the functional level during sub-acute rehabilitation after severe and moderate traumatic brain injury (TBI), and to evaluate the impact of pre-injury and injury-related factors as predictors of early recovery.

Material and methods: A prospective study of 55 patients with moderate (n=21) and severe (n=34) TBI who received specialized, sub-acute inpatient rehabilitation. Functional level was assessed by the Functional Independence Measure (FIM). Possible predictors were analyzed in a regression model using FIM total score at discharge as outcome.

Results: At discharge from sub-acute rehabilitation, on average 53 days post-injury, 95% of patients with moderate TBI, and 62% with severe TBI had a good functional level with a FIM total score of 109-126. Among 34 patients with severe TBI 24% had a poorer functional level with a FIM total score <72 and 1 patient did not improve.

Predictors of functional level were FIM total score at rehabilitation admission (B= 0.452), Glasgow Coma Scale (GCS) score at rehabilitation admission (B= 6.022), length of post-traumatic amnesia (PTA) (B= - 0.088), length of stay (LOS) at acute hospitalization (B= -.165) and sub-acute length of stay (LOS) in the rehabilitation unit (B= 0.315). Conclusion: A high FIM score, high GCS score, short PTA period, short length of acute hospitalization and long stay are positive predictors of functional level at discharge from sub-acute rehabilitation hospital.

IS-SS06 The ethics of enhancement in Sport and Exercise

TECHNOPHOBIA? RETHINKING FASTSKIN

MAGDALINSKI, T.

UNIVERSITY COLLEGE DUBLIN

In May 2009, FINA, the world governing authority for swimming, rejected just over 10 recently released elite racing costumes for not passing buoyancy and thickness tests and asked for modifications on a further 136 models. The decision is not without its consequences. World records established in now illegal suits will likely be returned to the previous holder, sponsorship arrangements may be hastily amended to ensure athletes have access to the best legal racing attire and manufacturers will race to meet FINA's thirty day deadline to resubmit their suits for approval.

The path of racing costumes over the past decade has not been easy. Heralded first as a timely and necessary innovation, the suits were almost immediately decried as unfair before being readily embraced in time for the Sydney 2000 Olympic Games. Although seemingly now a fixture in international swimming, there has, nevertheless, been an undercurrent of discontent bubbling under the surface, which erupted in 2008 with calls for the suits' review, if not immediate prohibition, following the release of Speedo's LZR and the bevy of broken records left in its wake.
In recent publications, I have argued that technologies applied to the body and those that enter the body – even where the physiological outcome is the same – are treated differently by a sportsworld willing to accept performance aids but not enhancement, however loosely it may be defined. Yet, the never-ending debate over the legitimacy of Fastskin suits presents a curious anomaly. External technologies, those that do not penetrate the skin, are typically more accepted than those that seek to alter the materiality of the body. Yet, the parameters established by FINA would seem to indicate a shift in how even external technologies are perceived and it would appear that a stricter conception of "performance enhancement" is being proffered, In this paper, I will review the debates that have surrounded Fastskin swimsuits over the past decade to determine whether, in the pursuit of the elusive "pure performance", recent conceptual shifts suggest the boundary between external and internal technologies are increasingly blurring.

ANTI-DOPING : TOWARDS UTOPIA OR DYSTOPIA ?

KAYSER, B.

UNIVERSITY OF GENEVA

In January 2009 new WADA anti-doping rules went into application, obliging elite athletes to be available for testing one hour each day of the year. Athletes must provide authorities in advance with 3-month daily programs and inform of changes. Three missed tests in 18 months are a doping offence. Even though the new regulation is somewhat easier for the athletes since only concerning a single hour a day, the wider application of the new rule is causing controversy and unrest. In Belgium a group of athletes has asked a court to probe the legality of the 365 day rule. FIFPro, a European soccer player union, is also questioning the legality of the rule. In the Netherlands an athlete union is considering launching a legal case and a national data protection institute is studying compliance of the rule and procedures with the law. Euro-parliamentarians are also studying the problem. Several athletes in tennis (Murray, Nadal, Serena) have voiced discontent in the media. It thus seems that both subjectively and legally limits to anti-doping regulation are potentially reached. Nevertheless, GPS-carrying by athletes to ease localization is proposed and actual experiments are underway with cyclists. Apart from urine, blood samples are taken, DNA profiling is used for forensic purposes and hair is discussed as another potential material. These developments revive the question on how far the quest for a drug-free sport should go and how far athlete surveillance can be pushed. Critical analysis must take into account several other problematic aspects of anti-doping: because of the limits of technology a negative test cannot exclude doping and winners can therefore never be declared clean with certainty. In fact, because of the limits to testing technology and procedures, the goal of anti-doping, the eradication of doping, is a utopian and impossible goal. These problems cannot be seen in a sports only framework since there is increased substance use for performance enhancement in society in general. The tendency of society is rather relaxed with regard to the use of performance enhancement outside sports, but there are signs of application of anti-doping principles in society at large. Anti-doping promises a utopian solution to a constructed problem, which should perhaps not be perceived as a problem in the first place, but delivers a rather dystopian outcome where a subset of civilians is treated in paternalistic fashion with increasingly repressive means in a climate of suspicion. The prospect of the application of the same principles elsewhere in society like in schools, universities, fitness clubs and in general, aimed at ridding humanity from all substance use for enhancement or pleasure is worrisome at the least.

ETHICS AND PHYSICAL ENHANCEMENT: WHAT BASELINE, WHOSE JUDGEMENT?

HOLM, S., MCNAMEE, M.

CARDIFF UNIVERSITY AND SWANSEA UNIVERSITY

The aim of this presentation is to analyse the philosophical and ethical issues that arise in sports and health-related contexts regarding the use of biotechnological techniques that aim at enhancing one or more physical functions of human beings. New techniques have increased the scope and range of possible enhancement immensely. We first discuss the many different types of physical enhancement, noting that doping in sports is only a very minor part of the whole enhancement field. We then problematise the concept of enhancement and we show that deciding whether something should count as an enhancement is not a matter for pure personal decision. We then present the ethical arguments that have been put forward in the enhancement debate. We show that the validity of both the pro- and the anti-enhancement arguments is context-dependent and more specifically that some of the arguments against doping in sport are valid.

OP-HF07 Health and Fitness 7

CHANGES IN PHYSICAL FITNESS BETWEEN THE YEARS OF 2003 AND 2008 IN YOUNG ADULT MEN

KYRÖLÄINEN, H., SANTTILA, M., VAARA, J., OHRANKÄMMEN, O., HÄKKINEN, K., FOGELHOLM, M.

UNIVERSITY OF JYVÄSKYLÄ, NATIONAL DEFENSE UNIVERSITY, TRAINING DIVISION OF DEFENSE COMMAND, ACADEMY OF FINLAND

Introduction: It has been shown that physical fitness has decreased between the years of 1979 and 2004 in Finnish young men (Santtila et al. 2006), and obesity has increased during the last ten years in the Western countries (Blair and Church, 2004). The purpose of the present study was to further examine changes in physical fitness and body characteristics between the years of 2003 and 2008 among young adult males.

Methods: The study design was a repeated cross-sectional, with independent samples in 2003 and 2008. A total of 849 (2003) and 783 (2008) men, who were invited to refresher training organized by the Finnish Defense Forces, volunteered for the present study. Because their mean age (29±4 vs. 24±3 yrs., p<0.001) differed significantly, all data have been adjusted for age. Height, body mass and waist circumference (WC) were recorded. Physical fitness tests consisted of grip strength, muscle endurance (recording the number of repetitions in one-minute push-up, sit-up and squat actions) and maximal oxygen uptake (VO2max). The initial work load in the bicycle ergometer test was 50 W increasing by 25 W every second minute until exhaustion (Fogelholm et al. 2006). Heart rate was recorded continuously by heart rate monitor (Polar Electro, Kempele, Finland). In addition, subjects fulfilled a questionnaire of physical activity and health.

Results: Mean (±SE) height of the subjects was 1.80±0.06 both in 2003 and 2008, body mass 78.5±1.1 vs. 80.5±0.5 kg (p=0.09), body mass index (BMI) 24.3±0.3 vs. 24.8±0.1 (p=0.11), and WC 0.88±0.09 vs. 0.86±0.04 m (p=0.02). Number of reps/min was 36±1 and 38±1 in sit-ups (p<0.01), 23±1 and 29±1 (p<0.001) in push-ups and 40±1 and 44±1 (p<0.001) in squats. Grip strength was 54.7±0.8 and 52.9±0.3 kg (p=0.05) and VO2max 43.7±0.7 and 41.5±0.3 ml/kg/min (p<0.01). In both years, WC (negative) and amount of physical activity (positive) were the main predictors of VO2max (together r2=0.49 and 0.46 in 2003 and 2008, respectively).

Conclusion: The present study demonstrated that in a large group of young adult men, aerobic fitness has decreased and muscle fitness increased during the last 5 years. At the same time, no changes (26-28% in both years) were observed in vigorous types of physical activity performed at least 3 times a week, body mass and BMI but, however, WC has decreased. These observed changes in physical fitness can partly be explained by changes (p<0.001) in their leisure-time physical activity. In 2003, 19.3 % reported to have performed endurance type physical activity, while its contribution was only 4.0 % in 2008. In conclusion, the changes in physical fitness are associated with the type and amount of physical activity, and WC is closely related to aerobic fitness.

THE EFFECT OF EXERCISE INTENSITY ON NEAT IN OVERWEIGHT/OBESE INDIVIDUALS

ALAHMADI, M.A., HILLS, A.P., KING, N.A., BYRNE, N.M.

THE QUEENSLAND UNIVERSITY OF TECHNOLOGY

Introduction: It has been often reported that the weight loss achieved through exercise interventions is less than expected. A possible reason is a compensatory decrease in non-exercise activity thermogenesis (NEAT) subsequent to the exercise bout. Research on obese boys has shown that NEAT increased with moderate-intensity exercise, but decreased after vigorous exercise (Kriemler et al., 1999). However, to our knowledge, a similar investigation in overweight/obese adults has not been published. The aim of this study, therefore, was to determine whether an acute bout of walking exercise impacts NEAT in overweight/obese adults, and most importantly to determine whether there is a difference between the impact of moderate- versus high-intensity walking exercise on NEAT.

Methods: 15 overweight/obese male adults with mean BMI of 30.4 ± 6.5 kg/m2 and mean age of 26.5 ± 3.0 years performed two single bouts of exercise at either moderate- or high-intensity walking exercise in two different occasions. The moderate-intensity exercise consisted of walking for 60 minutes on a motorized treadmill at 6 km/h. The high-intensity exercise consisted of walking at 6 km/h at 10% for five minutes followed by five minutes at 0% repeated for 60 minutes. NEAT was assessed by accelerometer on three days before, the day of, and three days following the exercise sessions.

Results: The average NEAT (counts/min) for moderate and high intensity protocols were: pre-exercise days (104.7 ± 25.7; 105.5 ± 25.9), exercise day (101.1 ± 42.9; 104.8 ± 43.1) and post-exercise days (113.7 ± 24.1; 113.2 ± 30.8). A two-way repeated measures analysis of variance (ANOVA) was conducted and showed that no significant changes in NEAT between moderate- and high-intensity (P = 0.74). ANOVA also revealed that no significant main effect for time (pre, the same day and post-exercise) was found (P = 0.26). The interaction effect between exercise intensity and days was also not statistically significant (P = 0.92).

Discussion: The primary finding from this study was that neither exercise intensity had a pronounced effect on NEAT on the day of exercise, nor on the 3 days subsequent to the exercise. Our results are contrary to those found by Kriemler et al., (1999) in obese boys, and by Goran and Poehlman (1992) in the elderly. Addition of 8 days exercise training has been reported to have no compensatory effect on NEAT in a lean, moderately active, group of men and women (McLaughlin et al., 2006). The current study reveals that the addition of a single bout of either low-moderate or more intense walking exercise does not adversely impact on NEAT in overweight and obese men. A longer term study in overweight and obese adults is needed to determine the effect on NEAT of accumulated exercise sessions in a week.

LONG WORKING HOURS INDUCE CHANGES IN HEALTH BEHAVIOR BUT NOT IN PHYSICAL FITNESS CHARACTERISTICS IN YOUNG MEN

VAARA, J., OHRANKÄMMEN, O., SANTTILA, M., HÄKKINEN, K., HÄKKINEN, A., KYRÖLÄINEN, H.

NATIONAL DEFENCE UNIVERSITY

Introduction: Among the working population, 11-26% work more than 50 hours per week (Caruso 2006, Kauppinen & Rantanen 2002). Some of the previous studies have demonstrated that prolonged working hours are associated with negative health behavior and health, decreased cognitive and psychological functions and increased general fatigue. However, there is not much information of physical characteristics of people with prolonged working hours (Caruso 2006). Therefore, the aim of the study was to investigate the effect of working hours on the health behavior and physical fitness characteristics in young men.

Methods

A total of 846 young Finnish men (24 ± 4 yrs.) volunteered to study. Volunteers were divided into the long (LW) and normal groups (NW) according to their working hours. LW consisted of persons with working hours of 51-60 per week (n=67) and NW persons with working hours of 31-40 per week (n=432). Health behavior was screened by a questionnaire of physical activity, smoking, alcohol consumption,

sleep duration and nutrition. Questions of stress perception, back pain and amount of sickness absence were also included. Body composition (height, weight, BMI, fat percent, waist circumference) and heart rate in rest were measured as well as aerobic capacity (VO2max) by bicycle ergometer test. Blood samples were taken to analyze serum concentrations of cortisol and testosterone concentrations.

Results: LW showed more negative health behavior such as more smoking ($p<0.05$) and lesser healthy nutrition ($p<0.05$) than NW. In addition, their self-reported sleep duration was shorter (7:00 vs. 7:25 h, $p<0.05$). They also suffered more from back pain ($p<0.05$) than NW. However, there were no differences between the groups in perception of stress, alcohol consumption or sickness absence. LW reported to be less physically active than NW ($p<0.05$), and had also higher resting heart rate (69 vs. 66 bpm, $p<0.05$). No significant differences between the groups were found in body composition, VO2max or serum hormones.

Conclusion

Prolonged working hours are negatively associated with health behavior, but not physical fitness characteristics or hormonal profile in young men. However, since many of the lifestyle-related diseases have a long latency period, more negative health behavior may cumulate further during the working career by leading to unfavorable changes also in physical fitness characteristics.

HEALTH RISK ANALYSIS FOR THE INDIVIDUALS PARTICIPATING IN SPORT

ODABAS, I., GULER, L.

HALIC UNIVERSITY, SCHOOL OF PHYISICAL EDUCATION AND SPORT

Introduction: It is obvious that there is a positive relation between the health and starting sport in early ages. But nowadays, people have acquired different habits in advancing ages except for the sport habit they acquire in early ages. While they want to improve the life quality on the one hand, they can damage their body without being aware on the other hand. In this study, we wanted to examine the relation between the sport habits and the lifestyle-related habits. The purpose of this study was to evaluate the relation between the changeable and unchangeable risk factors of the individuals doing exercises.

Method

A cross sectional study was done on the individuals who have applied to a fitness club for a long time. 761 female and 911 male, total 1675 subjects (age= 32.77 ±10, 57) took part in this study. A detailed risk factors (tobacco and alcohol use, family history, injuries, metabolic and chronic diseases) analysis with Par Q test was applied to the participants before they start doing exercises by a doctor. The study lasted for a year. The data was collected in a fitness program and transferred to SPSS program. The relation between the risk factors were evaluated using correlation analyses ($p>0.05$).

Results: A significant correlation has been found between regular exercise and sex, tobacco and alcohol use. Also it has been found a positive relation between regular exercises and ankle injuries but a negative relation between regular exercises and waist and hip injuries. A negative correlation has been observed between the sport participants and Par Q test results. That is, the sport participants do not have any heart or respiratory complaints.

Discussion: It has been seen that the subjects who regularly participated in sport were mostly tobacco and alcohol users. It is also remarkable that some participants have problems in some joints. It has been observed that the most positive effect of exercise was that the cardio- vascular and cardio-pulmonary health of the participants was very good.

EFFECTS OF STRENGTH AND/OR ENDURANCE TRAINING AND NUTRITION ON SERUM HORMONES AND PHYSICAL FITNESS IN MIDDLE-AGED AND OLDER ADULTS

SILLANPÄÄ, E., HÄKKINEN, A., LAAKSONEN, D.E., GARCÍA-LOPÉZ, D., KARAVIRTA, L., KRAEMER, W.J., PAKARINEN, A., HÄKKINEN, K.

UNIVERSITY OF JYVÄSKYLÄ

Introduction: Strength training can minimize age-related loss of muscle strength and mass. Endurance training improves aerobic capacity and has a preventing role in several diseases. Physical adaptation during training is regulated through several mechanisms including hormonal and nutritional factors. The purpose of this study was to examine effects of 21 weeks of strength and/or endurance training and nutrition on serum basal hormone concentrations and physical fitness in 39-65 year old healthy adults.

Methods: Both women (W, n=81) and men (M, n=83) were randomized into strength training (S), endurance training (E), combined training (SE) or controls. S performed total body strength training and E performed bicycle training twice a week. SE did both strength and endurance training (2+2). All measurements were performed before and after the 21-week training period. Dietary intake was measured by 3+1 day dietary diaries. Muscle strength was measured by isometric knee extension and aerobic performance as maximal aerobic workload (pmax) during a gradual bicycle ergometer test. Serum basal concentrations of testosterone, cortisol and dehydroepiandrosteronesulfate were measured. Percent body fat (BF) and lean mass (LM) were estimated by dual X-ray absorptiometry.

Results: In a total group of W average dietary intake at week 0 were for energy (En) 7.4±1.4MJ, carbohydrates 47±6 En%, protein 19±3 En% and total fat 32±5 En% and in M 8.6±1.5MJ, 47±7 En%, 18±2 En% and 31±5 En%, respectively. Nutrition intake was similar in all four groups and did not change during the intervention in W (n=79) or in M (n=56). In both W and M, knee extension strength increased significantly in S (7±10% and 12±13%) and SE (11±10% and 10±10%), and in M also in E (5±10%), but not in the control groups. Pmax increased in all training groups ($p<0.001$), but not in the controls (between groups $p<0.001$). Average increases in Pmax were significantly higher in W and M in E (16±8% and 14±10%) and SE (17±9% and 14±7%) than in S (8±9% and 6±8%). Only minor changes occurred in serum hormones during training and there were no differences between groups. In W, the decrease in BF (by -1.0-2.0% units) was significant in all training groups and in M in E (by -2.1% units) and SE (by -1.9% units). In both genders SE increased total body LM significantly (2.2±2.6% and 2.1±2.4%) and the changes differed significantly between groups in W ($p=0.044$).

Discussion: As expected, strength and endurance training led to large training-specific improvements in muscle strength and aerobic performance. Combined strength and endurance training improved both neuromuscular and aerobic performance and also increased total body lean mass. Nutrition intake did not change during training. Typical Finnish diet was sufficient during high-intensity training which led to large improvements in physical fitness and to minor changes in serum basal hormones in middle-aged and older adults.

RELATIONSHIP BETWEEN PHYSICAL ACTIVITY AND HEALTH IN GERMAN ADOLESCENTS – FINDINGS FROM THE KIGGS- AND THE MOMO-STUDY

TITTLBACH, S., SYGUSCH, R., BREHM, W., BÖS, K.

1. UNIVERSITY OF BAYREUTH, 2. UNIVERSITY OF MAINZ, 3. UNIVERSITY OF KARLSRUHE

Introduction: The German Health Interview and Examination Survey for Children and Adolescents (KiGGS) is a representative, nationwide cross-sectional study on the health status of children and adolescents from ages 0 – 17. It was conducted by the Robert-Koch Institute of Berlin (RKI). The KiGGS study was complemented by the Motoric-Module (MoMo) for the more differentiated recording of physical activity and physical fitness.

A broad conceptualization was used in KiGGS for the assessment of health. In this understanding health is subdivided in health resources (e.g. fitness, self-esteem), risk factors and complaints (e.g. BMI, emotional problems) and a subjective over-all health measure.

The analyses presented will focus on adolescents. We aim to answer the questions, (a) if there are any positive associations between physical activity and different health measures, and (b) if there are stronger associations between physical activity and health resources than between physical activity and risk factors.

Methods: The common sample of the KiGGS- and the MoMo-study consists of 4,529 children and adolescents from 4-17 years of age. Subjects were randomly selected from the KiGGS-study. Focusing on the links between adolescents' physical activity and health, a sub sample of N= 2,281 adolescents (M= 14.13, SD= 1.97; range 11-17 years of age; 50.5% boys) was used. The recording of physical activity, psychosocial health resources, physical and psychosocial complaints as well as over-all health measure was done by means of self assessment of the adolescents via questionnaire and that of the socio demographic characteristics by means of a questionnaire for parents. Physical risk factors were assessed by medical examination respectively lab findings and physical health resources by sport-motor tests. Hierarchical re-gression analyses were carried out for statistical evaluation.

Results: The data reveal that (highly) active adolescents have better results in most health parameters than somewhat or never physically active adolescents. Regression analyses reveal that physical activity explains up to 10% of variance in physical health resources (endurance, strength) and psychosocial health resources (self-perception of physical fitness), but is only slightly related to risk factors and complaints (e.g. BMI, cholesterol) and overall subjective health measures (e.g. wellbeing).

Discussion: The results correspond to international reports, which also found only weak links between physical activity and health parameters, especially risk factors (e.g. Biddle et al., 2004). Our findings show that the relationship between physical activity and health should be conceptu-alized not only under the perspective of reducing risk factors, but rather should focus on the enhancement of physical and psychosocial resources.

IS-BC03 The role of the inflammation process in exercised muscles

INFLAMMATORY REACTIONS IN MUSCLE AFTER EXERCISE: ARE HUMANS AND ANIMALS ALIKE?

PEAKE, J.

QUEENSLAND ACADEMY OF SPORT

Researchers have investigated inflammatory reactions to exercise-induced muscle damage in both humans and animals, using a variety of methods to induce muscle damage and assess inflammation. In humans, muscle damage is induced using downhill running, box-stepping, drop-jumps and exercise on an isokinetic dynamometer. In rats, mice and rabbits, muscle damage is induced using downhill running, electrically-stimulated lengthening muscle contractions, and local injection of cardiotoxin or snake venom. In humans, researchers have investigated alterations in leukocyte infiltration in skeletal muscle after exercise from several different perspectives, including the effects of sex, age, repeated bouts of muscle damage, exercise intensity, antioxidant supplements, and drugs (e.g., calcium channel blockers, analgesics, non-steroidal anti-inflammatory drugs). Data from these studies indicate that sex, age and repeated bouts of muscle damage influence leukocyte infiltration. Research into the relationship between leukocyte infiltration, delayed onset muscle soreness (DOMS) and changes in muscular strength is inconsistent. The effects of multiple muscle biopsies on leukocyte infiltration following exercise-induced muscle damage are also questionable. In general, animal research has produced more consistent findings concerning the effects of sex, age, oestrogen, repeated bouts of muscle damage and non-steroidal anti-inflammatory drugs. Animal models of muscle damage and inflammation provide some advantages over research involving humans. In particular, animal models allow the removal of whole muscle, and more direct interventions to modulate leukocyte infiltration (e.g., gene knockout, antibodies against macrophages and neutrophils, clodronate). Comparisons between humans and animals are limited, however, for several reasons. First, fibre type distribution, oxygen delivery, oxidative potential and enzyme activity differ between human and animal muscle tissue (1). Second, the physical stress resulting from downhill running in humans likely differs from the physical stress that caged animals experience when running1. Last, electrically-stimulated contractions and injections of cardiotoxin or snake venom typically induce considerably greater muscle damage than voluntary exercise1. In summary, we can potentially learn more about muscle damage and inflammation from animal studies than we can from human studies, but caution is advised when translating animal physiology to human physiology.

ANIMAL MODELS OF POST-EXERCISE LEUKOCYTE INFILTRATION: DETERMINING ROLE AND FUNCTION

TIIDUS, P.

WILFRID LAURIER UNIVERSITY

Animal models of post-exercise leukocyte infiltration: determining role and function

Peter M. Tiidus, Ph.D.

Department of Kinesiology & Physical Education and Faculty of Science,

Wilfrid Laurier University, Waterloo ON Canada, Email: ptiidus@wlu.ca

A wide range of muscle damage scenarios have been used in animal studies of leukocyte infiltration. The most consistent support for a direct relationship between leukocyte infiltration, secondary muscle damage and subsequent repair comes from more extensive animal muscle damage models such as ischemia-reperfusion induced injury. Muscle contraction induced damage using running or electrically stimulated muscle eccentric loading in animals have occasionally produced controversial results. Although most exercise based animal studies also suggest that leukocytes are directly involved in accentuating secondary muscle injury as well as activating repair, some studies report muscle injury in the absence of leukocyte infiltration as well as leukocyte infiltration without evidence of muscle injury. Differences in experimental factors such as the type of exercise employed, the methods used for leukocyte detection, potential muscle fibre type differences as well as gender and hormonal related issues among others, may contribute to these occasionally divergent findings. In addition, the simple detection of leukocyte presence within muscle following exercise will not necessarily confirm that the leukocytes are actually active. The mechanisms by which neutrophils and macrophages can contribute to the necessary removal of post-damage muscle debris, their inadvertent contribution to secondary muscle damage and their critical role in initiating muscle repair mechanisms such as muscle satellite cell activation and proliferation have also been extensively documented using animal models. It is generally accepted that as well as actively participating in the removal of damaged tissue, neutrophils and more importantly, specific macrophage subspecies will directly contribute to the activation and proliferation of muscle satellite cells and the initiation of repair processes. Indeed, the inhibition of post-damage muscle leukocyte infiltration in animal models will completely prevent satellite cell activation and muscle repair. Oestrogen and gender can also play a role in post-exercise muscle inflammation and repair processes. Animal models have consistently demonstrated that oestrogen will attenuate post-exercise leukocyte infiltration and provided insight into the mechanisms associated with this effect. Despite this attenuation of leukocyte infiltration, recent studies have found that oestrogen will nevertheless also enhance post-damage muscle satellite cell activation and proliferation. The potential mechanisms for these effects of oestrogen highlight the complexity of mechanisms regulating post-exercise muscle damage, inflammation and repair. The role and advantages of using animal models in experimentally elucidating these mechanisms is also noted.

HUMAN MODELS OF POST-EXERCISE MUSCLE LEUKOCYTE INFILTRATION: STATUS, CHALLENGES AND LIMITATIONS

PAULSEN, G.

NORWEGIAN SCHOOL OF SPORT SCIENCE

During high-force exercise the force-generating capacity of muscle is gradually reduced, and in some cases the impaired muscle function persists for more than one week. Muscle damage may explain some of this weakness, and because tissue regeneration requires increased presence of inflammatory cells, the inflammatory reaction can be expected to develop after muscle-damaging exercise. However, in opposition to what is reported in experimental animals exposed to electrically evoked lengthening (eccentric) muscle actions, the prevalence of exercised-induced muscle damage in humans is under debate (1; 2; 4). On the basis of changes in muscle function, downhill running and conventional resistance exercise (weight lifting) seem to cause very modest amount of damage compared with single-joint maximal eccentric exercise. The discrepancy among studies investigating muscle damage and inflammation may consequently be explained by the degree of damage inflicted during exercise. Because several relevant human studies did not measure muscle function, the debate about muscle damage and inflammation lacks an important element. Recent results from our laboratory demonstrate that a significant accumulation of leukocytes occurs in "high-responder subjects", defined by large loss of force-generating capacity (>50%) and necrosis in the exercised muscle. Investigating leukocyte infiltration in human muscles after exercise is difficult because of the large individual response differences and methodological challenges with the biopsy procedure. For instance, repeated biopsies alone cause leukocytes accumulation, and obtaining biopsies from non-exercised muscles is required for appropriate experimental control (2). Non-invasive techniques, such as radionuclide imaging, can reveal accumulation of leukocytes in the exercised muscles, but leukocyte trans-migration through the vessel wall cannot be ascertained from these analyses. The presence of neutrophilic granulocytes in human exercised muscle is another unresolved issue (3). Some of the inconsistency between studies might be due to the use of non-specific antibodies for identification of neutrophils. In summary, leukocyte infiltration in human skeletal muscles after exercise seems to take place, but primarily when the degree of exercise-induced muscle damage is large. Tests of muscle function are imperative for assessing the degree of muscle damage. Additionally, obtaining and analysing biopsies involves certain methodological limitations, but it is the only way to directly verify leukocyte infiltration in the exercised muscles of humans.

FACTORS INFLUENCING INDIVIDUAL TRAINING RESPONSE IN FOOTBALL PLAYERS

IMPELLIZZERI, F.M., ATKINSON, G., BIZZINI, M., WESTON, M., STOOP, R., CASTAGNA, C.

SCHULTHESS KLINIK

INTRODUCTION. Several researchers have examined the effect of particular training interventions on various physical capacities in football players. However, the presence of confounding factors can influence the results of the training study, for example obscuring important differences during comparative studies. Confounding occurs when one or more separate factors (that are of no interest to the research) influence the outcome variable that the intervention is designed to moderate. However, if known, potentially confounding variables can be controlled using experimental or statistical techniques. The purpose of this study was to examine the factors influencing the individual training response in football players.

METHODS. 31 players [age 23(4)yrs, body mass 72(7)kg, height 178(5)cm] out of 46 assessed for eligibility completed the Yo Yo Intermittent Recovery (YYIRT) and a VO2max test at the end of the competitive season (end), at the beginning of the following season (pre), and after 7 weeks of training (post). During the training period heart rate and rating of perceived exertion (RPE) were measured. A hierarchical multiple regression model was applied with absolute pre-post change scores as dependent variable. All change scores entered in the models were corrected for the regression towards the mean (RTM) to control for statistical artifacts. The entering order was established based on collection feasibility of the variables: step 1) age; 2) pre-training values; 3) training load (TL) quantified with heart rate (TRIMP) or session-RPE relative to physical, technical training sessions and matches; step 4) changes in YYIRT or VO2max between the end of the previous competitive season and the start of the training.

RESULTS. Age explained 6% of variance in YYIRT changes (P=0.172). The absolute pre-training values explained only 2% (P=0.410) of variance (6% if RTM is not taken into account). TRIMPs explained an additional 22% (P=0.030) and end-pre change scores accounted for a further 14% (P=0.021). The total adjusted R2 of the full model was 0.33. When the session-RPE was entered instead of TRIMPs, the additional explained variance was 44% (P=0.001). The end-pre change scores explained a further 6% (P=0.078). The adjusted R2 of the full model was 0.48. Similar results were found for VO2max (data not presented).

DISCUSSION. The findings of this study indicate that TL accounted for a greater proportion of variance in pre-post changes of YYIRT and VO2max. The TL induced by technical-tactical sessions did not significantly influence the training outcomes (P>0.176). Furthermore, the additional proportion of variance explained by end-pre change scores suggests that the pre-experimental training level (and not the starting absolute value especially if corrected for the RTM) is a factor that may influence the individual training responses. These findings should be taken into consideration when designing and analyzing training studies for football players.

TRAINING LOAD, RECOVERY AND INTERVAL ENDURANCE CAPACITY IN ELITE FEMALE SOCCER PLAYERS

BRINK, M., VISSCHER, C., MOL, J., LEMMINK, K.

UNIVERSITY MEDICAL CENTER GRONINGEN, UNIVERSITY OF GRONINGEN

Introduction: In 2007, Dutch female soccer players kicked-off for the first time in a new national premier league. Goal of this premier league was to stimulate female soccer in the Netherlands and qualify for international tournaments. Therefore, training load increased tremendously. However, little is know about the training-performance relation in elite female soccer. The purpose of this study was to monitor load and recovery in relation to interval endurance capacity.

Methods

At the start of the season in 2007, thirteen elite female soccer players (mean ± SD: age 22.8 ± 4.31 (range 17-30) years, body weight 64.4 ± 10.7 kg and body fat 25.1 ± 3.14 %) performed two Interval Shuttle Run Tests (ISRT) with eight weeks in between (Lemmink, et al. 2004).

During the ISRT, player alternately ran 30 seconds and walked 15 seconds, until exhaustion. The number of completed runs was registered as outcome of performance. Additional, heart rate was recorded at 5-s intervals (Polar, Kempele, Finland).

By means of training logs, training and match duration (minutes), session-RPE and Total Quality Recovery (TQR) scores were collected (Kenttä et al. 1998). Training load was calculated by multiplying training and match duration with session-RPE.

A paired samples t-test was used to test performance changes. Pearson's correlation coefficients were used to relate training load and recovery to performance.

Results: Average maximal heart rate was 193,6 ± 4,46 b•min-1 after the first and 191,9 ± 5,97 b•min-1 after the second ISRT. The female soccer players completed significantly more runs at the second ISRT (82.8 ± 10.8 runs) compared to the first (73.7 ± 8.1) (p<0.001). Average training and match duration was 349 ± 36 minutes per week. Average session-RPE and TQR scores were 13,3 ± 0,92 and 13.8 ± 1,2 respectively, indicating "somewhat hard" intensity and "reasonable to good" recovery. Improvement in endurance capacity was not significantly related to training load and recovery.

Discussion: It can be concluded that interval endurance capacity improved during the first eight weeks of the season, but was not related to training load and recovery. This might be due to a relative long period between both tests (Brink et al. 2009). Since the training response depends on individual characteristics, the heterogeneity (i.e. wide range in age) of the group might as well disturb this relation. Based on these results coaches should more frequently execute field tests and evaluate the individual training response.

MHC COMPOSITION, SATELLITE CELLS AND SOCCER PERFORMANCE IN YOUNG PLAYERS AT DIFFERENT AGES

METAXAS, T., MANDROUKAS, A., SENDELIDES, T., CHRISTOULAS, K., VAMVAKOUDIS, E., KOUTLIANOS, N., EKBLOM, B., MANDROUKAS, K.

ARISTOTLE UNIVERSITY OF THESSALONIKI

Introduction: Various studies have evaluated the physical fitness of soccer players (Bangsbo 1994; Ekblom, 1986) and numerous performance testing have been suggested (Metaxas et al., 2004; Svensson and Drust, 2005). The purpose of this study was to examine the muscle fiber types and satellite cells in young soccer players at different ages and to compare with cardiorespiratory indices and isokinetic muscle strength.

Methods: The participants formed three groups: Group A, 15.2±0.6 yrs old (n=9), group B, 13.1±0.5 yrs old (n=10) and group C, 11.2±0.4 yrs old (n=13). Muscle biopsies were obtained from V.Lateralis and the analysis was performed by immunohistochemistry. Peak torque values was recorded of the quadriceps and hamstrings, at velocities of 60, 180, and 300°žsec-1. Maximal oxygen uptake (VO2max) was measured via a breath-by-breath analyzer system on treadmill.

Results: Group A had decreased type I percentage distribution compared to C by 21.3% (p<.01), while the type IIA relative percentage was higher by 18.4% and 18.1% compared to groups B and C (p<.05). Groups A and B had higher CSA values in all fiber types compared to C (.05<p<.001). Group A exhibited higher cross –sectional area (CSA) in type I fibers by 28.6% compared to B (p<.01). The number of muscle fibers and satellite cells as well as their ratio did not differ between the groups. Groups A and B had higher peak torques values at all velocities compared to C (.05<p<.001). VO2max in terms of mlּmin-1 was higher in groups A and B compared to C (p<.001). Correlation analyses showed a significant coefficient between CSA of type I and the maximal strength of quadriceps at 60ο in group A (r=.669, p=.049) while the percentage distribution of the type I fibers was correlated with the VO2max in group B (r=.661, p=.038). Significant coefficients were established in group C between the distribution of type I fibers and the maximal strength of quadriceps at 60ο (r=.845, p<.001) as well as the distribution of IIA fibers and the maximal strength of hamstrings at 300οžsec-1 (r=.611, p=.026).

Discussion: Τhe increased percentage of muscle fibers ΙΙΑ noticed in 15yrs old compared to the other groups should be mainly attributed to the different training program as well as to the age factor, since these fibers are strongly activated during exercise of increased workload. CSA, muscle strength and VO2max values seems to be expressed according to age. Nevertheless, the sampling and the heredity do play an important role in the formation of the results. It is suggested that the application of specific training in the developmental ages could lead to the differentiation of the muscular metabolic properties in a way that the muscular performance would be maximized.

SIMILAR EFFECTS OF HIGH-INTENSITY INTERVALS AND CONTINUOUS ENDURANCE RUNS DURING THE PREPARATION PERIOD IN HIGH LEVEL FOOTBALL

FAUDE, O., SCHNITTKER, R., MÜLLER, F., SCHULTE-ZURHAUSEN, R., MEYER, T.,2

1. UNIVERSITY OF SAARLAND, 2. UNIVERSITY PADERBORN

Aerobic fitness in elite football players has received considerable scientific attention during the last decade. Mainly, two considerably different endurance training methods are used. These are, on the one hand, classical continuous endurance runs and, on the other hand, high-intensity intervals. Scientific data comparing these methods is lacking. The present study aimed at analysing performance effects of continuous endurance runs vs. high-intensity intervals during the preparation period in high level youth football teams.

5 youth teams from German professional clubs playing in the two highest divisions (2xU19, 1xU18, 2xU17; 16.5±1.1 yrs, 69.8±8.4 kg, 1.77±0.07 m) were randomly assigned to either a high-intensity (2 teams, N=22, HIT) or a continuous endurance training group (3 teams, N=40, CON). Endurance training was conducted on average two times a week over the 5-week preparation period. HIT consisted of 2x12-15 repetitions of 15-30 s high-intensity runs (125-140% of maximal lactate steady state velocity, MLSS, Stegmann et al. 1981, rest: 15-30 s), whereas CON included continuous endurance runs (80-95% MLSS for 30-60 min). Before and after the training period several performance tests were conducted: a multi-stage exercise test (GXT) to determine MLSS, a straight sprint test (5x30 m), an agility test (20 m course involving 6 turns) and vertical jump tests (drop jump, counter movement jump).

Both groups significantly improved MLSS (HIT: +0.7 km/h, effect size (ES)=0.96, CON: +0.6 km/h, ES=0.74, p<0.001 for pre-post intra-group comparisons) as well as maximal velocity during GXT (+0.3 km/h each, p=0.002) with no significant interactions between groups (p>0.26). Whereas straight sprint times did not change, agility was slightly improved (p=0.03, ES=0.26). Vertical jumping height was significantly decreased (p<0.001, ES=0.26 to 0.59) and drop jump contact time was slightly enhanced (p=0.06). No significant group interactions were observed (p>0.25).

The results of the present study suggest that continuous endurance runs and high intensity intervals induce similar improvements in endurance performance. In addition, both training programs have no different effects on speed and power abilities. The improvement in endurance capacity is within the range of values previously reported after a preparation period. As recently shown, high intensity intervals induce similar enzymatic and metabolic adaptations compared to continuous endurance exercise (Burgomaster et al. 2008) and, thus, the underlying changes in physiological processes may be similar for both training Methods: In conclusion, continuous endurance runs as well as high intensity intervals revealed similar effects in high level youth football players and, thus, may be used interchangeably in sports practice.

FASTER PLAYERS SLOWER TO RECOVER AFTER TRAINING AND COMPETITION, WITH POSSIBLE ADVERSE EFFECTS ON FOOTBALL PERFORMANCE

GASTIN, P., FAHRNER, B., MEYER, D., ROBINSON, D., COOK, J.

DEAKIN UNIVERSITY (MELBOURNE, AUSTRALIA), SWINBURNE UT (MELBOURNE, AUSTRALIA), GEELONG FC (GEELONG, AUSTRALIA)

Introduction: Speed and speed endurance are positively related to success in the football codes and are often included in talent identification and selection criteria of players (Reilly and Gilbourne 2003; Pyne, Gardner et al., 2005). These desirable characteristics, however, may predispose the player to greater post training and competition muscle damage (Paddon-Jones, Keech et al. 2005), potentially affecting the time course of recovery and performance in the next game. To explore this hypothesis, performance data routinely collected in a professional Australian Rules football club were analysed to assess the influence of selected player characteristics on recovery and playing performance.

Methods: Data were collected over a full competition season from a squad of 27 professional Australian Rules football players. Player characteristics assessed during the pre-season, including maximal speed over 40 m and time to complete six 40 m sprints (speed endurance), were used as moderating variables in hierarchical linear modelling of the data. The first analysis considered trends over the week in player self-ratings on six physical wellness items (general muscle, quadriceps and hamstring strain, fatigue, pain/stiffness, power). The second analysis explored the relationship between training load and weekly performance from playing statistics.

Results: A total of 2,583 self-rating questionnaires were analysed from completions on 183 days throughout the season. Ratings for all physical wellness items were worse in the days immediately post competition, improving steadily over the week to a game day low. Four of the six physical items (muscle, hamstring and quadriceps strain, power; $p<0.01$) were slower to recover for players with high maximal speed.

In the second analysis, player speed endurance was found to have a significant moderating effect ($p<0.05$) on the relationship between weekly training load and playing performance. Game performance in players who performed well on the six 40 m sprint test was adversely affected when training load increased above the mean.

Discussion: Analysis of self-ratings of wellness indicates that players with high maximal speed take longer to physically recover from weekly competition. Furthermore, players with good speed endurance find that their playing performance is adversely affected following a week when the main training session is heavier in load than usual. The practical implications of these finding are that players with high maximal speed need to be particularly diligent with recovery practices in the days following competition and heavy training sessions and may need to be protected from heavy intense training in the middle of the week.

THE USE OF THE FUNCTIONAL HAMSTRINGS:QUADRICEPS RATIO (HECC:QCON) TO ASSESS FATIGUE AND INJURY RISK IN SOCCER

DELEXTRAT, A., GREGORY, J., COHEN, D.

LONDON METROPOLITAN UNIVERSITY

Introduction: The high occurrence of hamstring strains in football has been associated with an imbalance in the strength of hamstrings and quadriceps muscles (Sangnier, 20073). This imbalance usually increases with fatigue and is classically assessed by the concentric hamstring:quadriceps ratio (Hcon:Qcon). However, the relevance of this ratio has been questioned, and it has been suggested to use the more functional eccentric hamstrings:concentric quadriceps ratio (Hecc:Qcon), (Hole et al., 20001). Only one study has investigated the effects of a soccer match on this ratio, showing a significant decrease in Hecc:Qcon at 120°.s-1 in the dominant leg only (Rahnama et al., 20032).Therefore the aim of the present study was to investigate the effects of fatigue induced by soccer on Hcon:Qcon and Hecc:Qcon in university-level soccer players.

Methods: 8 male soccer players (21.3±2.3 years; 178±8 cm; 78±8 kg) performed first a Yo-Yo intermittent recovery level 2 test to estimate their maximal aerobic capacity and a week later 3 tests within one session: a pre-test to assess the strength of their hamstrings and quadriceps on an isokinetic dynamometer (Cybex Norm, Phoenix Healthcare, Nottingham, UK) on both legs at 60°.s-1 and 180°.s1, followed by a simulated soccer test (Loughborouh Intermittent Soccer Test) and a post-test similar to the pre-test. During the LIST, HR was continuously measured (Polar S810, Kempele, Finland), and blood samples were taken every 15-min to analyse blood lactate concentration ([La-]b, Analox LM5, Analox Instruments Ltd., London, UK). Differences between pre- and post tests were analysed by a student T-test for paired samples. The relationship between the physiological parameters recorded in the LIST and the variation in H:Q ratios (ΔH:Q) between pre- and post-tests was assessed by a Pearson correlation. Statistical significance was set at $p<0.05$.

Results: All H:Q ratios were lower in the pre-test compared to the pre-test, however these differences were significant for Hcon:Qcon in the dominant leg at 180°.s-1only (0.76±0.09 vs.0.50±0.16, $p<0.05$), and for Hecc:Qcon ratios in the dominant leg at 60°.s-1 only (0.79±0.17 vs.0.65±0.08, $p<0.05$). Significant correlations were observed between HR and [La-]b and ΔHecc:Qcon ratios only.

Discussion-Conclusion

These results indicated that the functional ratio is a good way to assess fatigue and injury risk in football players and should be used instead of or in addition to the conventional ratio. Using an angular speed of 60°.s-1 provides better Results: References

EFFECT OF HIGH-INTENSITY TRAINING IN HYPOXIA ON CYCLING PERFORMANCE AND LACTATE METABOLISM.

LECOULTRE, V., TAPPY, L., SCHNEITER, PH., SCHUTZ, Y.

UNIVERSITY OF LAUSANNE

Living and training at low altitude and adding some key training sessions in hypoxia (Live Low Train High (LLTH)) may be considered as an effective way of using altitude as a training stimulus for endurance athletes. It has also been shown to be effective in improving glucose tolerance in untrained individuals. However, its effects on performance are debated. Our hypothesis was that 4 weeks of LLTH would increase more endurance performance and lactate turnover rate of well trained cyclists than the same training regimen performed in normoxia. 14 cyclists participated to this study and replaced part of their weekly training schedule by 3 sessions performed in normobaric hypoxia (HYP) (~3000m) or normoxia (NOR) during 4 weeks. Before and after the training period, endurance performance was assessed during incremental tests performed in normoxia and hypoxia and a 40-km time-trial (TT) performed in normoxia. Lactate and glucose turnover rates were measured by means of stable isotope tracer infusion. After training TT performance was similarly and significantly improved in NOR and HYP. Maximal oxygen uptake was significantly ($p<0.05$) increased in NOR only. In hypoxia, a slight increase of maximal aerobic power and maximal ventilation ($p<0.05$) were measured in HYP. No effect of training was found on lactate turnover rates. In contrast, glucose metabolic clearance rate was decreased ($p<0.05$) and plasma concentration of insulin and glucose were increased after training in HYP ($p<0.05$). 3 athletes involved in HYP exhibited overtraining symptoms. Our results show no further effect of LLTH on sea-level endurance performance than does normoxic training and that LLTH may not improve performance at altitude. Thus questions are raised about the effectiveness of a LLTH protocol for performance enhancements and the athletes health with regard to the altered glucoregulation and overtraining.

EFFECTS OF BLOCK PERIODIZATION OF HIGH-INTENSITY INTERVAL TRAINING SESSIONS ON VO2MAX IN SUBELITE AND ELITE ATHLETES.

VOGT, M., BREIL, F., WEBER, S., WEISSKOPF, R., SCHLEGEL, CH., HOPPELER, H.

UNIVERSITY OF BERN

Introduction:

High-intensity aerobic interval training is very effective in improving VO2max in subjects of various fitness levels (2, 5). In highly-trained athletes, concurrent strength and endurance training programs may compromise the adaptive response to such high-intensity training sessions (1, 3). According to the alternative concept of block periodization (3, 4), we tested the effects of 7-14 days high-intensity interval training blocks in endurance trained subjects, elite cross country skiers, and junior and world class alpine skiers.

Methods & Results:

Study 1: 7 endurance-trained subjects (VO2max: 58.5 +/- 4.9ml/min/kg) performed 18 sessions of 4 x 4-min interval training on a cycle ergometer at 90-95% of HRmax in 14 days. Increase in VO2max (mean: +5.6 +/- 3.2%) was positively correlated to training intensity ($r = 0.81$, $p < 0.05$)

Study 2: During the summer preparation period, 9 elite cross country skiers (68.3 +/- 4.8ml/min/kg) performed three 5-day high-intensity interval training blocks separated by 4-week base training periods. Athletes were advised to execute all sessions at intensities above individual ventilatory threshold 2. VO2max increased by 6.4 +/- 4.2% ($p < 0.001$)

Study 3: 9 male (54.2 +/- 3.1ml/min/kg) and 4 female (50.4 +/- 6.6ml/min/kg) junior alpine skiers performed 12 cycle ergometer and 3 obstacle-run 4 x 4-min interval training sessions at 90-95% of HRmax in 11 days. VO2max and ski-specific field test scores increased in male skiers (+7.4 +/- 2.9%, $p < 0.001$; +8.8 +/- 3.9%, $p = 0.001$) but not in female skiers (+2.2 +/- 1.3%, $p = 0.35$; -7.6 +/- 3.1%, $p = 0.06$).

Study 4: Three world class alpine skiers performed 8 – 10 interval training sessions at 90-95% of HRmax in 14 days, followed by a 14-day low-intensity (<75% HRmax) high-volume (700 km) training period. All athletes improved VO2max (mean: +11.1%) and maximal power output (+7.3%).

Conclusion:

With a mean duration of only 13 days, high-intensity interval block training is very efficient in improving VO2max (on average by 6.5% or 0.5% per session) and performance. It should be considered that this adaptive response might be influenced by differences in training intensity (study 1) as well as gender (study 3). Persistent fatigue after the intensity block may be an issue.

EFFECTS OF GROUP EXERCISE VERSUS AEROBIC INTERVAL TRAINING UPON PEAK OXYGEN UPTAKE IN MYOCARDIAL INFARCTION PATIENTS

MOHOLDT, T., AAMOT, I.L., STØYLEN, A., STØLEN, T., GRANØIEN, I., MYKLEBUST, G., WALDERHAUG, L., GJERDE, L., HOLE, T., BRATTBAKK, L., GRAVEN, T., WISLØFF, U., SLØRDAHL, S.A.

NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY

Introduction: Myocardial infarction (MI) patients from Norwegian hospitals are often offered to participate in group exercise training (GET). The effect of these rehabilitation programs is not well documented. We aimed to compare the traditional GET with treadmill interval training (INT) regarding peak oxygen uptake (VO2peak) in MI patients.

Methods: This study was based on data from three hospitals in Norway. Eighty-nine MI patients referred to hospital based rehabilitation were randomised to GET (n=59) or INT (n=30) in a 2:1 manner. Patients were recruited 2-12 weeks post MI. All patients were asked to meet for organised exercise training two times per week for 12 weeks and to exercise once weekly on their own. VO2peak was measured at baseline, at the end of the training period and again at a follow-up six months later. Patients randomised to GET participated in the usual exercise training program at the hospitals. The intensity of their exercise was supervised using heart rate monitors. In the INT group each training sessions consisted of four times four minutes intervals at 85-95% of HRpeak with lower intensity periods in between. All patients were encouraged to maintain exercise training until follow-up testing.

Results: VO2peak increased significantly more ($p = 0.006$) after INT than after GET (from 31.6 (SD 5.8) to 36.2 (SD 8.6) ml/min/kg (13.8%) in INT, and from 32.3 (SD 6.7) to 34.6 (SD 7.7) ml/min/kg (7.3%) in GET, both $p<0.0001$). Eighty-two patients came back for follow-up testing six months later. Compared to baseline, both groups had significantly higher VO2peak at follow-up, with an increase of 3.1 (SD 3.6) ml/min/kg in INT ($p <0.0001$) and 1.8 (SD 3.3) ml/min/kg in GET ($p = 0.0002$). The difference between the groups was not significant anymore after six month ($p = 0.12$)

Discussion: INT increased VO2peak more than GET during 12 weeks of exercise training in MI patients. Six months later there was no longer a significant difference between the increases in the two groups compared to baseline values. The results of this study may have implications for future organization of cardiac rehabilitation.

COMPARISON OF METABOLIC RESPONSES TO SELF-PACED, HIGH-INTENSITY INTERVALS IN TRAINED VERSUS WELL-TRAINED MALES

HETLELID, K., HEROLD, E., SEILER, S.

UNIVERSITY OF AGDER

Purpose

During steady state exercise, well-trained endurance (WT) athletes oxidize more fat at the same relative intensity compared to recreationally trained people (RT). However, less is known about substrate oxidation during high intensity intermittent exercise. We have compared total energy expenditure (TEE) and fat oxidation during a fixed duration, high-intensity, self-paced interval training prescription in WT and RT subjects.

Methods

Nine elite orienteers (WT, VO2max 71 ± 5 ml.min-1.kg-1) and 9 recreationally trained runners (RT, 55 ± 5 ml.min-1.kg-1) performed preliminary testing followed on a separate day by a 34 min interval-training session consisting of six, 4 min work bouts separated by 2 min recovery periods on a motorized treadmill with a constant 5 % incline. The session was prescribed as a high-intensity workout with the goal being to achieve the highest possible average running speed for the work bouts. Energy expenditure and fat oxidation were calculated from continuous measurements of VO2 consumption and CO2 production. Due to some net CO2 contribution from bicarbonate buffering during intermittent high intensity exercise, fat oxidation rates are presumably underestimated and should be considered minimum estimates.

Results: Blood lactate (6.2 ± 2.1 vs. 6.4 ± 2.5 mmol.L-1) and perceived exertion (RPE, 16.2 ± 1.4 vs. 16.2 ± 1.7) responses throughout the interval session were not different between WT and RT. However, VO2 during the last 3 minutes of each work bout was higher in WT (92 ± 1 vs. 87 ± 2 % VO2max, $p< 0.01$). TEE in the 34 min interval session was higher in WT (641 ± 46 Kcal vs. 552 ± 75 Kcal ($p = 0.009$). Fat oxidation during the interval session was 23.2 ± 4 g in WT vs. 9.4 ± 3 g in RT ($p < 0.001$). Estimated fat oxidation accounted for 35 ± 6 % of TEE in WT vs. 17 ± 7 % in RT. Despite the higher exercise intensity observed and equivalent RPE, Respiratory exchange ratio (RER) exceeded 1.0 only 2.7 ± 2 min of the 34 min session in WT vs. 10 ± 4 min in T ($p<0.001$).

Conclusions

When provided a verbal and written exercise description, WT and RT perform interval training at similar perceived intensity. However, WT oxidize more fat despite higher relative oxygen consumption rates. These results suggest that the superior fat oxidation of well trained athletes seen during low intensity continuous exercise extends to high intensity intermittent exercise, accepting the limitations associated with respiratory gas exchange measurements during intermittent exercise above the lactate threshold.

EARLIER TASK FAILURE FOLLOWING OVERTRAINING IS NOT ASSOCIATED WITH THE EARLIER ACCUMULATION OF MAXIMAL LEVELS OF BLOOD LACTATE

BISHOP, D., DE VRIJER, A., RUSSELL, S.

UNIVERSITÀ DEGLI STUDI DI VERONA

Introduction: While high-intensity interval training (HIT) can improve performance (2), excessive HIT may result in the development of overtraining syndrome (OTS) (4). To date, most research has been directed towards determining indicators of OTS in an effort to predict and therefore prevent overtraining in athletes. However, less research has investigated why overtraining limits performance. Potential mechanisms include an increase in metabolic end products such as lactate (La), earlier attainment of VO2peak and an increased "sensation" of fatigue.

Methods: 18 males performed a graded exercise test to determine VO2peak and the lactate threshold (LT). Time-to-fatigue (TTF) at 20% of the difference between VO2peak and the LT was also assessed. Subjects were then matched and randomly assigned to either a control (CON) or training (TRAIN) group. Those assigned to TRAIN completed HIT 2/day, 7 days/wk for up to 3 wk. A TTF test replaced one of the training sessions every second day. Training continued until TTF decreased to 75% of the Day 1 time. VO2, [BLa] and RPE were determined at 75 & 100% of TTF on Day 1, and at 100% of TTF for all subsequent tests.

Results: TTF was not significantly different between TRAIN and CON at baseline (427 +/- 80 vs 449 +/- 101 s), but was significantly different at the final TTF test (375 +/- 71 vs 562 +/- 105 s; P< 0.05). For TRAIN, [BLa] measured at fatigue during the final TTF test (12.5 +/- 4.2 mmol/L) was not significantly different from the [BLa] measured at 75% of TTF on Day 1 (12.9 +/- 3.3 mmol/L), but was significantly less than the [BLa] measured at 100% of TTF on Day 1 (16.4 +/- 3.9 mmol/L). However, in TRAIN, both endVO2 and RPE during the final TTF test (54.9 +/- 6.9 mL/kg/min and 18 +/- 2 respectively) were significantly greater than the values recorded at 75% (49.8 +/- 4.2 mL/kg/min and 16 +/- 1), but not 100%, of TTF on Day 1 (53.7 +/- 5.8 mL/kg/min and 18 +/- 1).
Discussion: HIT resulted in significant performance decrements as assessed by the TTF test. These results are comparable to those of Fry et al. (3) who showed decreased TTF in 5 well-trained men after a period of intense training performed 2/day for ten days. The earlier task failure was not associated with the earlier accumulation of maximal levels of blood lactate. This is consistent with our previous results showing that fatigue is not related to muscle lactate levels (1). However, the earlier task failure was associated with the earlier attainment of VO2peak and the earlier sensation of fatigue. Future research should therefore examine additional mechanisms that may be associated with the earlier attainment of task failure following overtraining.

THE EFFECTS OF INTERVAL VS. HEAVY CONTINUOUS EXERCISE PROGRAMS ON OXYGEN CONSUMPTION, HEART RATE, AND LACTATE RESPONSES IN ADOLESCENTS

ZAFEIRIDIS, A., SARIVASILIOU, H., DIPLA, K., VRABAS, I.
ARISTOTLE UNIVERSITY OF THESSALONIKI AT SERRES

Short and long high-intensity intermittent exercise (SIE and LIE), as well as continuous exercise (CE) have been consistently used to improve aerobic performance. Studies in adults have reported that SIE elicits greater VO2 responses compared to moderate intensity (50-75% VO2max) CE. However, when CE is performed at heavy intensity (above lactate thresholds for ~25min) a slow component that is developed drives the metabolic rate closer to VO2max. No study has compared VO2 responses among SIE, LIE, and heavy CE. The study of VO2 response during different aerobic regimens is essential since it characterizes the exercise stimulus and thereby aerobic adaptations. The VO2 responses to exercise depend also on VO2 kinetics that is likely to be different during growth from those of adults. Thus, this study compared the physiological responses of SIE, LIE, and heavy CE, matched for exhaustion, in young adolescents. Nine teens (14 yrs.) performed a treadmill test to assess VO2max (55.5±4.6ml/kg/min), vVO2max (15±0.5km/h), and HRmax (200±4bpm). Then, they performed a SIE (30s at 110% vVO2max with 30s recovery at 50% vVO2max), a LIE (3min at 95% vVO2max with 3min recovery at 35% vVO2max) and a heavy CE (at 83% vVO2max). End-point for all protocols was a HR of 5bpm below HRmax. VO2 and HR were continuously measured and blood samples were obtained prior and after protocols to determine lactate (La-mmol/L). The results (mean ±SE) for LIE are presented including only exercise (LIE-EXE) for mean responses, and exercise and recovery times (LIE-PR) for times spent above 85%, 90%, and 95% VO2max. The time (min) of CE (22.4±1.9) and LIE-PR (28.3±2.8) were longer (p<.05) vs. LIE-EXE (15.7±1.4) and SIE (15.5±2.6), while the distance (m) covered in CE (4,586±384) and LIE-PR (4,836±462) was greater (p<.05) vs. LIE-EXE (3,726±338) and SIE (2,918±311). There were no differences among CE, LIE-EXE and SIE in mean VO2 (47.4±1.5, 44.8±1.2, 45.2±1.2), %VO2max (85.7±3.0, 81.3±3.3, 81.7±2.0), VE (92.5±4.0, 92.5±3.5, 92.7±3.3), RER (0.99±0.02, 0.96±0.1, 1.00±0.2) and HRmax (194±2, 195±2, 195±2). Mean HR was lower (in LIE-EXE vs. CE and SIE (179±2 vs. 183±2 and 185±2; p<.05), while La was higher in LIE vs. CE (8.9±1.1 vs. 6.8±1.1; p<.05) but not vs. SIE (7.6±1.1). All subjects reached 85% VO2max in LIE and SIE and 8 in CE; more subjects reached 95% and 100% VO2max in SIE vs. CE. However, the time (min) spent above 85% VO2max was higher (p<.05) in CE and LIE-PR vs. SIE (8.5±2.3, 9.4±1.3 vs. 4.6±1.2), and the time above 90% and 95% was higher (p<.05) only in LIE-PR vs. SIE (6.5±1.5 vs. 2.5±0.8 for 90%, and 3.7±1.3 vs. 0.9±0.4 for 95%) and not vs. CE (4.2±2.0 and 1.4±1.1). In conclusion, when matched for total work and exhaustion heavy CE (at 83% vVO2max) performed above the anaerobic threshold for ~25min elicits mean VO2, HR, lactate responses, and time spent above 90 and 95% VO2max similar to those in SIE, while LIE appears to generate a greater aerobic stimulus compared to SIE.

MUSCULAR EXERCISE CAPACITY IN CHF PATIENTS AND ADAPTATIONS TO ONE-LEGGED KNEE EXTENSION ENDURANCE TRAINING

SLETTALØKKEN, G., REHN, T.A., MUNKVIK, M., RUD, B., NYMARK, B.S., SVARSTAD, S.O., SÖKJER-PETERSEN, M., LUNDE, P.K., SJAASTAD, I., SEJERSTED, O.M., HALLÉN, J.
NORWEGIAN SCHOOL OF SPORT SCIENCES, OSLO; OSLO UNIVERSITY HOSPITAL-ULLEVÅL, OSLO; UNIVERSITY OF OSLO, OSLO; LILLEHAMMER UNIVERSITY COLLEGE, LILLEHAMMER

Congestive heart failure patients (CHF) are characterized by a low work capacity even during exercise with a small muscle mass (~2kg) when oxygen supply is not limited by cardiac output. We wanted to investigate whether CHF patients have a normal response to endurance training as compared to healthy subjects (HS). Work capacity as well as metabolic- and hemodynamic adoptions in the skeletal muscle was evaluated during fatiguing exercise.
Nine CHF patients and eleven HS performed six weeks of supervised one-legged knee extension (1-KE) endurance training (TL) four days a week, leaving the untrained leg as control (CL). After the training period, the subjects performed two-legged knee extension (2-KE) exercise on two submaximal intensities to test work economy, and a 1-KE time to exhaustion (TTE) endurance test (~14 min) with TL and CL

separately. Leg oxygen uptake (VO2) was measured invasively in both legs. Biopsies from vastus lateralis and CT scan of quadriceps femoris (QF) were obtained for both legs after the training period.

In the endurance tests the workload in CL was 23.1 (1.9) (mean ± SE) and 34.3 (1.8) W for CHF patients and HS respectively ($p<0.01$) while TTE was not different (11.5 (2.9) and 13.9 (3.3) min for HS and CHF, respectively). Hence work capacity was lower in CHF patients. To avoid TTE longer than 60 min in TL, workload was set based on pretests and was 7.6 (1.4)% and 16.4 (3.1)% higher in TL than in CL in HS and CHF patients respectively ($p<0.01$). Despite this, TTE was 0.8 (2.9) (ns) and 2.8 (1.0) ($p<0.05$) min longer in TL than CL for HS and CHF patients respectively. This demonstrates a training induced increase in work capacity that was higher in CHF patients than HS ($p<0.05$).

Evaluated from VO2 during 2-KE on submaximal intensities, the two groups showed same work economy which was unaltered by training. At exhaustion, leg blood flow and VO2 in CHF patients was 72 and 70% of that of HS respectively, and both variables were related to the mass of QF ($R=0.57$ and $R=0.77$ respectively; $p<0.01$). Hence leg perfusion and mass specific VO2 was not different between the groups. CHF patients had a higher oxygen extraction in TL compared to CL, but none of the groups showed any leg differences in blood flow or VO2. Number of capillaries around muscle fibers was lower for CHF patients than HS (86% of HS $p<0.05$) with no differences between legs. There was 65 (4)% and 58 (2)% muscle fiber type II in CHF patients and HS, respectively (ns) with no differences between legs. Fiber area and citrate synthase activity was the same between groups and legs.

In conclusion CHF patients have a lower work capacity during one legged exercise which was related to active muscle mass involved. In contrast to HS, CHF patients increased O2-extraction in trained leg, but no other changes in metabolic or hemodynamic variables were detected. However, CHF patients increased their work capacity even more than HS.

MAXIMUM STRENGTH IN CHRONIC CARDIOVASCULAR PATIENTS

SCARPA, S.,3, SARTO, P., MERLO, L., ASTOLFO, P., MAZZOCCATO, D., NOVENTA, D.

UNIVERSITY OF PADUA

Introduction: Patients suffering from heart disease display diminished exercise tolerance, which can be attributed not only to a reduction in aerobic capacity but probably also to a strength deficit. Cardiovascular rehabilitation is a well-established means of improving the functional capacity and resistance training is now recommended as a component of cardiac rehabilitation by the major guidelines. Aim of this study was to evaluate maximum dynamic strength of upper and lower limbs in patients affected by chronic cardiovascular disease.

Methods: The maximum strength of brachial biceps, brachial triceps, deltoids, femoral quadriceps and sural triceps was assessed in 20 healthy sedentary volunteers and 100 male patients with chronic cardiovascular disease: 26 patients who had undergone coronary angioplasty (PTCA), 46 patients suffering from chronic heart failure (CHF), 21 patients suffering from peripheral arterial disease of the legs and claudication (PAD), 7 patients who had undergone heart transplant (HT).

The maximum strength of each group of muscles was assessed by means of submaximal tests. The tests were deemed valid when, for a given load, the subject was able to carry out 10 or fewer repetitions of the movement before fatigue. Once the load and the number of repetitions valid for the test had been established, an indirect formula was used to calculate the value of 1 repetition maximum.

Results: Maximum strength of all the muscles tested was significantly ($p<.001$) lower in patients (mean and standard deviation of maximum strength expressed in kilograms: 149±55 of quadriceps, 130±45 of sural triceps, 6.58±2.1 of deltoids, 11.3±2.3 of brachial biceps, 8.35±1.9 of brachial triceps) compared to the control group (mean and standard deviation of maximum strength expressed in kilograms: 194±52 of quadriceps, 175±45 of sural triceps, 10.7±3 of deltoids, 15.3±2.4 of brachial biceps, 10.8±1.8 of brachial triceps). When patients were subdivided according to the type of disease, a clear trend among groups was displayed with maximum strength being higher in controls, followed by the PTCA group, then the CHF group, the PAD group and the HT.

Discussion: This study shows that chronic patients have a great strength impairment which parallels the history of disease. In our opinion this peripheral de-conditioning requires a different approach in the rehabilitation setting with lower loads for a more prolonged period of time. This lower intensity phase should yield a initial aerobic and strength reconditioning which is recommended before switching to higher intensity training. This information should be kept in mind when planning a rehabilitation program.

INCREASED ACCUMULATION OF INORGANIC PHOSPHATE IN PATIENTS WITH DIFFUSE ATHEROSCLEROSIS DURING INCREMENTAL CALF EXERCISE - A 31P MRS STUDY

SCHOCKE, M., ESTERHAMMER, R., OSTERMANN, S., PESTA, D., JASCHKE, W., FRAEDRICH, G., GREINER, A.

INNSBRUCK MEDICAL UNIVERSITY

PURPOSE: Patients with diffuse peripheral arterial disease (PAD) often suffer from atypical symptom including leg pain during exercise without any high-grade stenosis. The impact of PAD of muscle function is still unclear. The purpose of this study was to investigate the high-energy phosphate metabolism during submaximal incremental calf exercise in PAD patients without high-grade stenosis at the limb arteries.

METHOD AND MATERIALS: 35 patients with diffuse uni- or bilateral PAD and 24 normal controls were included into this study. For phosphorus 31 magnetic resonance spectrscopy (31P MRS), we used a FID sequence (TR=1000 ms; TE=0.13 ms; 10 averages) during exercise increments at 2, 3, 4 and 5 W. MR angiography was performed in the patients by using FLASH 3D sequences at three levels during a gadobenate bolus of 16 mL and moving bed technique. The muscle weight was determined in each patient and each volunteer with the help of T1-weighted, transversal slices. The time constants of phosphocreatine (PCr) were calculated for each increment as well as for recovery. The end-incremental PCr and inorganic phosphate (Pi) were correlated to the power output corrected for muscle size.

RESULTS: Patients with diffuse PAD showed significantly ($p<0.01$) increased PCr time constants during the incements at 4 and 5 W, but not at 2 and 3 W as well as during recovery. Both patients and volunteers showed a linear relationship between end-incremental PCr level and power output, whereby the slopes were significantly steeper in the patients (-6.28 vs. -4.97, $p<0.001$). The end-incremental Pi levels showed an exponential increase with workload in both groups. The patients showed a significantly higher exponent compared to the volunteers (0.2 vs. 0.15, $p<0.001$).

CONCLUSION: As indicated by the increased PCr time constants, muscle metabolism is impaired in patients with diffuse PAD at relatively high work intensities, whereby the normal PCr recovery time constants suggest a normal mitochondrial function. This finding might reflect remodelling processes within the calf muscle, which also corresponds to the patients' higher exponents in the observed exponential relationship between end-incremental Pi level and power output. Pi accumulation is supposed to play a key role in muscle fatique and limits muscle strength. This might explain the atypical symptoms in patients with diffuse atherosclerosis.

EFFECT OF OBESITY AND HEALTH-RELATED FITNESS MEASURES ON CIRCULATORY HEMODYNAMICS IN HEALTHY SEDENTARY COLLAGE STUDENTS

ALOMARI, M., KEEWAN, E., QHATAN, R., IBRAHEEM, R., ALAWNEH, K.

JORDAN UNIVERSITY OF SCIENCE AND TECHNOLOGY

INTRODUCTION: Vascular function (VF) and pulse pressure (PP) are clinically relevant as they are predictors for increased risk of cardiovascular diseases in young healthy individuals. However the relationships of obesity and health-related fitness measures with PP and VF are not clear. Therefore, this study examined the relationships of obesity and health-related fitness measures with circulatory hemodynamics in 19 apparently healthy sedentary collage students with age range 18-23 years.

METHODOLOGY: Obesity measures including body weight (BW), percent body fat (%BF), muscle mass (Mmass), waist/hip (W/H) ratio, and body mass index (BMI) were obtained. Additionally, health-related fitness including maximum walking distance achieved in 6 minutes (6MWD), maximum handgrip strength (MHG) and short-form international physical activity questionnaire (IPAQ) were assessed. For circulatory hemodynamics, strain-gauge plethysmography was used to measure blood flow at rest (RBF) and after 5-minute of occlusion (OcBf) while PP was calculated as systolic – diastolic blood pressure. Vascular resistance at rest (Rvr) and after occlusion (OcVr) were calculated with mean arterial blood pressure/blood flow whereas reactive hyperemia (RHBF) was calculated as OcBF-RBF. Subsequently, Person correlation was used to examine the relationships between obesity and health-related measures verses circulatory indices.

RESULTS: Measures of obesity including BW correlated with RHBF (r=0.4; p=0.05), OcVr (-r=0.4; p=0.07), and PP (r=0.7; p=0.002), while Mmass correlated with RHBF (r=0.4; p=0.04), OcVr (r=-0.5; p=0.03), and PP (r=0.6; p=0.01). Moreover, W/H ratio (r=0.5; p=0.05), and BMI (r=0.4; p=0.06) correlated with PP. As to health-related fitness, 6MWD correlated with RBF (r=0.5; p=0.03) and Rvr (r=-0.5; p=0.03) while MHG (r=0.7; p=0.002) and walking item of the IPAQ (r=0.6; p=0.01) correlated with PP. Interestingly, PP also correlated with OcBF (r=0.5; p=0.03), RHBF (r=0.5; p=0.04) and OcVr (r=-0.5; p=0.03).

CONCLUSION: The associations of obesity and health-related fitness measures with circulatory indices show that VF and PP are affected by BW, fat distribution, Mmass and level of fitness. These relationships are clinically significant as they pertain to circulatory hemodynamics.

MHC COMPOSITION OF SINGLE MUSCLE FIBRES, SATELLITE CELLS AND MYONUCLEI IN WRESTLERS

MANDROUKAS, A., METAXAS, T., CHRISTOULAS, K., VAMVAKOUDIS, E., STEFANIDIS, P., PAPAVASILIOU, A., KOTOGLOU, K., BALASAS, D., HELLER, J., EKBLOM, B., MANDROUKAS, K.

ARISTOTLE UNIVERSITY OF THESSALONIKI

Introduction: Few studies have examined the effects of long-term wrestling training on muscle morphology and function (Adams et al., 1993; Tesch and Karlsson, 1985). All the above mentioned studies were conducted more than 20 years ago and they used mATPase staining methodology and not the modern sensitive immunohistochemical analytic method in order to study changes in the patterns of Myosin Heavy Chain (MHC) isoform expression. The aim of this study was to investigate the long-term effects of high intensity resistance wrestling training on MHC isoforms composition, on satellite cells and myonuclei behavior, on embryonic and neonatal MHCs and to compare with untrained subjects.

Methods

Nine Greco-Roman competitive wrestlers (mean age 20.1±2.7yrs, height 175.0±0.6cm, weight 83.2±12.5kg, yrs of training 7.6±2.7yrs) and six healthy physical education students (mean age 21.2±0.9yrs, height 180.0±0.3cm, weight 80.1±9.4kg) participated in this study. Muscle biopsies were obtained from deltoid muscle in order to investigate muscle fibre distribution, cross sectional area (CSA), single fibres, satellite cells and myonuclei by immunohistochemistry. MHC isoform composition of single fibres was determined with protein electrophoresis.

Results: Immunohistochemical analysis showed that muscle fibre distribution of the MHC I and IIA were significantly higher in wrestlers than in students ($p<.05$). The proportion of MHC IIX was higher by 7% in students compared to wrestlers. Electrophoretic analysis of single muscle fibres revealed a significantly higher proportion of fibres containing MHC I and hybrid fibres containing MHC IIC in wrestlers compared to students ($p<.05$). However, students displayed a significant higher proportion of MHC IIX compared to wrestlers ($p<.001$). The mean CSA of type IIA fibres and the number of myonuclei per type II fibres was significantly higher in wrestlers compared to students ($p<.05$). In wrestlers, myotubes were observed as well as internal nuclei, intermediate and small sized skeletal muscle fibres expressing embryonic and neonatal MHC and none in students.

Discussion: The present study revealed that the deltoid muscle of wrestlers contains a larger proportion of fibres with MHC I, IIA and single muscle fibres MHC I and IIC isoforms and very few fibres containing MHC IIX isoforms. Long-term wrestling training may cause hypertrophy especially in MHC IIA, and a transformation of MHC IIX into IIA and IIC of the deltoid muscle. The hypertrophy of MHC IIA seems to be associated with an increase in the number of the myonuclei attached to them and an increase in the number of satellite cells. It is suggested that the observed muscle fibre profile in the deltoid muscle of wrestlers may represent an adaptation based on the mechanical and biochemical demands of the long-term training.

EFFECTS OF ENDURANCE AND RESISTANCE TRAINING ON CALCITONIN GENE-RELATED PEPTIDE (CGRP) CONTENT IN SLOW AND FAST RAT'S MUSCLES

PARNOW, A., GHARAKHANLOU, R., HEDAYATI, M., MAHDIAN, R., RAJABI, S.

UNIVERSITY

Calcitonin Gene-Related Peptide (CGRP), a 37-amino acid peptide generated by alternative processing of primary transcripts from calcitonin gene, is broadly distributed in the peripheral and central nervous systems of vertebrate and invertebrate species. CGRP plays a main role in Neuromuscular Junction (NMJ). This paper investigates the effects of Endurance and Resistance training on the content of CGRP in Slow and Fast Muscles. A number of twenty-two male Wistar rats (10 mo of age, 220± 20 gr, Iran Pasteur Institute) randomly were divided to three groups (Control (n=7), Endurance training (n=7), and Resistance training (n=8)) and followed 12 weeks training according protocols. Animals of the resistance training group were housed in metal cage with a wire-mesh tower; Endurance training (5 days a week, 60 min/day, 30 m/min speed) was performed by animals in endurance group. Forty-eight hours after last session of protocols, animals were anaesthetized with a mixture of KetamineTM and Xylazine. The right soleus (slow muscle) and anterior tibialis (fast muscle) were removed under sterile condition via an incision on dorsolatral aspect of the hindlimb. After removal, tissues were frizzed quickly in liquid nitrogen and kept at -70 ° C for later using. For CGRP assay, ELISA kit was used. For data analyses, One-way ANOVA was used. Data analysis showed that there was not a significant different between control and endurance training groups in slow and fast muscle's CGRP. But, the content of CGRP in both fast and slow muscles was significantly different in resistance training group compared with control group. It is expressed that training can be a main factor for CGRP releasing in muscles. In addition, the type and intensity of activity probably are contributed to CGRP content increase. Therefore, as recognized role of CGRP in NMJ and former researches reported that CGRP contant increse in motoneurons followed by exercise, the present research findings that has investeagated effect of different training on CGRP content in muscles is attractive.

THE EXTERNAL FORCES ACTING IN THE DIRECTION OF TRAVEL AND THEIR RELATION TO MECHANICAL ENERGY DISSIPATION IN SLALOM.

GILGIEN, M., REID, R., HAUGEN, P., SMITH, G.

NORWEGIAN SCHOOL FOR SPORT SCIENCES

Introduction:

The literature quantifying the external forces acting on an alpine skier is limited in general, but particularly in the slalom discipline. This study therefore describes the size and time course of the external forces acting on a skier parallel to the direction of travel based on the kinematics of a group of highly skilled slalom racers. Subsequently, the braking forces of ski-snow friction and wind drag are related to mechanical energy dissipation.

Method:

The derivation of the external forces was based on the kinematics of 6 members of the Norwegian Europa Cup team (aged 17-20). Skier kinematics were captured during 2 turns of a slalom race simulation by 4 panning and synchronized camcorders [1]. The centre of mass (COM) position calculation was based on the Zatsiorsky body segment parameter model and the de Leva adjustments. The component of gravity accelerating the skier downhill and the resultant force were both calculated from the COM position data. To calculate the air drag force, frontal area was estimated using a kinematics-based procedure, drag coefficients were adapted from a study of cross country skiers [2], and COM velocity was calculated using finite central differences. The remaining frictional force in the ski snow interaction was calculated as the difference between the resultant force, the air drag force and the component of gravity accelerating the skier downhill.

Skier mechanical energy dissipation, defined as the amount of total mechanical energy dissipated to the surroundings per meter altitude skied [3], was derived from the COM position data. The braking forces were then correlated to mechanical energy dissipation.

Results:

The air drag force acting in slalom is rather small and constant (25 - 50N), while the frictional force between ski and snow alters rapidly during a turn cycle with peak values as high as 500N occurring at about gate passage.

Energy dissipation showed a strong inverse statistical correlation with the frictional force in the ski-snow interaction ($R2 = -0.96$, $p < 0.001$), while the relation between energy dissipation and the air drag force was not significant.

PHYSIOLOGICAL RESPONSE OF ELDERLY ALPINE SKIERS DEPENDS ON INDIVIDUAL MOVEMENT PATTERN.

SCHEIBER, P., SEIFERT, J., MÜLLER, E.

UNIVERSITY OF SALZBURG, DEPARTMENT OF SPORT SCIENCE & KINESIOLOGY

Introduction: It has been demonstrated that there are skiers who have a low physiological response when skiing, while other skiers have greater physiological responses at similar skiing velocities (Scheiber et al. 2009). Interestingly, the aerobic capacity of these skiers seemed to have little effect on the physiological responses of these technically homogenous skiers while skiing. It has also been reported that blood lactate is a valid predictor for cumulative physiological stress in alpine skiing (Seifert et al. 2008). It can be speculated that the inter-individual variation in kinematical variables of subjects skiing technique may also influence physiological response. Thus, the purpose of this study was to quantify the influence of kinematic variables on the physiological response in recreational alpine skiing.

Method: Nineteen older alpine skiers (61.1±5.7 years) performed two different ski-instructor paced (LP and HP) and one self paced (SP) skiing mode on a medium pitch, well prepared slope. Blood lactate (LA), HR, blood pressure (BP), and knee angle were determined. Mean knee angle (MKA), as well as the range of knee angle (RKA) of twenty double turns were calculated for each run. Pearson correlations were obtained between kinematical and physiological variables. Independent t-tests were performed to calculate mean group differences in kinematic and physiological variables of low (LO) vs. high lactate (HI) skiers.

Results: The most interesting physiological findings were found for LA. Mean LA of the whole group was 1.40±0.34 mmol.L-1 for LP runs, 1.94±0.59 mmol.L-1 for HP runs, and 2.34±0.87 mmol.L-1 for SP runs. MKA of LP runs was 123.8±6.1°, for HP runs 117.5±6.0° and for SP runs 117.1±6.0°. The RKA of LP runs was 19.0±3.9°, for HP runs 20.3±3.7° and for SP runs 17.7±3.6°. A significant correlation was found only for RKA and LA during SP runs, ($r^2=.465$; $p<.005$). Additionally, RKA of LO was significantly ($eta^2=.399$; $p<.012$) lower (15.3±2.5°) than those of HI skiers (19.8±3.3°). No correlations were found between physiological and kinematic variables for the ski-instructor paced skiing modes.

Discussion: These findings demonstrate that skiing with a lower vertical movement of the skiers' centre of gravity results in a lower lactate accumulation, than skiing with a greater movement. From a physiological standpoint, there might be an optimum of active bending/stretching in combination with the use of external forces, to minimize vasoconstriction of blood vessels as a result of static muscle work and to avoid unnecessary body movement.

THE RELATIONSHIP BETWEEN THE TIMING OF TAKE-OFF ACTION AND FLIGHT LENGTH BY USING TWO DIFFERENT TYPES OF JUMP-DOLLS

SASAKI, T., TSUNODA, K., HOSHINO, H., MIYAKE, S.
HOKUSEI GAKUEN UNIVERSITY

Introduction: The purpose of this study is to detect the optimal timing of jump action in ski jumping. Assuming a jumper could always produce same motions, the timing of jump action would be the most important variable for the flight distance. In this study, the jump of the two different jump-dolls were observed on the hill model (1/100). Dolls always produce same power during jump action. Thus, the flight distance solely depends on the timing of initiating the action. Therefore, it is possible to clarify the relationship between the timing and the flight distance.
Methodology: Two different types of jump-dolls were developed. First doll was used two springs for producing softer power. Four springs were set in respective joints (knees and hips) of the second types of the doll. The jump doll can reproduce the same hopping action on the take-off platform. The critical point (K) in the model of jumping hill is 160 cm. The dolls are able to jump on this model hill. The position of start on in-run is 150 cm away from the edge of platform. The peg, which releases the strength of the jump doll, was put on six places every 4 cm away from the edge of platform. Five times trials in two jump dolls were executed for every peg point. All the jump actions were recorded by the NAC video camera with 500 fps.
Results: The elapsed time for jump actions from squat position to full extension and speed of take-off were almost the same in both types. Using the same release point, the maximum flight distance was occurred in each doll. The release point is 4 cm before the edge of platform. The flight distance is 125 cm in type 1, and 166 cm in type 2. On the other hand, the minimum flight distance was observed in initiating jump action at the 12 cm before the edge. The flight distance is 88 cm in type 1, and 128 cm in type 2.
Discussion: Smooth action on each joint is achieved by a bearing devices, although the doll is made by wood, The doll-model produces the same strength at take-off actions, because, it is possible to take the same squat position anytime. Therefore, the jump -doll can be used in the experiment of ski-jump. In this study, the difference in the flight distance is only attributed by the difference of the timing of the jump action. As an evidence of the transition of the power, the oscillation of skis was exactly observed during the initial flight phase. This phenomenon already pointed out even in the human action (Sasaki et al., 2005). In the flight distance, the most effective timing for beginning the action is clarified in this experiment by the jump-doll.
Conclusion: Until the 4 cm from the edge of platform, the later the timing of beginning the action is, the larger the flight distance is. The jump-doll always transmits almost same power.

OPTIMIZATION OF AERODYNAMIC STABILITY IN SKI JUMPING: THE TUG-OF-WAR BETWEEN SAFETY AND PERFORMANCE

MARQUES-BRUNA, P., GRIMSHAW, P.
EDGE HILL UNIVERSITY

Introduction: Past research in ski jumping has aimed to increase jump length and modify ski length and hill design to make the sport safer (Schwameder, 2008). However, the assessment of aerodynamic stability (Anderson, 2007) for improved safety has received less attention (Seo et al., 2004). Thus, this study aimed to model aerodynamic efficiency and stability in pitch in ski jumping as a function of athlete's posture. The findings may be used to optimise flight posture and warrant safer training and competition.
Methods: Mathematical modelling was carried out using a hypothetical ski jumper with a typical mass of 70 kg, height of 1.76 m and ski length of 2.57 m (Seo et al., 2004). Lift (FL), drag (FD), lift/drag ratio (FL/FD), dPitching-moment/dAngle-of-attack slope (dM/dAA) at the trim AA and oscillatory frequency (FREQ) (Anderson, 2007) were calculated as a function of AA, ski opening angle (SOA; at 20°, 25° and 30°) and forward-leaning angle (FLA; at 0°, 10°, 20°, 30° and 40°) (Seo et al., 2004). Air density was set at 1.18 kg/m3, and air speed at 25 m/s to simulate competition at a large jumping hill (Schwameder, 2008).
Results: FL was largest with SOA = 30° & FLA = 0°-10°. FD increased monotonically from AA = 10°. FL/FD peaked at AA = 2°-12°, at which FL was rather low. dM/dAA became steeper with increased SOA and FLA, ranging from – 0.82 Nm/° for SOA = 20° & FLA = 0° to – 2.67 Nm/° for SOA = 30° & FLA = 40°. FREQ increased as a function of SOA and FLA, showing about half a cycle per second (0.51 Hz) for SOA = 30° & FLA = 10°.
Discussion/Conclusion
An optimised flight posture of SOA = 30° & FLA = 10° is suggested. This is a high-lift configuration that yields steep dM/dAA and high oscillatory frequency upon sudden deviations from trimmed flight. The high frequency may initiate transitory dynamic oscillations (Anderson, 2007). The findings add to the current priority to warrant safety in the sport (Schwameder, 2008).

PHYSIOLOGIC RESPONSES OF LOW AND HIGH STRESS RESPONDING RECREATIONAL ALPINE SKIERS TO DIFFERENT SKIING PACES

SEIFERT, J., SCHEIBER, P., MÜLLER, E.
MONTANA STATE UNIVERSITY, BOZEMAN, MONTANA; UNIVERSITY OF SALZBURG, SALZBURG, AUSTRIA

Introduction: Previous studies have demonstrated that there are skiers who demonstrate a low physiological response (LO; low lactate and HR), while others have a high physiological response (HI; high lactate and HR) when skiing at similar velocities. However, it is unknown how LO and HI respond to different skiing paces when compared to their individual self-paced skiing. It is important to understand

if, and how, the skiing intensity can be regulated, to minimize physiological stress. Thus, the purpose of this study was to quantify differences in physiologic variables of LO and HI responding skiers while skiing at three different paces.

Methods

Twenty, recreational alpine skiers (mean age: 61.1+5.6 y) performed two different paced and one self-paced (SP) skiing trials. Skiers were separated into LO and HI groups according to blood lactate (LA) at the end of their SP runs. The on snow tests contained five skiing segments per day. For each segment, subjects performed three different, randomized skiing trials; parallel ski steering turns (LP), long radii carving turns (HP), and SP. LP and HP runs were paced for time and intensity by a certified ski instructor. LA, HR, BP, and RPE (overall and legs) were collected at the end of each run. Physical fitness was assessed by a physical work capacity test. Testing took place on a groomed slope at Abtenau, Austria at an altitude between 746 and 1,138 m. An ANOVA with repeated measures and Bonferroni adjustment were used to analyze data. Significance was noted with $p<.05$.

Results: LA accumulation was significantly lower for LO than HI during LP (1.21+0.31 vs 1.70+0.55 mM/L), HP (1.35+0.33 vs 2.00+0.66 mM/L), and SP (1.43+0.26 vs 2.56+0.62 mM/L). LA levels did not differ between trials for the LO skiers, but were different for all skiing paces for HI. HR was lower for LO than HI during SP runs (113+11 bpm vs. 128+16 bpm; $p<0.03$), but no differences were observed during LP and HP runs. MAP, RPE legs, RPE overall, and fitness level did not differ between groups. The HI group responded with significantly lower stress, when skiing under paced conditions, compared to their SP run. This change was not observed in the LO skiers. No significant differences between LO and HI were observed for fitness level, run times, BP, MAP, RPE legs, or RPE overall.

Conclusions

HI skiers responded with a disproportionately greater level of stress than LO when changing trials during skiing. LA, for example, increased significantly by 17.6% when comparing LP to HP and 23.1% for HP and SP runs for the HI group. LA levels were not different between paces for LO. Paced skiing may aid in minimizing the changes in fatigue indices and potentially enhance the recovery in the HI skiers. Results demonstrate that RPE is not sensitive enough for inter-individual comparison. Interestingly, physical fitness seemed to have little to no effect on the physiological responses of this technically homogeneous group of recreational skiers.

ENERGETIC AND RESPECTIVE PART OF LACTIC AND AEROBIC SOURCES OVER A GIANT SLALOM IN YOUNG SKI RACERS.

HINTZY, F., GRENIER, J., COULMY, N.

1. LABORATOIRE DE PHYSIOLOGIE DE L'EXERCICE, 2. CELLULE DE RECHERCHE DE LA FÉDÉRATION FRANÇAISE DE SKI

The energy cost of a giant slalom event was previously measured by Saibene et al. (1985) and Veicteinas et al. (1985) during exercise and during recovery from a complete lap, tacking into account the blood lactate and the oxygen consumption. The actual main criticism is the disrespect of the real skiing conditions (Douglass bag method, VO2 not continuously measured, sport equipment..). The purpose of this study was then to quantify the total net energetic output and the part of both aerobic and lactic sources in alpine skiing over a giant slalom in young ski racers; then to estimate the influence of the biological maturation on these parameters. Seven minor ski racers aged in average (±SD) 14,0 ± 0,5 years were investigated and divided in two groups according to the gender or the biologic stages of maturation. They performed both a giant slalom in a field study and a incremental test (to determine the maximal aerobic capability). The oxygen consumption was measured breath to breath with an automatic gas analyzer system (Cosmed K4b², Rome, Italy) during the whole giant slalom and the blood lactate concentration was calculated before and 2 min after the slalom in order to respectively determine both aerobic and lactic energy sources. Average (±SD) V02, lactate and total net energetic output were respectively 44.8% VO2peak, 5.7 mmol.l-1 and 33,3 ± 6,6 kJ.min-1 with important inter-individual variations. The relative part of lactic and aerobic sources averaged 28.4% and 71.6%, respectively. The more advanced biologic maturation of some subjects tends to increase the participation of the lactic source. Present results showed low energy expenditure during a giant slalom in young racers, which increases with the subject's biologic maturation.

THE ROLE OF GROWTH HORMONE IN MODULATING THE PATHWAY OF APOPTOSIS IN EXPERIMENTAL MODELS OF SKELETAL AND CARDIAC MUSCLE CELLS

DIMAURO, I., FANTINI, C., PITTALUGA, M., PARISI, P., CAPOROSSI, D.

UNIVERSITY OF ROME

Growth hormone (GH) is a peptide hormone capable to exert anabolic and lipolytic effects in muscle tissue (1-2). Moreover, recent studies report on beneficial effects of GH in protecting skeletal and cardiac tissues from damage caused by cell death (3). Based on these premises, we investigated whether supra-physiological concentration of exogenous rhGH could modulate cellular response to apoptosis-induced with free radicals (H2O2) on in vitro models of skeletal (C2C12, L6C5) and cardiac (HL-1) muscle cells.

To this aim we treated the cells, grown in presence or absence of GH (200ng/ml-1µg/ml), with H2O2 (100-500µM), thus analysing the features of cell death induced by ROS. We analysed cell growth and cell survival (MTS assay) and the morphological and molecular markers of cell death (nuclear fragmentation by Hoechst 33342 and TUNEL assays); chromatin fragmentation by DNA laddering; expression of the pro- and anti-apoptotic proteins (PARP, caspase-8, caspase-9, Bcl-xL and Bcl-2).

Through semi-quantitative RT-PCR, we verified that the GH receptor (GHR) is expressed in our cellular models, and that its mRNA level is strongly up-regulated by GH complementation. In skeletal myoblasts and cardiomyocites GH neither modulates cell growth nor cell survival under oxidative stress condition. After treatments with cytotoxic concentrations of H2O2 (100-500µM), the induction of apoptosis was clearly detectable in all cell lines, either as nuclear fragmentation and/or DNA laddering, but the frequencies of apoptotic nuclei or

the intensity of DNA fragmentation resulted not statistically different ($p > 0.05$) with respect GH complementation (C2C12: Ctrl 39% vs GH 51%; L6C5: Ctrl 49% vs GH 38%; HL-1: Ctrl 28.5% vs GH 20%). Indeed, the presence of GH in the culture medium did not affect the expression of the anti-apoptotic proteins Bcl-xL and Bcl-2, neither in basal conditions, nor after treatments with H2O2 radicals. As for the expression of the molecular markers of apoptosis, we found that oxidative stress determined in skeletal and cardiac muscle cells the activation of the intrinsic pathway of apoptosis, since the cleavage of the effector PARP protein was paralleled by the activation of pro-caspase 9, without involvement of caspase-8. Regarding the effect of Growth Hormone, the results from molecular analysis fully overlapped the morphological results, since the expression of caspase-8, caspase-9 and PARP resulted comparable between standard or GH-enriched conditions of culture.

In conclusion, our study indicated that, although sensible to the presence of GH in the culture medium, skeletal and cardiac muscle cell lines did not show modulation by growth hormone itself of the molecular pathways involved in the susceptibility to cell death induced by oxidative stress.

METABOLIC AND PRO-APOPTOTIC FEATURES OF SKELETAL MUSCLE CELLS EXPOSED "IN VITRO" TO HIGH SALMETEROL CONCENTRATION

DURANTI, G., LA ROSA, P., DIMAURO, I., PARISI, P., SABATINI, S., CAPOROSSI, D.

UNIVERSITY OF ROME

Salmeterol is a long-acting β-2 adrenergic receptor agonist, producing smooth airway muscle relaxation and bronchodilation (1), prescribed for asthma treatment. β-2 agonists induce muscle hypertrophy, thus there is big concern about the possible abuse of the this drug by the athletes. Actually, WADA included Salmeterol in the proibited list, as anabolic substance, allowing its utilization only under specific medical exemption. Since the mechanism for the anabolic activity of Salmeterol is still unknown (2), and could underline some adverse effects reported recently, we investigated the link between the metabolic and citotoxic effects of Salmeterol on L6C5 and C2C12 muscle cells, identifying the genes possibly modulated by this drug. Proliferating and differentiated cells, exposed to different Salmeterol concentrations (0,1 -10μM) for 6 - 72 hours, were analysed for cell growth and survival (Mitotic Index, MI; MTS and Trypan blue exclusion essays), apoptosis pathway (nuclear fragmentation, TUNEL, PARP, Bcl-xL, caspases 8 and 9) and metabolic enzymatic activities [Glyceraldehydephosphate dehydrogenase (GAPDH), lactate dehydrogenase (LDH), citrate synthase (CS) and 3-OH acylCoA dehydrogenase (HAD)]. Through the MTS assay, we identified that Salmeterol induces anabolic effect in proliferating myoblasts ($p<0.01$), clearly already detectable after 6 hrs exposure to concentration of 2,5μM. This increase is paralleled by an inhibition of cell grow rate as evidenced by analysis of MI performed through Hoechst staining. The anabolic effect of Salmeterol was maintained constant up to 48hrs exposure, when a strong dose-dependent decrease in MTS absorbance determined by cell death (Trypan exclusion test) resulted apparent ($p<0.01$). The anabolic effect of Salmeterol was verified by glucose and fatty acid metabolism. Results indicate an increase of GAPDH, CS, HAD, and a decrease of LDH activities. Interestingly, differently from the physiological situation occurring during myoblasts differentiation, the double anabolic/cytostatic effect of Salmeterol was neither related to increase in cell resistance, since the expression of the anti-apoptotic Bcl-xL protein resulted unaffected, nor to differentiation, as demonstrated by lack of myogenin expression (western bloth analysis). Finally, the exposure of myoblasts to high concentration of Salmeterol (10μM) for 48 and 72hrs resulted toxic in both cell lines: the frequency of apoptotic nuclei (nuclear fragmentation and TUNEL), statistically higher with respect to control ($p< 0,01$) and the analysis of apoptotic markers (cleaved PARP and caspase 9 cleaved fragment) confirmed the putative Salmeterol activation of the intrinsic apoptotic pathway. In conclusion, in our cellular models for skeletal myoblasts, low Salmeterol exposure increases oxidative metabolic pathways and inhibits cell growth, while high Salmeterol exposure clearly exerts pro-apoptotic effects.

THE ROLE OF NRF-1 IN REGULATING GLUT4 EXPRESSION.

MUKWEVHO, E., OJUKA, E.

UNIVERSITY OF CAPE TOWN

Introduction: Nuclear respiratory factor (NRF)-1 is a transcriptional factor that regulates mitochondrial biogenesis. Overexpression of NRF-1 in transgenic mice has been reported to have a dramatic increase in GLUT4 and myocyte enhancing factor (MEF)-2 (1). The increase in GLUT4 was surprising since NRF-1 has no binding sites in the Glut4 gene; hence the question is how does NRF-1 regulate GLUT4? The mechanism by which NRF-1 regulates Glut4 gene expression has not been studied. Because the Glut4 gene does not have the cis-element for NRF-1, it has been hypothesize that the increase in its expression when NRF-1 is over expressed (1), is a secondary to the effect of NRF-1 on the Mef2a gene, which has NRF-1 binding sites (2): NRF-1 induces increased MEF2A which, in turn, binds to its cis-element on the Glut4 gene to upregulate its expression. The aim of this study was investigate the molecular mechanism leading to GLUT4 upregulation.

Methodology: C2C12 cells were used to develop a tetracycline based gene expression system (Tet-On). The Tet-On system involves two plasmids, namely, the regulatory and response vectors and were transfected after G418 and hygromycin selection respectively to form a double stable cell line and the system activated by Doxycycline (1mg/ml). Small interference RNA for MEF2A was transfected to the double stable cell line at 6pmol. Western blotting was used to assess the level of expression. Binding was assessed by chromatin immuno precipitation (ChIP) assay.

Results: Results showed that NRF-1 overexpression showed a 4 fold increase in Mef2a binding, MEF2A to Glut4 binding increased 3.5 fold and NRF-1 to Alas gene binding increased 4.5 fold. Protein expressions for MEF2A and GLUT4 were increased 2.3 and 2.6 respectively.

Discussion: From these results we could conclude that NRF-1 overexpression increases GLUT4 via Mef2a binding resulting in increased MEF2A which in turn increases its binding to the Glut4 gene resulting in GLUT4 expression. Increases in mitochondrial and GLUT4 expression are essential in alleviating metabolic disease such as type II diabetes. Increase in mitochondrial content and oxidative capacity has been reported to reduce ceramide, diacylglycerol and long chain fatty acyl CoA which interferes with the insulin signalling pathway resulting in impaired insulin stimulated glucose transport and GLUT4 translocation (3). On the hand GLUT4 expression is necessary in glucose transport thereby maintaining euglycemia. NRF-1 can be an important target for drugs needed for the treatment and management of type II diabetes.

INSULIN RESISTANCE IN OBESITY: A NEW CELLULAR MODEL

SIMAR, D., JACQUES, A., CAILLAUD, C.
UNIVERSITY OF NEW SOUTH WALES

Background: Obesity is associated with the development of insulin resistance and further leads to type 2 diabetes. In insulin resistance, glucose uptake is compromised, due to a decreased translocation of glucose transporter (GLUT4) on the plasma membrane. This defect is linked to a serine phosphorylation of the insulin receptor substrate (p-ser IRS-1), under the action of 2 kinases: IkappaB kinase-β (IKK-β) and c-Jun N-terminal kinase (JNK), rendering it a poor substrate for the activated insulin receptor. It has been observed that heat shock proteins (HSP) could modulate the activity of IKK-β and JNK and could then restore insulin sensitivity. Interestingly, it has recently been reported that monocytes from healthy subjects showed an insulin-stimulated increased expression of GLUT4. This could support the hypothesis that monocytes represent an innovative and powerful cellular model to investigate insulin-stimulated glucose uptake. The aim of this study was to investigate insulin signaling and the effect of HSP induction on insulin sensitivity in monocytes from obese people.

Method: 16 people (8men and 8 women, 44yr) were divided into 2 groups based on their BMI (control group or CG=21kg/m2, obese group or OG=31kg/m2). They performed an oral glucose tolerance test (OGTT) under fasting conditions. Blood samples were taken at rest and every 30min up to 2h post glucose ingestion. Area under the curve was calculated for glucose and insulin and index of insulin resistance (IR) and insulin sensitivity (%S) were measured using the HOMA2 model. GLUT4 was measured at every time points, while pJNK, pIKK-β, p-ser IRS-1, Hsp27 and Hsp72 were measured in fasting samples before and after a 2h incubation at 42C.

Results: Significantly higher BMI, IR and area under the curve for glucose and insulin during the OGTT were observed in OG compared to CG. Significantly lower %S and GLUT4 levels were observed at every time points in OG compared to CG. Negative correlations were observed between resting GLUT4 and BMI or %S (r<-0.6) and a positive one with IR (r>0.6). No significant difference was observed between the 2 groups for pJNK, pIKK-β, p-ser IRS-1, Hsp27 at rest whereas Hsp72 was significantly higher in CG. pJNK and pIKK were both positively correlated with p-ser IRS-1 (r>0.7). Heat shock significantly induced Hsp72 in both groups but induced Hsp27 only in CG. Hsp72 induction contributed to decrease pJNK in both groups but resulted in decreased p-ser IRS-1 only in CG.

Conclusion: Obesity is characterized by impaired insulin signaling and altered glucose transport capacity in monocytes. Although heat stress can modulate critical kinases activity, it does not restore insulin signaling in obese subjects and could then explain the impaired glucose transport in this population. Monocytes seem to provide a useful and powerful cellular model to investigate alterations in insulin signaling in metabolic disorders.

Т<–786>→С POLYMORPHISM OF ENDOTHELIAL NO-SYNTHASE <еNOS> IS A MARKER OF SPORTSMEN'S RESISTANCE TO EXERCISE-INDUCED HYPOXIA

DROZDOVSKA, S., FILIPPOV, M., DOSENKO, V., KUZMINA, L.
NATIONAL UNIVERSITY OF PHYSICAL EDUCATION AND SPORT OF UKRAINE

Introduction: Nitric oxide (NO), blood concentration of which is dependent from NO-synthase activity is known to be involved in various adaptation processes to hypoxia. These gene polymorphisms might affect the gene expression and hence individual possibilities of triggering hypoxia compensation mechanisms. The purpose of this study was to elucidate the frequency of polymorphisms in the eNOS gene in endurance athletes with adaptation to hypoxia.

Methods: During the course of the study a total of 42 highly qualified endurance athletes with adaptation to hypoxia (underwater swimming, rowing) and 35 athletes specialized in speed-power kinds of sports were enrolled.

A total of 84 subjects not involved in sport activities were recruited in the control arm. DNA was extracted from buccal epithelial cells.

The polymerase chain reaction (PCR) with following analysis of the length of restriction fragments was used to determine the Т(–786)→С polymorphism of the promoter and G(894)→T polymorphism of exon 7 of eNOS gene.

Results: Frequency analysis of Т(–786)→С polymorphism of the promoter demonstrated that the frequency of normal homozygous genotype T/T in endurance athletes with adaptation to hypoxia was 42,4% (Р=0,001) higher in comparison to those in the control population. In athletes specialized in speed-power kinds of sports the frequency of normal homozygous genotype T/T exceeded control only by 8,3% (Р=0,001). Genotype C/C was not found in the athletes group in our study. The еNOS activity accompanying the G/G variant of exon 7 polymorphism was 1.5 times higher in endurance athletes with adaptation to hypoxia than in those specialized in speed-power kinds of sports. Frequency of genotype G/T in both trained groups almost three times exceeded the control. Genotype T/T was not found in endurance athletes with adaptation to hypoxia, while it was two times higher in the control group in comparison to the group of subjects specialized in speed-power kinds of sports.

Discussion: Our data suggest possible influence of eNOS gene polymorphisms on the formation of the phenotype resistant to exercise-induced hypoxia. In endurance athletes with adaptation to hypoxia the frequency of C/C variant Т(–786)→С polymorphism of the promoter and T/T variant of exon 7 of eNOS gene was found to be lower than in those specialized in speed-power kinds of sports or not trained at all. That can be used for the selection process and have an importance in hypoxia resistance's assessment.

EFFECT OF CAFFEINE INGESTION DURING PROLONGED EXHAUSTIVE EXERCISE ON SALIVARY IMMUNOGLOBULIN A, A-AMYLASE AND CORTISOL

ALLGROVE, J., OLIVEIRA, M., SILVER, B., GLEESON, M.

UNIVERSITY OF GREENWICH AT MEDWAY

Exercise can have deleterious effects on the secretion of salivary immunoglobulin A (s-IgA), which appears to be related to perturbations in sympatheticoadrenal activation (Teeuw et al., 2004). Caffeine, commonly used for its ergogenic properties is associated with increased sympathetic nervous system activity, and it has been previously shown that caffeine ingestion before intensive cycling enhances s-IgA responses during exercise (Bishop et al., 2006). Therefore, the aim of the present study was to examine the effect of a performance cereal bar, containing caffeine, before and during prolonged exhaustive cycling on exercise performance and the salivary secretion of IgA, α-amylase activity and cortisol. Using a randomised cross-over design and following a 10 – 12 hour overnight fast, 12 trained cyclists, mean (SEM) age: 21(1) yr; height: 179(2) cm; body mass: 73.6(2.5) kg; maximal oxygen uptake, VO2max: 57.9(1.2) completed 2.5 h of cycling at 60%VO2max (with regular water ingestion) on a stationary ergometer, which was followed by a ride to exhaustion at 75% VO2max. Immediately before exercise, and after 55 min and 115 min of exercise participants ingested a 0.9 MJ cereal bar containing 45 g carbohydrate, 5 g protein, 3 g fat and 100 mg of caffeine (CAF) or an isocaloric noncaffeine bar (PLA). Unstimulated timed saliva samples were collected immediately before exercise, after 70 min and 130 min of exercise, and immediately after the exhaustive exercise bout. Saliva was analysed for s-IgA, α-amylase activity and cortisol concentration. Saliva flow rates were determined to calculate the s-IgA secretion rate. Data were analysed using a 2-way repeated measures ANOVA and post-hoc t-tests with Holm Bonferroni adjustments applied where appropriate. Time to exhaustion was 35% longer in CAF compared with PLA ((2177 (0.2) vs 1615 (0.16) s; $P < 0.05$)). Saliva flow rate did not change significantly during the exercise protocol. Exercise was associated with elevations in s-IgA concentration (9% increase), s-IgA secretion rate (24% increase) and α-amylase activity (224% increase) post-exhaustion ($P < 0.01$), but there was no effect of CAF on these responses. Salivary cortisol concentration increased by 64% post-exhaustion in the CAF trial only ($P < 0.05$), indicating an increase in adrenal activity following caffeine ingestion. Values were 35.7 (5.5) and 19.6 (3.4) nmol/L post-exhaustion for CAF and PLA, respectively. These findings show that ingestion of a caffeine containing cereal bar during prolonged exhaustive cycling enhances endurance performance, increases salivary cortisol secretion post-exhaustion, but does not affect the exercise-induced increases in s-IgA or α-amylase activity.

ESTIMATING THE TIME DEPENDENCY OF THE DEMAND IN RESPONSE TO AND RECOVERY FROM HEAVY EXERCISE

STIRLING, J., ZAKYNTHINAKI, M.S.

UNIVERSIDAD POLITECNICA DE MADRID

Introduction: The problem of estimating the time dependency of the physiological demand in response to exercise is a fundamental problem in exercise physiology, where the lack of appropriate tools and techniques forces the assumption of a constant demand during heavy exercise. Models such as those developed by (Stirling et al, 2008a, 2008b, 2005) based on methods from nonlinear dynamical systems use such information when modeling the oxygen uptake and heart rate kinetics. The aim of this study is to apply the ALOPEX IV stochastic optimization method to estimate the heart rate demand in response to and in recovery from various heavy exercise intensities (Zakynthinaki and Stirling, 2008).

Methods: Beat to beat heart rate data were obtained from an athlete who performed a series of bouts of exercise at different constant intensities. The optimal fit of the heart rate model to the basic response pattern (Zakynthinaki et al, 2007) of the raw un averaged data for low exercise intensities was obtained used the stochastic optimization algorithm (Zakynthinaki and Stirling, 2007). The model was then fit to heavy exercise intensities by the use of an appropriate partition of the physiological time series and by means of stochastic optimization Zakynthinaki and Stirling (2008). This enabled us to estimate the time dependency of the heart rate demand for heavy intensity exercise and its subsequent recovery.

Results: For the first time the demand of the heart rate as a function of time was found for a heavy constant exercise intensity and the subsequent recovery. It was observed that time dependency of this demand was very different from the constant demand assumption.

Discussion: A method for estimating the demand in response to heavy constant intensity exercises was shown to provide new previously unobtainable information regarding the time dependent nature of the demand. This method was applied to the heart rate, however the method is equally as applicable to oxygen uptake kinetics and hence has many possible applications both in fundamental exercise physiology, medicine and sport.

WHAT IS THE BEST METHOD TO NORMALISE MEASUREMENTS OF ENDOTHELIAL FUNCTION FOR SHEAR STRESS?

ATKINSON, G., DAWSON, E.A., HOPKINS, N.D., JONES, H., THIJSSEN, D.H.J., TINKEN, T.M., GREEN, D.J.
LIVERPOOL JOHN MOORES UNIVERSITY

Introduction: Endothelial dysfunction is a key factor in the development of atherosclerosis. Pyke and Tschakovsky (2005) thought it critical to account for shear stress when examining group differences in flow-mediated dilatation (FMD), which is a surrogate marker of endothelial function in vivo. They introduced a method of normalisation by dividing FMD by the area under the curve of its eliciting shear rate (SR) stimulus (FMD/SR). Nevertheless, Harris and Padilla (2007) postulated that analysis of covariance (ANCOVA) is a more appropriate normalisation approach. Therefore, Tschakovsky et al. (2007) questioned whether different normalisation methods altered interpretations of group-differences in FMD. Our aims are to address this question and to explore the influence of different normalization methods on results from a repeated-measures experiment involving exercise.

Methods: In a cross-sectional study, forearm cuff inflation to supra-systolic pressure was undertaken for a period of 5 min in 16 children (9.90.3 yrs), 48 young-adults (25.34.2 yrs) and 15 older participants (57.54.3 yrs). Brachial artery FMD was calculated as change in artery diameter from the baseline preceding cuff inflation (%), whilst the area under the curve of SR was quantified from cuff deflation to the time of peak arterial diameter. In a further experiment, 10 males, aged 287 yrs, completed three 10-min bouts of cycling at 70%VO2max, interspaced with 10 min rest periods at 08:00 and 16:00 h. Brachial artery FMD was again measured 30 min before and after each bout of exercise. After exploring the relevant statistical assumptions, FMD/SR data were analysed using conventional ANOVA. Results were compared to those using the ANCOVA approach with SR as the covariate.

Results: In the cross-sectional study, the residuals from ANCOVA were normally distributed, which was not the case when FMD/SR data were analysed. The assumption of parallelism in ANCOVA was also upheld. Whilst ANCOVA revealed a significant age-related decline in FMD (9.9±1.0% to 5.7±0.9%; P=0.009), normalisation using FMD/SR resulted in no statistically significant differences being observed (P=0.101). Statistical power was 34% higher with ANCOVA than with FMD/SR. In the repeated measures experiment, FMD at rest was 3.7±1.6% lower at 08:00 h than at 16:00 h, but this diurnal variation was not evident post-exercise. The P-value for this interaction between time of day and exercise was 0.01 for ANCOVA but 0.06 for FMD/SR.

Conclusion: These data suggest that the ANCOVA approach to normalizing FMD for differences in SR holds more statistical power than the FMD/SR method. Statistical assumptions were also upheld with ANCOVA but not with FMD/SR. For these reasons, we support the use of ANCOVA to normalise measurements of FMD for differences in shear stimulus.

LEFT-VENTRICULAR HYPERTROPHY ASSOCIATES TO IMPAIRED MAXIMAL MYOCARDIAL PERFUSION IN ENDURANCE-TRAINED MEN

LAAKSONEN, M.S., HEINONEN, I., LUOTOLAHTI, M., NUUTILA, P., RAITAKARI, O., KNUUTI, J., KALLIOKOSKI, K.K.
MID SWEDEN UNIVERSITY

Long-term endurance training induces morphological adaptations in heart, such as left-ventricular (LV) hypertrophy caused by wall thickening and cavity enlargement. Interestingly, these anatomical changes in the heart are strikingly similar to certain pathophysiological changes (Pellicia 2000). Previous studies have shown that the perfusion response in myocardium during dipyridamole- or adenosine infusion is decreased in several pathophysiological states with LV hypertrophy (e.g. Stolen et al. 2004). However, studies in endurance athletes with LV hypertrophy have shown contradictory results on myocardial perfusion response ranging from reduced to increased myocardial perfusion during dipyridamole- or adenosine-induced vasodilation compared to untrained men (Kjaer et al. 2005; Kalliokoski et al. 2002). The degree of hypertrophy could explain the discrepant findings in studies in athletes, but it has not been thoroughly investigated. Thus, we examined totally 31 endurance athletes (ET) and 25 untrained (UT) men in order to study the association between myocardial functional and anatomical parameters measured with echocardiography, and myocardial perfusion (at rest and during maximal vasodilation induced by iv adenosine) measured with Positron Emission Tomography. Both VO2max (60+-5 vs 42+-8 ml/kg/min, p<0.001) and LVmass index (169+-27 vs 102+-15 g/m2, p<0.001) were markedly higher in ET. Resting myocardial perfusion was similar between the groups (ET 0.7+-0.2 vs UT 0.8+-0.2 ml/g/min, p=0.22) whereas adenosine-stimulated perfusion was lower in ET (2.9+-1.0 vs 3.7+-1.0 ml/g/min, p<0.01). VO2max correlated inversely with adenosine-stimulated perfusion in ET (r=-0.39, p=0.03) and with resting perfusion in UT (-0.49, p=0.01). Forward LV work correlated linearly with resting perfusion in both groups (ET r=0.54, p<0.01; UT r=0.50, p=0.01). ET group was further divided into three subgroups according to LVmass index (ET1: LVmass index <150g/m2, n=9; ET2 LVmass index 150-180 g/m2, n=12; ET3 LVmass index >180 gm2, n=10). Adenosine-induced myocardial perfusion decreased gradually when LVmass increased (UT 3.7+-1.+0 vs ET1 3.3+-0.9 vs ET2 2.7+-1.4 vs ET3 2.6+-0.5 mL g-1 min-1, p=0.008). LVmass index was also inversely related to adenosine-induced perfusion in entire study population (r=-0.46, p<0.01). Therefore, these results suggest that endurance training-induced severe cardiac hypertrophy impairs myocardial perfusion capacity.

METABOREFLEX SENSITIVITY IN INDIVIDUALS WITH MENTAL RETARDATION AND NON-DISABLED ADULT MALES

DIPLA, K., VRABAS, I., ZAFEIRIDIS, A., PAPADOPOULOS, S., GIAGAZOGLOU, P., EVAGGELINOU, C., GELADAS, N.
ARISTOTLE UNIVERSITY OF THESSALONIKI

Introduction: The exercise pressor reflex is a peripheral feedback neural system, composed of group III mechanically sensitive (mechanoreflex) and group IV metabolically sensitive (metaboreflex) afferent nerves. Stimulation of both of these reflexes results in increased sympathetic activity and elicits a blood pressure raising effect. Individuals with mental retardation (MR) have diminished work capacity, reduced peak oxygen consumption, and chronotropic incompetence compared to non-disabled (ND) individuals possibly due to auto-

nomic nervous system alterations. The aim of the study was to assess the contribution of the metaboreflex to the control of blood pressure and heart rate in individuals with MR and ND individuals.

Methods: Eleven healthy ND males (25.1±0.5 years) and ten healthy males with MR (26.4±5.5 years) volunteered for the study. The responses to isometric handgrip (HG) exercise and the persistence of active metaboreflex via local post exercise circulatory occlusion (PECO) were evaluated. The testing protocol involved a 3-min rest period, 3 min HG exercise at 30%MVC, followed by 3 min of post-exercise circulatory occlusion and 3 min of recovery (+PECO protocol). Following a 45-min rest, the same protocol was repeated without circulatory occlusion (-PECO protocol). Beat to beat blood pressure (Finometer) and heart rate were measured non-invasively throughout the protocol.

Results: Significant differences ($p<0.05$) in Mean Arterial Pressure (MAP) responses were observed between the two groups. In ND, during the +PECO protocol, MAP was similar in HG and post-exercise occlusion (delta change from rest 22.6±1.9 vs. 22.4±2.2mmHg, in HG and occlusion, respectively), while during the –PECO protocol, MAP was significantly higher in HG than in non-occlusion (delta change from rest 22.9±2.4 vs. 4.5±1.3mmHg, HG and non-occlusion, respectively; $p<0.05$). In MR, during the +PECO protocol, no differences were observed between HG and occlusion (delta change from rest 17.2±2.5 vs. 12.5±2.7mmHg, in HG and occlusion), while during the –PECO protocol, MAP was higher in HG than in non-occlusion (delta from rest 20.9±2.2 vs. 2.5±1.1mmHg, respectively). Comparisons between the groups revealed that during the post-exercise occlusion period MAP was significantly higher ($p<0.05$) in ND than MR (delta compared to baseline levels 22.4±2.2 vs. 12.5±2.7mmHg, ND and MR, respectively), indicating a lower metaboreflex activation in MR. Heart rate significantly decreased ($p<.05$) during the occlusion and non-occlusion periods in ND and MR; no differences in heart rate were detected during the occlusion between the two groups.

Conclusions: The significantly lower MAP response during the post exercise occlusion period in MR than ND, indicates a diminished metaboreflex sensitivity in individuals with mental retardation compared to non-disabled individuals.

THE STRUCTURAL ADAPTATION TO OVERLOAD IN SKELETAL MUSCLE IS INFLUENCED BY NITRIC OXIDE <NO> AND REACTIVE OXYGEN SPECIES <ROS>

BAUM, O., HALM, S., GRABER, F., ODRIOZOLA, A., ZAKRZEWICZ, A., HOPPELER, H.

UNIVERSITY OF BERNE (BERNE, SWITZERLAND), CHARITE (BERLIN, GERMANY)

Introduction: We have recently shown that skeletal muscles of nitric oxide (NO)-producing neuronal NO synthase (nNOS)-knockout (KO) mice contain higher levels of reactive oxygen species (ROS). To determine whether this molecular adaptation has a functional impact, we have now characterized the influence of nNOS and reactive oxygen species (ROS) on the ultrastructure of skeletal muscle in response to overload.

Methods: Groups of wild type (WT)- and KO-mice (n= 8 animals each) were subjected to extirpation of the tibialis anterior muscle (TA). This established protocol leads to overload in its functional antagonist extensor digitorum muscle (EDL) within 14 days. Other groups of WT- and KO-mice (n= 8 animals each) were fed with a combination of ROS scavengers (vitamin C, N-acetyl-cysteine, coenzyme Q) for 14 days prior TA extirpation and during the 14 days of muscle stretch. Both the overloaded and the contralateral EDL were subjected to morphometric analysis at the light microscopy level.

Results and Discussion: Compared to the values in the contralateral EDL, muscle stretch raised significantly the capillary/fiber (C/F)-ratio and capillary density in the overloaded EDL of WT- and KO-mice but not of those animals that were treated with ROS scavengers. These results indicate that ROS rather than NO influence the growth of the capillary network in skeletal muscle. Interestingly, the basic values for C/F-ratio and the capillary density were significantly higher in mice of both strains fed with ROS scavengers than in those not treated with the scavengers suggesting that the reduction in ROS levels per se induced angiogenesis in skeletal muscle. The mean fiber area of skeletal muscle fibers was significantly lower in KO than in WT-mice but not changed by ROS scavenging pointing out that nNOS-derived NO but not ROS participates in hypertrophy of skeletal muscle fibers. In summary, overload-induced angiogenesis in skeletal muscle is controlled by ROS, while hypertrophy depends on NO only. These data might be of fundamental relevance to analyze and understand the functional impact of free radicals on skeletal muscle physiology.

ASSESSMENT OF SEDENTARY-TO-MODERATE INTENSITY PHYSICAL ACTIVITY BY A SHIRT POCKET-IN ACTIVITY MONITOR

OKURA, M., NISHIBAYASHI, K., OGATA, H., MIYASHITA, A., SHIOKAWA, T., KUMPEI, T., IKEDA, Y.

TANITA CORPORATION, UNIVERSITY OF TOKYO, UNIVERSITY OF TSUKUBA

BACKGROUND: There is considerable public health interest in the physical activity levels of adults, in part because an increased prevalence of obesity associated with lower levels of physical activity. However, there are currently few effective methods to objectively, noninvasively, and accurately evaluate the quantity of low-to-moderate intensity physical activities in free-living conditions. Triaxial accelerometers that are small in size and minimally intrusive to normal subject movement can be useful devices for predicting energy expenditure (EE) for various physical activities. Previous studies demonstrated higher correlation coefficients between acceleration counts obtained with waist-mounted triaxial accelerometer and the EE measured. However, some studies suggest that waist-mounted accelerometers tend to underestimate the EE for daily physical activity because they couldn't pick up signals during upper body movement, which mainly contributes to EE during sedentary-to-moderate physical activities. Thus, we hypothesized that methods for estimating EE would be improved by mounting the activity monitor in the upper body, for example, in a shirt-pocket. The purpose of this study was to develop a regression-based equation that estimates EE for sedentary-to-moderate intensity activities using total acceleration obtained by the shirt

pocket-in activity monitor. METHODS: Twenty Japanese adults equipped a shirt pocket-in activity monitor (AM-101, D30×W 80×H17, 19 grams; TANITA Co. Ltd) while in a whole body indirect calorimetry for 24 hours (6 PM to 6 PM the next day). The triaxial accelerometers measure acceleration in three dimentional directions. It samples acceleration at 16 Hz and assesses values from – 2 to 2 G (1 G is equal to the acceleration of free fall). The acceleration count was calculated as the average of the absolute values for acceleration for a given interval (1 minute). The protocol time was composed of sleep (8 hours) and various structured activity periods. Acceleration data from various activities and their relationship to energy expenditure obtained from the whole body indirect calorimetry allowed for the development of EE equations for daily physical activities. The developed EE equation was cross-validated on 9 Japanese adults. RESULTS: The acceleration data of various activities was strongly correlated with the actual EE measured by the whole body indirect calorimetry. The predicted physical activity EE (PAEE) was highly correlated with the actual PAEE measured by the indirect calorimetry, although the predicted PAEE was slightly higher than the measured PAEE. CONCLUSION: In conclusion, we found that the total acceleration obtained from the shirt pocket-in activity monitor was strongly and linearly correlated with the EE measured by the indirect calorimetery. The attachment of a triaxial accelerometer in a shirt-pocket is an ideal method to pick up the upper body movement in daily physical activity.

HEALTH-RELATED PHYSICAL FITNESS AMONG ADULTS AND ELDERLY POPULATION. PILOT DATA FROM THE KAN PROJECT PHASE II.

LOHNE-SEILER, H., HANSEN, B.H.

UNIVERSITY OF AGDER, NORWEGIAN SCHOOL OF SPORT SCIENCES

Introduction: On instructions of the Public Health Department, the work with KAN (Kartlegging Aktivitet Norge) is part of the follow-up of the national plan "Working together for physical activity", and the goal is to make a system to monitor the level of physical activity (phase I) and health-related physical fitness (phase II) among the adults and the elderly population in Norway. The project is financed by the Norwegian Directorate of Health. The Norwegian School of Sport Sciences is in charge of the project in cooperation with 9 educational institutions at university and college level. Phase 2 will measure health-related physical fitness in an objective way. Therefore, the purpose of this pilot study was to accomplish a pilot study based on standardized test battery for registering health-related fitness in the age group 30-85 years.

Methods: A total of 31 men (n=16) and women (n=15), initially 56.3±14.2 years participated in the pilot study. The test battery is partly based on the ALPHA group recommendation by Suni et al. (2008), measuring muscle strength and motor fitness. Tests measuring flexibility were also chosen because of the connection between mobility and the ability to cope with activities of daily living according Rikli and Jones (1999).

Results: The participants (n=31) used 114.6 sec (SD 68.3) in the Static back extension test. In the Handgrip test (n=31) the score was 44.7 kg (SD 14.1). The results in the One leg standing test (n=31) was 33.0 sec (SD 20.6) and in the Modified push-up test the participants (n=24) accomplished 15.0 push-ups (SD 5.7) in 40 sec. Seven participants carried through the test on their knees and managed to do 9.6 push-ups (SD 3.8) in 40 sec. The results from the Chair Sit-and-Reach and Back Stretch tests 6.7 cm (n=30, SD 14.2), left arm over 0.6 cm (n=30, SD 13.3) and right arm over -4.1 (n=30, SD 10.4) respectively.

Discussion: Based on the high standard deviation shown on some of the tests and our subjective test experience, it is necessary to standardize all the tests in a way it makes it possible to implement the KAN test battery to all the 10 involved educational institutions.

CONCURRENT VALIDITY OF SIMPLE BODY FAT COMPOSITION ASSESSMENT METHODS IN RECREATIONAL ATHLETES

TRAN, H., THIEL, C., VOGT, L., ROSENHAGEN, A., BANZER, W.

INSTITUTE OF SPORTS SCIENCES

Introduction: A variety of methods can be used to determine percent body fat (% BF) as a cardiovascular risk factor and to classify recreational athletes of under-, normal- or overweight. However, various assessment methods may yield different results. Therefore the present study compared the most commonly used inexpensive, operationally simple, non-invasive techniques: bioelectrical impedance analysis (BIA), near infrared body composition analyzer (NIR) and hand-held caliper (Cal) measurements.

Methods: The sample of 120 young recreational athletes (80 male (M), 40 female (F), 23.9±2.8 yrs, 1.76±0.08 m, 73.63±10.16 kg and BMI 23.58±2.21 kg/m2) with a history of at least 3 years active participation in organized sport (>2 times activity/week) was measured by experienced examiners. For assessment, 3-point skinfold thickness (Lange skinfold caliper, Beta Technology, Santa Cruz, USA), near infrared body composition analyzer (Futrex, Futrex Software Services Europe, Bitburg, Germany) in a standardized sitting position and two different bioelectrical impedance analysis, standing (BIA-st) (Omron BF-500, Omron Healthcare, Mannheim, Germany) and prone lying (BIA-ly) (Nutriguard-S, Data-Input, Darmstadt, Germany) were performed in a randomized order. Percentage body fat calculations were used for device comparison and classification into the body fat categories (% BF) normal (10-19.9% (M), 20-29.9% (F)), underweight (<10% (M), <20% (F)), overweight (20-24.9% (M), 30-34.9% (F)) or obese (>25% (M), >35% (F)).

Results: The subjects show different percentage BF (mean±SD) in accordance to the four measurement methods used: BIA-ly 18.5±6.2%, BIA-st 20.3±7.0%, NIR 17.5±6.0% and Cal 12.0±6.6%. Due to BIA-ly/ BIA-st and NIR measurements the study population is classified into the categories underweight (7-15%), normal (71-77%), overweight (7-20%) and obese (0-7%). In contrast caliper measures lead to a somewhat different frequency distribution: underweight (70%), normal (27%), overweight (2%) and obese (1%).

Discussion: Many commonly used body fat assessment methods can be used at reasonable costs within minimal time (< 5 minutes) and require only limited investigator experience. However, the current results illustrate varying body composition classification according to the assessment method used in recreational athletes. The magnitude of difference seems to be linked to the underlying measuring mechanism. Whereas BIA and NIR measures revealed almost comparable results, great differences were observed in relation to the caliper method.

DUE TO THE RECENT FINDINGS NUTRITIONISTS AND CLIENTS ALIKE SHOULD BE CAREFUL COMPARING BODY FAT CALCULATIONS BETWEEN DIFFERENT ASSESSMENT METHODS: TOTAL AMOUNT AND INTENSITIES OF PHYSICAL ACTIVITY AS PREDICTORS OF LOW CARDIORESPIRATORY FITNESS

SILVA, G., AIRES, L., SILVA, P., MOTA, J., OLIVEIRA, J., RIBEIRO, J.C.

FACULTY OF SPORT - UNIVERSITY OF PORTO

Introduction: Cardiorespiratory fitness (CRF) is a powerful marker of health and is specially related to cardiovascular disease risk factors. The rationale behind CRF suggests that physical activity (PA) have some effect to change it. However, the discussion about whether PA amounts and intensities are related with CRF levels remains.

Purpose: To determine whether total amount and intensities of PA could define the risk of being in lower levels of CRF in young Portuguese students.

Methods: This is a cross-sectional study of 240 adolescents aged 12 – 18 y from Porto district in the North of Portugal. CRF was determined by the maximal number of laps attained in the 20m Shuttle Run Test. CRF levels (low fit or fit) were classified according to FITNESSGRAM reference standards. PA was measured by accelerometers during 7 consecutive days and classified in total PA (TPA), sedentary PA (SPA), light PA (LPA), moderate PA (MPA) and vigorous PA (VPA). Previous single logistic regressions were performed for each PA variable separately. Final logistic regression was used to determine the risk of being low fit for CRF from previous significant variables. Significance level was set at $p < 0.05$.

Results: Previous single logistic regression indicates that only gender, TPA, MPA and VPA were related with CRF. Final logistic regression model considering gender, TPA, MPA, and VPA pointed that VPA was the only significant indicator of the risk of being at low fit level of CRF. Odds ratio for being low fit was 0,844 (0,729 – 0,977) for VPA. In other words, as long as the levels of VPA are higher, lower is the change of being low fit.

Conclusion: The results indicate that VPA is the most important PA intensity to determine the risk of being at lower CRF levels. Thus, it would be reasonable to promote physical activity of vigorous intensities to improve CRF and by consequence to improve cardiovascular health in early ages.

EVALUATION OF A HEALTH PROMOTION PROGRAM FOR MUSIC STUDENTS

DIKETMÜLLER, R.

UNIVERSITY OF VIENNA

Introduction: Confronted with an increasingly large number of students suffering from medical problems (Zander 2006), the need of a health prevention program became obvious at the University of Music and Performing Arts Vienna. Based on the concept of Physioprophylaxis the project 'music and muscles' was initiated and an interdisciplinary health program was established. Courses in a groupsetting are offered for students to strengthen their individual fitness (f.e. Body fit, Strength Training, Rhythm, Dispokinesis) as well as teamteaching courses with additional experts in Spiral Dynamics and Franklin–Method to show students and teachers healthier ways of playing music.

Methods: The aim of the study was to investigate the implementation process and the effectiveness of this health program for the prevention of playing-related health problems. It was hypothesized that the program would have positive effects on different aspects of health of the students and on their work as musicians in training. By now, 134 students participated in the evaluation studies with pre and post measurements (standardized questionnaires at the beginning and at the end of each course (Spahn 2006, Spahn et al. 2001, Spaulding 1995, Zander 2006), document analysis of the program, interviews with the project coordinator, teachers and trainers).

Results: Based on the pre-to-post measurements of the students, the overall distress has decreased as well as playing-related symptoms, general symptom frequency, and emotional disturbances and anxiety level. General coping with work as a musician and security in performance situations have improved and their behavior of practicing preventive exercises in their life and within daily routines of playing music have changed significantly.

Discussion: Although the project has initiated changes in individual (health) behavior of the students (daily training, body awareness and posture), more measures will be necessary to build up sustainable structures for health promotion. Especially the support of the teaching stuff of the university will be an important factor in catalyzing a broader acceptance for the prevention program in students and the distribution of healthier ways in learning procedures, ways of playing and performing music (Spaulding 2002).

RELIABILITY OF PERCEPTIONS OF ENVIRONMENTAL VARIABLES CONNECTED TO PHYSICALLY ACTIVE COMMUTING ROUTES

WAHLGREN, L., STIGELL, E., SCHANTZ, P.

THE SWEDISH SCHOOL OF SPORT AND HEALTH SCIENCES

Purpose

The ecological approach on physical activity behaviours emphasizes the environment as an important factor influencing physical activity levels. Some instruments have been developed to assess the neighbourhood or the local environment (1, 2). Physically active commuting, however, make use of an extended environment as compared to the local ditto. Furthermore, there is a need for developing models for ratings of environmental variables connected to commuting route environments. The purpose of this study is therefore to report on a

questionnaire developed for assessment of the perception of various aspects of the commuting route environment believed to be associated to physically active commuting by bicycle.

Methods: A questionnaire was designed including 18 questions developed to assess the perception of the commuting route environment. The questions address variables in three environmental domains: physical, traffic, and social environment. Variables include areas such as greenness, aesthetics, exhaust fumes, noise, flow, velocities, congestion, and conflicts as well as overall perception of the commuting route environment. Fifteen-point response scales ranging from e.g. very low to very high were used.

The participants, physically active commuters, were recruited in mid November 2005, when they bicycled in the inner urban area of Stockholm, Sweden (n=53). The participants answered the questionnaires on two occasions, about two weeks apart, and their responses were used to assess the test-retest reliabilities. This study reports on 13 questions.

Three types of analysis were used: 1) order effects analyzed with Student's paired t-test, 2) the typical error, and 3) intraclass correlations coefficients based on a one-way model.

Results: No significant order effects were seen, except for in the variables called conflicts (8.7%, $p<0.05$), congestion of bicyclists (7.8%, $p<0.05$), and overall perception of the commuting route environment (7.5%, $p<0.05$). The typical errors ranged between 0.94-2.03. The variables called velocities of bicyclists (ICC=0.87), and congestion of bicyclists (0.83) produced the two highest ICCs and the variables noise (0.41), velocities of motorized vehicles (0.51), flow of motorized vehicles (0.57), and exhaust fumes (0.58) produced the four lowest ICCs.

Conclusion: The overall result indicates a generally reasonable to substantial test-retest reliability. These results support that the studied questions may be useful for the assessment of the commuting route environment believed to be associated to physically active commuting by bicycle. The questions can contribute to the growing knowledge regarding physically active commuting.

OP-PP03 Physical Education and Pedagogics 3

PHYSICAL EDUCATION IN THE FOUNDATION PHASE (GRADES R-3): A SURVEY

VAN DEVENTER, K.

STELLENBOSCH UNIVERSITY

In an attempt to break the cycle aimed at maintaining social and ideological control, the new South African government has established a new legal and policy framework for education and training. The result was the National Curriculum Statement (NCS). As a reform the NCS promised to improve the quality of education for all in South Africa (SA). In this article, the emphasis is on Life Orientation (LO), a Learning Area of the NCS, in the Foundation Phase (PF) of the General Education and Training Band (GET). The main problem was to determine the perspectives of LO teachers regarding the implementation of LO and particularly the Learning Outcome, Physical Education (PE) in the FP in selected Western Cape high schools, a province in SA. Quantitative data captured by a questionnaire typifies the research design as a survey. In the survey primary schools (N=124) were randomly selected of which 50 FP teachers (N=50) returned questionnaires. Summary statistics using frequency tables and histograms were utilised. The data was analysed by Statistica 8.0 (2007). Every aspect as stipulated by the NCS seemed to be in place for the presentation of LO in the FP. However, the majority of teachers were not qualified to present PE which creates major problems in the sense that it nullified many of the other conclusions. Notwithstanding the status of LO, the situation holds specific implications for the growth and development of FP learners. It is recommended that the Department of Education (DoE) should take the initiative and lead in this regard to urgently provide specialist PE teachers for the FP. However, Higher Education Institutions (HEI's) should become more involved in training initiatives for prospective teachers in LO.

ASSESSMENT FOR LEARNING AND GENDER EQUITY IN PHYSICAL EDUCATION. A PROSPECT FROM NORWAY AFTER THE IMPLEMENTATION OF THE NEW NATIONAL CURRICULUM 2006

ARNESEN, T.E., NILSEN, A.K., LEIRHAUG, P.E.

STORD/HAUGESUND UNIVERSITY COLLEGE, BERGEN UNIVERSITY COLLEGE, SOGN OG FJORDANE UNIVERSITY COLLEGE

Introduction: Gender differences and stereotyping in Physical Education (PE) are well documented since the 70ties. Despite this, Davis(2003) highlights the fact that there are few recent research studies in which the authors have failed to show gender inequitable treatment. Klomsten(2006) concluded that a more conscious view of gender was required in Norway as well.

In Norway a new National Curriculum(Lk06) led to an increased focus on assessment and its role in education. All subject curriculums included competence aims, specifications of learning expected of pupils at various ages. These aims form the overall basis of assessment. Assessment for learning, focusing on goal guided feedback from the teacher as well as self assessment, is emphasized.

To what extent have the new assessment regulations led to changes in topics/contents and methods of teaching and assessment? How do they influence the issue of gender equity in PE? This presentation seeks to explore and discuss these questions.

Methods: Quantitative and qualitative analyses of data from three studies each being parts of a larger project which purpose is to investigate the complex relations between assessments and learning in PE: a survey of 89 PE-teachers from all over Norway; a study of expec-

tations, ambitions and activity preferences in PE of 140 pupils in upper secondary school. An interview based study of selected teachers and pupils.

Results: The study of pupils reveals significant gender differences on grade aspiration before the start of the semester. Girls and boys show significantly different preferences on football, athletics and dance. The survey of PE-teachers shows that 74 % spend less than 20 % of total teaching time on dance. 83 % spend 40-100% on sport. 0 % spend 40-100 % on dance. Nearly one half of the teachers report that they have changed their way of assessment since the introduction of Lk06.

Discussion: The data indicates that content and practice in PE is influenced by well-known gender stereotyping. Lk06 has not made a difference in respect of this. Activities that are stereotypically referred to as 'feminine appropriate', like dance, occupy very little of teaching time in PE. 'Stereotypical' is precise here, because football is the largest sport among girls in Norway. Why, then, is it not so popular in PE? A girl says that ballgames are fun when they practice skills and techniques. Not surprisingly it seems that how the activity is taught is more important than the activity itself. Assessment for learning presents itself as a way to tell the pupils how to understand and work with the competence aims.

ENVIRONMENTAL CORRELATES TO PHYSICAL ACTIVITY IN ADOLESCENTS: TRACKING ACTIVITY PATTERNS IN SCHOOLYARDS

FJØRTOFT, I., LÖFMAN, O., HALVORSEN THORÉN, K., FRY, G.

TELEMARK UNIVERSITY COLLEGE, NORWAY, UNIVERSITY OF LIFE SCIENCES, NORWAY

Physical activity is recognized to be an important factor preventing life-style risks at an early age and can be related to the quality of life and subjective experience in early ages. Environmental settings seem to influence the activity patterns of children in neighbourhoods and schoolyard, the latter being an important arena to promote PA in school children. However, physical activity seems to decrease, starting in early teenage years, somewhat more pronounced in girls than in boys and previous studies have described sedentary lifestyle characteristics among young people. This study focused on environmental facilitation of schoolyards and how environments promote physical activity in 9 graders in two different schoolyards. Methods: Schoolyards and facilities for PA were described and identified through ortophoto maps. The children's movement patterns and activity levels were measured during the main school break applying a GPS Garmin Forerunner 305 with combined heart rate monitoring. Data were then transferred to and structured in a Microsoft Access data base and further exported in dbf format to an attribute table in ArcInfo (ESRI). Spatial reference data were converted to a projected coordinate system and geocoded in ArcGIS using metric units. Variation of heart rate within schoolyard area were analysed in a 20 x 20 meter grid. For the grid analysis, the average heart rate of measured point recordings was used as a summary measure.

We also modelled a continuous area depicting the variation of average heart rate over the schoolyard, using ordinary kriging interpolation. The schoolyard surface was thus further smoothed and the resulting data projected as a 3-dimensional wire graph showing the variation of average heart rate over the school yard. Basic geostatics was calculated for sub-sets of data representing separate attributes like gender (Mean center, Standard distance deviation etc.). Ordinary statistics and graphs were calculated using SPSS, Axum and ArcGIS, including plug-in modules such as Hawth Tools, Spatial Analyst and Geostatistical Analyst. Results: Typical movement patterns such as walking around the school buildings were identified and a handball goal area was a typical determinant for PA in one school with monitored HR>160 bpm in girls. Generally, low activity levels (mean HR<120 bpm) were registered for both schools. In spite of available facilities for PA these were not extensively used during recess. Conclusion: GPS tracking and HR monitoring showed traditional movement patterns of low PA levels during recess at both schools and the students did not utilize available sport facilities. Activity did not meet recommended daily time and levels of PA in children and youth.

A SCHOOL-BASED PHYSICAL ACTIVITY PROGRAM INCREASES FITNESS AND DECREASES ADIPOSITY IN PRIMARY SCHOOL CHILDREN <KISS>: A CLUSTER-RANDOMIZED TRIAL

KRIEMLER, S.

INSTITUTE OF EXERCISE AND HEALTH SCIENCES

Background: Childhood obesity and physical inactivity are increasing dramatically worldwide with detrimental effects on fitness, cardiovascular health and quality of life. Schools provide an ideal setting for preventive interventions. We therefore conducted a randomised controlled trial to determine whether a school-based physical activity (PA) program during a full school-year improves body composition, fitness, cardiovascular health, PA and quality of life in primary school children.

Methods: Twenty-eight classes from two of 26 provinces in Switzerland were cluster randomized to the intervention (16 classes, n=297) and control (12 classes, n=205) groups. The intervention consisted of a multi-component PA intervention including daily physical education. Primary outcomes included body fat (skinfold thickness), aerobic fitness (shuttle run test), PA (accelerometry), and quality of life (questionnaires). Children and parents in the control group were not aware of the existence of an intervention group. Analyses were done according to intention to treat.

Results: 502/540 students consented to participate, 498 completed the pre- and postintervention assessment, mean age was 6.9 (SD 0.3) years for 1st grade and 11.1 (0.5) years for 5th grade. After adjustment for grade, gender and cluster, children in the intervention arm compared with controls showed statistically significant additional average changes in body mass index by -0.22 (95% CI -0.38 to -0.05, p=0.009), in sum of four skinfolds by -1.78mm (-3.38 to -0.19, p=0.02), in aerobic fitness z-scores by 0.22 (0.01 to 0.42, p=0.04), in moderate-vigorous physical activity in school by 14 min (5 to 23, p=0.008) and in the cardiovascular risk score by -0.18 (-0.30 to -0.05, p=0.005). Overall daily physical activity and quality of life did not change differently.

Conclusions A school-based multicomponent physical activity intervention including compulsory elements can improve physical fitness and reduce adiposity and a composite cardiovascular risk factor score in children. Implementation of such a program may help to improve health and fitness of our children, and also improve health later in life by reducing cardiovascular and other diseases.

EXPLORING THE INFLUENCE OF PHYSICAL EDUCATION PREDISPOSITIONS ON PHYSICAL EDUCATION OUTCOMES

HILLAND, T., FAIRCLOUGH, S., STRATTON, G., RIDGERS, N.

LIVERPOOL JOHN MOORES UNIVERSITY, UK

Introduction: The Youth Physical Activity Promotion Model (YPAPM; Welk, 1999) describes predisposing factors of attitude, enjoyment, perceived competence and self efficacy as key influences on young people's physical activity. These factors may be important within the school Physical Education (PE) setting which has been identified as an influential context for enhancing young people's physical activity. A key goal of PE is to develop physically educated and physically active youth (NASPE, 2004). The study purpose was to explore the influence of psychological predispositions in PE on theoretical outcomes of PE, including physical activity levels, knowledge and understanding of physical activity, and perceived links to opportunities available for out of school physical activity.

Methods: Two hundred and ninety-one Year 8 and 9 children (208 girls, 83 boys; aged 12-14 years) from three schools in the North West of England participated in this study. They completed a questionnaire pack which included the Physical Activity Questionnaire for Older Children (PAQ-C; Crocker et al., 1997), and items relating to knowledge and understanding of health-related exercise, perceived PE ability and worth, and how PE impacts upon physical activity participation outside of school. Sex-specific multiple regression analyses were used to explore the inter-relationships between variables.

Results: Perceived PE Worth and Ability accounted for similar amounts of variance in self-reported physical activity and knowledge of physical activity opportunities available outside of school, for boys (19.4-26.2%), and girls (14-16.3%). The significant predictor within each model differed between boys and girls; boys' Perceived PE Worth predicted physical activity levels ($p < 0.03$, B = 0.2, [S.E. = 0.09], β = .26), while for girls Perceived PE Ability was the most important variable ($p < 0.01$, B = 0.30, [S.E. = 0.07], β = .35). Types of physical activities participated in outside of school was impacted upon by Perceived PE Ability for boys ($p < 0.01$, B = 0.7, [S.E. = 0.16], β = .5), and by Perceived PE Worth for girls ($p < 0.01$, B = 0.35, [S.E. = 0.09], β = .33). Boys' Perceived PE Ability influenced their awareness of physical activity opportunities outside of school ($p = 0.008$, B = 0.47, [S.E. = 0.17], β = .33) but for girls Perceived PE Worth had greater effect ($p < 0.01$, B = 0.48, [S.E. = 0.1], β = .38).

Discussion: These results suggest that gender differences exist in how psychological predispositions in PE affect intended theoretical PE outcomes. Physical educators should be aware of these gender differences in order to develop targeted pedagogical strategies to enhance students' attainment of positive PE outcomes.

THE WORLD GYMNAESTRADA - A MODERN FORM OF LING GYMNASTICS?

MECKBACH, J., LUNDQUIST WANNEBERG, P.

THE SWEDISH SCHOOL OF SPORT AND HEALTH SCIENCES

The World Gymnaestrada – A Modern Form of Ling Gymnastics?

Introduction: Different forms of kinetic culture were developed in Europe at the beginning of the 19th century. One of these was Ling gymnastics (Lundvall & Meckbach, 2003; Lundquist Wanneberg, 2004; Pfister, 2003). Ling gymnastics has been described as one of Sweden's biggest cultural export products and in 1939 an international gymnastic display, the Lingiad, was held in Stockholm. But Gymnastics festivals are not a select Swedish phenomenon (Pfister 2007). The first World Gymnaestrada (WG) was held in Rotterdam in 1953. The focus in this study is on the conceptual content of Ling gymnastics evident in the type of gymnastics performed, Gymnastics For All (GFA), at the WG.

Methods: Three concept pairs General-Elite, Collectivism-Individualism, and Modesty-Ambition have been used to both capture and analyse the elements of Ling gymnastics evident in the WG. The study is based on 20 group interviews (semi-structured) with a total of 53 gymnasts and 87 observations (semi-structures with an observational list) carried out during 2007 WG.

Results: The results show: i) one similarity between the two forms of gymnastics is amateurism: no one profited financially from their involvement, ii) another similarity is the view of collectivism and general: gymnastics should be done together and should be available for all, iii) the idea behind both gives everyone an opportunity to participate.

Discussion: The answer to the question whether the WG's concept of gymnastics, GFA, can be regarded as a modern form of Ling gymnastics is yes, with certain reservations. The study has shown that there also are differences in content; differences that to some extent can be explained by structural changes when it comes to the view of the individual versus the collective. But in terms of the approach to the type of display and an emphasis on diversity, the basic principles are the same. The final question is how a Swedish gymnastics form that is rooted in the early 19th century can live on in an international context today? As been pointed out by the Norwegian sociologist, Augestad (2001) and the German historian, Pfister (2003) the universality of the Ling gymnastics made it compatible with cultures other than Swedish. Obviously so even today – at least part of it.

OP-SM02 Sports Medicine 2

IMPLICATION OF PPARS IN ANTI-ATHEROGENIC EFFECT OF SWIMMING EXERCISE IN APOLIPOPROTEIN E DEFICIENT MICE (APOE-/-).

SZOSTAK, J., MIGUET-ALFONSI, C., PELLEGRIN, M., BOUZOURENE, K., BERTHELOT, A., MAZZOLAI, L., LAURANT, P.
UFR MEDECINE PHARMACIE

Introduction: Atherosclerosis is a chronic inflammatory disease. Physical exercise significantly reduces atherosclerosis lesions. However, the precise mechanisms implicated are still unknown. Recent studies suggest that PPARs may have some anti-atherogenic effects. We assess the hypothesis that exercise training reduces atherosclerosis in ApoE-/- deficient mice by increasing PPARs expression.
Methods: Male ApoE-/- deficient mice and normal C57Bl/6J mice were used. ApoE-/- mice were fed with a high fat diet and randomized into tree groups: 1/ one exercise group underwent exercise training (60 min swimming, 5 times/week) for 13 weeks, 2/ one sedentary group, and 3/ one supplementary exercise group supplied with an antagonist of PPAR-g Bisphenol A-diglycide ether named BADGE. C57BL/6J mice were used as control and divided into two groups: control exercise and control sedentary. Implications of PPARs in anti-atherogenic effects induced by exercise training are measured by quantification of PPAR mRNA by PCR quantitative in aorta and muscle solaris.
Results: Atherosclerotic lesions in ApoE-/- deficient mice were significant decreased in ApoE-/- mice underwent protocol swimming for 13 weeks in comparison to the ApoE-/- sedentary group. In contrast, exercise in mice supplied with BADGE did not suppress the atherosclerotic lesions. Exercise significantly increased expression of PPAR-g in aorta of ApoE-/- mice. Interestingly, the increased expression of PPAR-g in vascular wall was inversely correlated with the atherosclerotic plaque area. PPAR-b and a were not modulated in response to exercise training in aorta.
In soleus muscle, expression of PPAR-b was modulated by exercise training. Expression of PPAR-b in ApoE-/- mice was significantly increased in response to exercise training. Moreover, expression of PPAR-b was significantly decreased in ApoE-/- mice in relation to control mice. Interestingly, exercise in ApoE-/-mice supplied with BADGE, generated a significant decrease of PPAR-g and PPAR-b expression in comparison to ApoE-/- mice underwent exercise.
Conclusion: exercise prevents the development of atherosclerotic lesions in aorta. Our findings indicate that PPAR-g are implicated in the anti-atherogenic effects induced by physical exercise. In soleus, exercise training was associated with increased PPAR-b expression. This may be due to an increase of the muscle oxidative capacity in response to exercise training.

EMG ACTIVITY OF ECCENTRIC QUADRICEPS MUSCLE ACTIONS IS GREATER DURING FLYWHEEL THAN WEIGHT STACK TRAINING

NORRBRAND, L., POZZO, M., TESCH, P.A.
MID SWEDEN UNIVERSITY

Potential neural training adaptations in response to identical resistance exercise programs, using either an isoinertial flywheel device or a traditional knee extension weight stack machine, were studied by measuring electromyographic (EMG) activity of superficial vastii muscles pre and post 5 wk training.
Methods: Seventeen healthy, untrained men were assigned to 5 wks unilateral knee extension training (2-3 sessions/wk, 4 sets of 7 repetitions) using either a weight stack machine (WS; n=8) or a flywheel device (FW; n=9). Training specific mean and angle specific (90, 120 and 150° knee angle) EMG root mean square of mm. vastus lateralis (VL) and vastus medialis (VM) of concentric (CON) and eccentric (ECC) actions were measured. EMG was normalized using EMG measured during a maximal isometric action as a reference.
Results: Pre training, grp FW showed greater overall angle specific normalized EMG of VL and VM ($p<0.05$), greater mean normalized EMG within the ECC action (FW VL; 0.71±0.26, FW VM; 0.67±0.22, WS VL; 0.37±0.10, WS VM; 0.41±0.13, $p<0.05$), and greater overall ECC-CON EMG ratio (FW VL; 0.72±0.10, FW VM; 0.71±0.10, WS VL; 0.49±0.05, WS VM; 0.47±0.07, $p<0.05$) compared with grp WS. There were no group differences for the CON action (FW VL; 1.04±0.58, FW VM; 1.00±0.43, WS VL; 0.75±0.19, WS VM; 0.87±0.25, $p>0.05$). Following training, both groups showed increased isometric and training specific strength of the trained limb ($p<0.05$). Neither group showed altered ($p>0.05$) CON or ECC mean normalized EMG with training. However, groups showed different training responses for CON angle specific normalized EMG ($p<0.05$). Grp WS showed trends to increased normalized EMG at 90° (VL: p=0.019, VM: p=0.036) and 120° (VL: p=0.016, VM: p=0.085) knee angle. The CON angle specific normalized EMG of grp FW was near maximal both pre and post training, and hence unchanged over time ($p>0.05$).
Conclusion: The current results suggest that, muscle activation (i.e., EMG amplitude), during FW resistance exercise is near maximal from onset of the training period. Hence, greater normalized ECC EMG and ECC-CON EMG ratios may explain the more robust hypertrophy reported earlier following FW compared with WS training (1, 2). Training using WS evoked markedly less EMG activity in a large part of the range of motion. Thus, the low normalized ECC EMG and ECC-CON ratio are commensurate with the observations that neural adaptations typically are very prominent during the first weeks of traditional weight training.

ASSOCIATION BETWEEN PHYSICAL FITNESS AND RISK OF INJURIES DURING 18 WEEKS IN THE SWISS ARMY RESCUE TECHNICIAN SCHOOL

WYSS, T., FREY, F., MÄDER, U.

SWISS FEDERAL OFFICE OF SPORTS

A mismatch between individual physical capability and job requirement can increase the risk for injury. Therefore, military organisations test the physical fitness of their conscripts to assign them to an adequate job. At the Swiss Army recruitment a new physical fitness test battery (1) was implemented. However, no objective fitness test related profiles of job requirements are available so far. The association of injuries incidence with initial physical fitness may provide information on the minimal physical demand of jobs.

In this study all participants were recruits of the Swiss Army rescue technician's school. Their physical fitness was assessed at the army recruitment with the test battery described elswhere (1). Overuse injuries were assessed continuously during the 18 weeks of military service by the local military medicine centre. The discriminative power of physical fitness tests for predicting the risk of overuse injuries was tested with receiver operating characteristic (ROC) analysis. ROC curves were plotted to identify the optimal cut-off values.

Data of 149 rescue technician's are used in these analyses. Overuse injuries forced 22.3% of recruits to receive medical treatments during 18 weeks of service. ROC curve analysis showed a significant ($p < 0.05$) area under the curve for standing long jump, trunk muscle strength test, progressive endurance run and fitness total score (0.640, 0.627, 0.621 and 0.646, respectively). The overuse injury rate among conscripts who exceeded the cut off distance of 2.2m in standing long jump (n = 100) was 17.3%, for those with lower jump distances 37.1%. The overuse injury rate among conscripts who exceeded the cut-off value of 130s in the trunk muscle strength test (n = 50) was 10.0%, for the others 31.3%. The overuse injury rate among conscripts who exceeded the cut-off score of 10.5 points in the progressive endurance run (n = 114) was 17.4%, for the others 38.9%. The overuse injury rate among conscripts who exceeded the cut-off score of 64 points in total fitness test (n = 119) was 17.6%, for the others 45.1%.

Muscle fitness of lower extremities and trunk as well as aerobic endurance do have a negative relation to risk of injury during military service of rescue technician. Discriminative power for predicting risk of overuse injuries of the three discussed fitness tests is comparable. To reduce overuse injuries in military service we suggest that physical fitness of some recruits shall be enhanced by systematic training or conscripts with fitness below the cut off values should be assigned to physically less demanding jobs. We finally conclude that ROC curves are a helpful statistical method in the process of determine job requirements in military organisations.

EFFECT OF DIFFERENT RHEPO DOSAGES ON CYCLING PERFORMANCE

ANNAHEIM, S., JACOB, M., KRAFFT, A., BOUTELLIER, U.

HUMAN MOVEMENT SCIENCES

Introduction: The administration of recombinant human erythropoietin (rhEPO) increases maximal as well as submaximal cycling performance (Birkeland et al., 2000; Russell et al., 2002; Thomsen et al., 2007). Less is known about the dose dependency of rhEPO administration on cycling performance and the time course of performance enhancement. Therefore, the aim of the study was to investigate increments in maximal and submaximal cycling performance at different time points and dosages.

Methods: In a double blind, placebo-controlled study design 40 subjects were assigned to 4 groups differing in dosage of rhEPO administered 3 times a week over a 4 weeks period (control [C]: saline injection, low concentration [L]: 20IU rhEPO/kg body mass, medium concentration [M]: 85IU rhEPO/kg body mass, high concentration [H]: 150IU rhEPO/kg body mass). Maximal and submaximal cycling performances were assessed by an incremental test (maximal power output [Pmax] and maximal oxygen consumption [VO2max]) and a constant-load test (time to exhaustion [tlim]) at 85% Pmax of incremental test performed before rhEPO treatment. Data is presented as mean [standard deviation].

Results: After 2 weeks of rhEPO administration, no significant changes in VO2max occurred while VO2max was increased after 4 weeks in H (+5.6 [4.3]%, $p<0.01$) and M (+5.7 [5.1]%, $p<0.01$). This improvement was accompanied by an increase in Pmax for H (+5.8 [4.1]%, $p<0.01$) and M (+2.5 [3.1]%, $p<0.05$) after 4 weeks of rhEPO administration. H and M improved tlim by 69.7 [73.4]% ($p<0.01$) and 44.8 [62.7]% ($p<0.05$), respectively. In contrast to VO2max and Pmax, tlim was already increased after 2 weeks of rhEPO administration for H (+32.1 [28.0]%, $p<0.001$) and M (+22.5 [31.5]%, $p<0.05$). Additionally, C improved tlim by 21.4 [23.8]% ($p<0.05$) after 4 weeks. Changes in Pmax and concomitant alterations in tlim were fitted best by an exponential curve equation ($y=0.033 \cdot \exp [3.577 \cdot x]$, $R2=0.26$, $p<0.001$).

Discussion: Improvements in submaximal cycling performance (tlim) occured after 2 weeks of rhEPO administration already, mainly for high and medium rhEPO dosage. The submaximal performance is enhanced further after 4 weeks of rhEPO treatment where significant improvements in maximal cycling performance (VO2max, Pmax) became apparent as well. This indicates that improvements in submaximal cycling performance are not only due to increased maximal cycling performance (explaining 26% of the variance of increased submaximal cycling performance). Probably other mechanisms, as increased oxygen availability in working muscles and concomitant metabolic changes or direct effects of rhEPO on skeletal muscles, are leading to more pronounced improvements in submaximal compared to maximal performance.

COMPLIANCE WITH THE ACTIVITY GUIDELINES FOR CHILDREN AND ADOLESCENTS IN GERMANY

JEKAUC, D., WOLL, A., WAGNER, M., BÖS, K.

UNIVERSITY OF KONSTANZ

Introduction: Being physically active is an important condition for a healthy development of children and adolescents. Compared to those who are inactive, physically active young people have higher levels of cardiorespiratory fitness, lower levels of body fat, stronger bones and mus-cles, as well as lower anxiety and depression rates (Strong et al., 2005). For this reason, some national governments published specific activity guidelines for children and adoles-cents. In the most recent activity guidelines from the Sport Unit of the European Commis-sion (2008), it is recommended that children and adolescents should have 60 minutes or more of moderate to vigorous physical

activity daily. This study represents a first survey which provides nation-wide representative data for physical activity and sports in Germany.

Methods: The target population of the study are all children and adolescents living and registered in the Federal Republic Germany aged between 4 and 17 years. The participants of the study were recruited in 167 sample points across Germany. The sample consists of 4529 children and adolescents who were tested in regard to physical activity, motor fitness, and health status. The measurement of the compliance with the activity guidelines was con-ducted on the basis of the screening questionnaire by Prochaska, Sallis and Long (2001).

Results and Discussion: Looking at the whole sample, only 15.3% of children and adolescents aged between 4 and 17 years meet the 60-min guideline. The proportion of girls (13.1%) meeting this guideline is significantly (chi2 = 14.0; df = 1; $p < .001$) lower than the proportion of boys (17.4%). Fur-thermore, the results of this study lead to the conclusion that the proportion of children and adolescents who meet the physical activity guidelines decreases with increasing age. Every third child of kindergarten age can achieve this activity guideline, however in primary school the compliance with the activity guidelines is reduced to only every fifth child. With the transition to the secondary school, there are less than 10% of adolescents meeting the 60-min guideline. Finally, in the age group between 14 and 17 years every 20th girl and every 12th boy comply with the activity guideline. These results suggest that only a small percentage of German children and adolescents are sufficiently physically active und em-phasise the importance of endeavours to promote physical activity and sports among chil-dren and adolescents.

MUSCULAR STRAIN RISK FACTORS IN YOUNG SOCCER PLAYERS

VENTURELLI, M., SCHENA, F., BISHOP, D.

UNIVERSITY OF VERONA

Introduction: Soccer is a popular game practiced all around the world by teenagers. However, despite being a relatively safe sport, muscle strain injuries during competitive matches are very common compared to other team-sports. Several studies have previously reported potential intrinsic and extrinsic risk factors for soccer players. These include exposure time to training and matches, increased age, previous injury, joint laxity, lack of training, and low endurance (Arnason 2004). While this information is valuable, few studies, to date, have investigated risk factors for soccer injuries using Cox regression, as recommended by UEFA (Hagglund 2005). The specific advantage of this advanced statistical is that it can be adjusted for actual playing time, which can vary greatly between players in the same team. The aim of this study was to investigate the survivor covariates probability to muscle strains, in young soccer players.

Methods: 75 young soccer players (16.4±1.6 y) were followed for a season (10 months). At baseline, all players were tested for body size e composition; yo-yo endurance test, flexibility, and jump performance (SJ, CMJ and DiHJ=CMJ-SJ). Team coaches and physicians recorded players' exposure (training and matches) and muscle thigh injuries (grade II lesions confirmed by echographic exam). A multivariate stepwise forward Cox proportional hazards model was used to evaluate survival probability predictors, for thigh muscle strains.

Results: Significant correlations were recorded between thigh strain survival probability and: previous injury, field positions (defenders as midfields), height, body mass, BMI, percent body fat, yo-yo step result, SJ and DiHJ. However, the multivariate Cox regression result (Haz. Ratio; C.I. 95%) showed that, only previous injuries 2.74 (1.17-6.40), DiHJ 0.79 (0.72-0.88), and height 1.15 (1.05-1.25) were significantly correlated to thigh strain survival probability.

Conclusion: This study confirms that previous injuries are an important risk factor, as reported by other investigations (Arnason 2004). However, we also found that low jump ability and an elevated players stature increased the probability of a grade II thigh strain. This could be explained by poor player coordination, influencing jumping ability (Bobbert 2001), which may be even more evident in tall young players. An early evaluation, and regular monitoring, of these parameters could assist teams to identify players at high risk who needs to be placed in preventative training programs.

PROTECTIVE EFFECTS CONFERRED BY FOUR BOUTS OF SUBMAXIMAL ECCENTRIC EXERCISE IN COMPARISON TO ONE BOUT OF MAXIMAL ECCENTRIC EXERCISE

CHEN, T.C., CHEN, H.L., LIN, M.J., WU, C.J., NOSAKA, K.

NATIONAL CHIAYI UNIVERSITY

Introduction: A bout of eccentric exercise (ECC) confers protective effects against subsequent bout of more demanding ECC. Our recent study (1) showed that a submaximal ECC bout, in which 30 lengthening contractions with a load of 40% maximal isometric strength (MVC) were performed (40% ECC), conferred 20-60% protection against a subsequent bout of maximal ECC performed 2 weeks later. However, its magnitude of the protective effect was significantly less than that (65-100%) conferred by the maximal ECC. It is possible that repeating

the 40% ECC bouts several times increases the protective effect. This study tested the hypothesis that 4 bouts of 40% ECC performed every 2 weeks would confer similar protective effect to one bout of maximal ECC against subsequent bout of maximal ECC.

Methods: Thirty untrained men (22.2 ± 2.0 y) were placed into two groups (n=15 per group); 4 x 40% (40%) and control (CON) groups by matching the pre-exercise MVC. The 40% group performed 4 bouts of 40% ECC consisting of 30 lengthening contractions of the non-dominant elbow flexors every 2 weeks and 30 maximal lengthening contractions of the same muscle (100% ECC) 2 weeks after the last 40% ECC. The CON group performed two bouts of 100% ECC with the non-dominant arm separated by two weeks. MVC at 6 angles, optimum angle (OA), concentric isokinetic strength (30 and 300°/s), range of motion (ROM), upper arm circumference (CIR), plasma creatine kinase activity (CK) and myoglobin concentration (Mb), muscle soreness (SOR), and echo-intensity (EI) of B-mode ultrasound images were taken before, immediately after, and for 5 days following each ECC. Changes in the measures after 100% ECC were compared between the groups by a two-way repeated measures ANOVA. Changes in the measures after 40% ECC were also compared amongst 4 bouts.

Results: No significant differences in the changes in any measures were evident between the 100% bout of the 40% group and the second 100% bout of the CON group. For the 40% group, changes in all measures except for OA and CIR following the second to fourth bouts were significantly ($P<0.05$) smaller than those after the first bout, but the changes in all measures except for SOR were not significantly different amongst the second, third and fourth bouts. Moreover, compared with the changes after the first 40% ECC, the changes after the 100% ECC were similar for OA, MVC, ROM, CIR, and SOR, but were significantly ($P<0.05$) smaller for CK, Mb and EI.

Discussion: These results showed that the 4 x 40% ECC produced similar protective effect to that conferred by a bout of 100% ECC against 100% ECC. It should be noted that changes in the measures after 40% ECC were always smaller than those after 100% ECC. These results suggest that performing less damaging ECC repeatedly attenuates muscle damage in a similar magnitude to maximal ECC, and this can be used as a strategy to minimise muscle damage.

COMPARISON IN MUSCLE DAMAGE BETWEEN FIRST AND SECOND ELECTRICAL MUSCLE STIMULATION BOUTS OF THE KNEE EXTENSORS

ALDAYEL, A., MCGUIGAN, M., JUBEAU, M., NOSAKA, K.

EDITH COWAN UNIVERSITY

INTRODUCTION: Isometric contractions of the quadriceps femoris evoked by electromyostimulation (EMS) induce muscle damage indicated by decreases in maximal voluntary contraction strength (MVC), delayed onset muscle soreness, and increases in creatine kinase (CK) activity in the blood (1). It is known that muscle damage is attenuated in a subsequent bout eccentric exercise (2). A recent study (3) reported that such adaptation effect was induced in eclectically stimulated eccentric exercise. However, no previous study has examined if this is also the case for muscle damage induced by EMS isometric contractions. Therefore, this study compared between first and second bouts of EMS isometric exercise of the knee extensors for changes in MVC, muscle soreness and tenderness, and plasma CK activity.

METHODS: Nine healthy men (31 ± 4 yrs) with no resistance training experience for the last six months had two EMS bouts separated by 2-3 weeks. One of the knee extensors (randomly chosen) was stimulated by an Intelect Stim (Chattanooga, USA) while seating on a Biodex isokinetic dynamometer with the knee joint angle of 100° (0°: full extension). Four self-adhesive electrodes were placed on the anterior surface as follows: 2 positive electrodes over the motor point of the vastus lateralis and vastus medialis, and 2 negative electrodes on the proximal portion of the quadriceps femoris. Forty isometric contractions were induced by EMS with biphasic rectangular pulses (75 Hz, 400 μs, on-off ratio 5-15 s), while the current amplitude was consistently increased throughout contractions until maximal tolerable level. Criterion measures consisted of maximal isometric strength at 100°, muscle soreness (a 100-mm visual analogue scale), pressure pain threshold of the muscles, and plasma CK activity. These measures were taken before and 1, 24, 48, 72 and 96 h after EMS bout. Changes in the measures over time were compared between bouts by a two-way repeated measures ANOVA with a Tukey's post-hoc test.

RESULTS: The evoked torque produced during both bouts was approximately 30% of MVC, and no significant difference between bouts was evident for the changes in torque over 40 contractions. MVC decreased significantly ($P<0.05$) by 26% at 1 h after both bouts, but the recovery was significantly ($P<0.05$) faster after the second bout (100% at 96h) than the first bout (81% at 96h). Development of muscle soreness and increases in CK were significantly ($P<0.05$) smaller after the second bout than the first bout.

DISCUSSION: These results showed that the second bout resulted in less muscle damage than the first bout. This adaptation is similar to that shown in eccentric exercise-induced muscle damage (2,3). It appears that the protective adaptation is induced locally rather than centrally.

DELAYED ONSET MUSCLE SORENESS AFTER LOW-INTENSITY RESISTANCE EXERCISE WITH AND WITHOUT VASCULAR OCCLUSION

WERNBOM, M., RAASTAD, T., PAULSEN, G., NIELSEN, T.S., KOSKINEN, S., AUGUSTSSON, J.

LUNDBERG LABORATORY FOR ORTHOPAEDIC RESEARCH (GOTHENBURG, SWEDEN), NORWEGIAN SCHOOL OF SPORT SCIENCES (OSLO, NORWAY)

Introduction: Strength training with low loads in combination with vascular occlusion may induce moderate to severe delayed onset muscle soreness (DOMS) (Wernbom et al, 2006). Because DOMS after occlusion training has been largely unreported in the literature, we decided to review DOMS data collected from two recent experiments conducted in our laboratories.

Methods: In Experiment 1, ten subjects performed three sets of dynamic unilateral knee extensions with (randomized limb) and without (contralateral limb) cuff occlusion, at a load of ~30% of 1RM. For each limb, all sets were performed to concentric torque failure.

In Experiment 2, seven subjects performed five sets of dynamic unilateral knee extensions with and without cuff occlusion, at a load of ~30% of 1RM. The occluded limb performed all sets to failure, while the non-occluded contralateral limb was matched to perform exactly the same number of repetitions in each set as the occluded limb.

In both trials, a wide cuff was used, the occlusion pressure was 90-100 mm Hg (~50-60% reduction of femoral blood flow at rest) and the pressure was maintained between sets. The inter-set rest period was 45 seconds in both trials. The number of repetitions performed per set and in total were counted as a measure of the volume of work. DOMS was rated with a 0-10 visual-analog-scale (VAS) pre and post-exercise (at 0, 24, 48, 72, 96 and 120 hours).

Results: In Experiment 1, the total number of repetitions was 76 for the non-occluded limb and 53 for the occluded limb ($p<0.05$ for the difference in volume). The VAS-ratings peaked at 48h and reached a higher value for the non-occluded limb (5.0) than the occluded limb (3.3) ($p<0.05$).

In Experiment 2, the total number of repetitions was 57 for the occluded limb (and thus also for the non-occluded limb). The VAS-ratings peaked at 48h and reached a higher value for the occluded limb (6.2) than the non-occluded limb (5.3) ($p<0.05$).

Discussion: Both training with and without cuff occlusion resulted in DOMS and one likely explanation is that relative ischemia occurred even in the non-occluded condition (Wernbom et al, 2008). Collectively, the results indicate that both volume and the level of effort are important factors for muscle soreness induced by low-intensity ischemic strength training. Interestingly, new data suggests that the muscle activity increases not only during the concentric phase, but also during the eccentric phase as the point of torque failure draws closer, which may contribute to the DOMS (Wernbom et al, 2009). We are currently investigating muscle damage and recovery from an acute bout of occlusion training at the cellular level.

INFLUENCE OF COMPETITIVE LIFTING TASKS ON PLASMA CONCENTRATION OF BIOCHEMICAL CARDIAC MARKERS

TSCHAN, H.

INSTITUTE OF SPORTS SCIENCES

Introduction: The fear of damage to the cardiovascular system has led most exercise specialists to urge against any breath holding during resisted exercise. Possible detrimental effects include an increase in ventricular diastolic pressure and wall stress, possibly leading to unfavourable remodelling, myocardial ischemia and malignant arrhythmia. Circulating levels of the specific cardiac marker NT-proBNP reflect ventricular diastolic wall stress and are strongly related to mortality. The purpose of this study was to evaluate the effects of static and heavy lifting tasks (weightlifting and power-lifting exercises) on the plasma concentration of NT-proBNP a levels and on other bio-chemical cardiac markers in trained weightlifters.

Methods: 12 healthy well trained weightlifters (national class) performed 6 sets of 6 lifting exercises (snatch, clean, jerk, squat, deadlift, bench-press) with the goal to lift as much weight as possible. Blood samples were drawn from each subject 1 hour before the exercise training as well as immediately after finishing the exercise test and 2 hrs post-exercise. For detection of myocardial and skeletal muscle damage cardiac Troponin I (cTnI), total creatine kinase activity (CK) and myoglobin (Myo) were measured. Serum concentrations of cTnI and myoglobin were measured by immunassays total CK activity by routine photometric assay. For detection of myocardial overload NT-proBNP was analyzed within 24 hours using an electrochemiluminescence immunoassay. A one-way ANOVA with repeated measures was used to detect changes over time. The Tukey Honestly Significant Differences (HSD) post-hoc test was used to determine the location of differences when significant main effects were detected.

Results: Beside cTnI all markers showed significant elevations ($p < 0.05$-$p<0.001$) over the time course of the 3 blood draws. A significant percentage of laboratory parameters analyzed in this study (CK and Myo) were outside the reference ranges. However, the sensitive and specific biochemical markers for detecting myocardial damage (cTnI and NT-proBNP) stayed within the reference ranges and tended to decrease toward baseline levels already 2 hrs after exercise training.

Conclusion: From the present study it would appear that heavy resistance exercise is well tolerated by experienced weightlifters without showing any evidence that lifting tasks damages the myocardium. The elevation of the non-specific markers (CK and Myo) may reflect a transient inflammation-like response (mild tissue trauma of the skeletal muscles) following the very intense acute exercise.

TRAINING SPECIFIC ADAPTATIONS OF CONSTITUTIVE AND STRESS-INDUCIBLE HEAT SHOCK PROTEIN GENES IN TRAPEZIUS MUSCLE OF FEMALES WITH CHRONIC NECK MUSCLE PAIN

SJØGAARD, G., ZEBIS, M.K., KIILERICH, K., PILEGAARD, H., SALTIN, B.

UNIVERSITY OF SOUTHERN DENMARK

The prevalence of work-related chronic neck muscle pain has been steadily increasing through the past two decades and is particular frequent in the trapezius muscle, TM, among females with repetitive tasks. Physical exercise has been recommended as treatment to relieve neck muscle pain. However, the actual effect of various physical exercises on stress related gene profile of the painful TM is unclear. The potential role of heat shock proteins, HSPs, in preserving cells from stress and preparing them to survive various types of environmental challenges suggests that these proteins could also play a relevant role in mediating suitable adaptive response of skeletal muscle to physical exercise.

In a randomized controlled study, 25 female office workers with a clinical diagnosis of TM myalgia were assigned to either 10 wks of specific strength training of the TM, SST, general fitness training in terms of leg cycling only, GFT, or a reference intervention without physical activity, REF. Muscles biopsies were taken from the TM before and after 10 wks intervention and mRNA levels for the stress-related proteins HSP70 and HSP72 were measured.

At baseline the median values (5th - 95th percentile) mRNA content for HSP70 was 0.25 (0.09 – 0.59) and for HSP72 0.25 (0.08 – 0.49) expressed relative to single-stranded DNA content. After 10 wks intervention mRNA content for HSP70 decreased (~30%) in the SST group only ($P=0.066$), while HSP72 decreased (~40%) in SST ($n = 9$, $P= 0.041$) as well as GFT ($n= 10$, $P = 0.80$), while no changes occurred in the REF.

A novel finding of the present study is that 10 wks of SST lowered mRNA concentration of the stress-inducible HSP72 as well as the constitutive HSP70 in females with work-related TM myalgia. Strength training is associated with changes in protein synthesis and degradation, and since HSPs assist in these processes, the expression of HSP could increase initially but decline in the later phase of the training period. Mechanisms exist, which are able to attenuate the HSP response and the observed down-regulation of HSP mRNA content in the present study may reflect an improved cellular homeostasis of TM fibers. The GFT intervention also lowered the HSP72 mRNA content. Induction of stress protein synthesis after moderate-intensity exercise may occur in both active muscle and in less active muscle, indicating that the signal which initiates the stress response is produced by and affects the whole body. The existence of a generalized response of skeletal muscle to physical stress could explain the present finding in GFT, which did not involve exercise of TM, that HSP72 mRNA content in TM was lowered after a prolonged training period. In conclusion: The decrease in stress-inducible HSP72 mRNA content after 10 wks SST and GFT supports the notion of systemic signaling. However, only SST decreased the constitutive HSc70 underlining the significance of involving the painful muscle in training for improved cellular homeostasis.

TRAINING EFFECTS ON THE CHARACTERISTICS AND BEHAVIOUR OF HUMAN MOTOR UNITS

DUCHATEAU, J.
UNIVERSITE LIBRE DE BRUXELLES

The force generating capacity of an isolated muscle is strongly associated with its cross-sectional area. However, the strength produced during natural movements depends on the extent to which a muscle and its synergist and antagonist are activated by the nervous system (2). Although strength training is known to induce hypertrophy of the muscle fibres, some studies have suggested that increase in voluntary activation can also contribute to the improvement in performance. A greater activation can be the result of a more complete recruitment of motor units (ensemble comprising a motor neurone, its axon and the muscle fibres innervated by this axon) and/or an increase in discharge rate. In addition to the increase of the force produced by each motor unit after training (3), recent evidences indicate that the maximal discharge rate attained by motor unit is enhanced without any change in synchronization (4). This neural adaptation occurs mainly at the beginning of a training programme.

In many sports and activities of daily life, the ability to rapidly develop force is equally important, or even more important, than the maximal force itself. Movements that are performed with maximal velocity are usually defined as ballistic actions (1). The maximal rate of force development during a ballistic contraction is not only limited by muscle speed-related characteristics, but also by neural factors. Among them, the capacity of the nervous system to recruit a great percentage of the motor unit pool at the onset of muscle activation and to drive these units at a high discharge rate is an important aspect. In that context, it has been demonstrated that dynamic training consisting in rapid contractions against a small load (30-40% of maximum) augments both the rate of force development and the instantaneous discharge rate of motor units (5). In addition to the latter adaptation, the incidence of doublet discharges with an interval of less than 5 ms is increased. These neural changes, that contribute to enhance the maximal rate of force development, appear to adapt specifically to the training conditions. Together, these findings show that, in addition to intrinsic adaptations of the muscular system, the rate of force development during a ballistic contraction is modulated by chronic changes in motor units discharge pattern.

The presentation will synthesize current understanding on motor unit characteristics and behaviour during voluntary contraction and then evaluates the adaptations to strength and power training. The specificity of training adaptations will be highlighted.

TIME COURSE OF NEUROMUSCULAR ADAPTATIONS TO STRENGTH TRAINING

NARICI, M.V., SEYNNES, O.R.
MANCHESTER METROPOLITAN UNIVERSITY

The initial strength gain in resistive training (RT) is generally considered to be due to the intervention of neural factors while the contribution of hypertrophic factors occurs several weeks later (7). Indeed, a rapid increase in EMG activity occurs within few weeks of RT (3,6) whereas muscle hypertrophy seems to appear only after 8 to 12 weeks (4,6). However, considering that the molecular and cellular responses occur within hours or even minutes of a single bout of RT (1, 9) and that fibre hypertrophy is detectable within 4 weeks of training (10), the alleged delay in the onset of muscle hypertrophy seems mostly due to the sensitivity of the muscle size assessment method. Proliferation of muscle satellite cells has been found within 4 days of a single RT bout, sustained by an increase in myofibrillar protein synthesis within few hours of exercise (5). Hence these two fundamental adaptations necessary for muscle hypertrophy start in the very initial phases of RT, pointing to a progressive rather than to a 'sudden' increase in muscle. This scenario is consistent with the results of a recent 5-week, high-intensity, concentric/eccentric RT study in young males (8). In addition to the well expected increase in muscle strength and neural drive (EMG), changes in muscle architecture (assessed by ultrasound), indicating a rapid addition of sarcomere in series and in parallel, were found within 15 days of RT and gross muscle hypertrophy (assessed by MRI) was detectable after just 20 days of RT. This rapid skeletal muscle remodeling is probably modulated by changes in mechanosensitive proteins such as focal adhesion kinase whose content and activity increase within few days of overloading (2). These recent findings show that RT induces an immediate myogenic response leading to early structural alterations and suggest that the development of muscle hypertrophy is a progressive, rather than a delayed, process.

INHIBITORY AND FACILITATORY MECHANISMS WITH RESPECT TO STRENGTH AND POWER TRAINING

TAUBE, W., GOLLHOFER, A.
UNIVERSITY OF FREIBURG

Apart from muscle morphology, architecture and fiber type, the magnitude of efferent as well as afferent neural drive influences the capacity to produce maximal force (7). Increases in strength therefore depend on the facilitation of the efferent drive and/or the improved utilization of afferent excitation. To start with the second point, it is unlikely that strength training modulates the sensory information per se. Training may rather improve the integration of afferent excitation into the voluntary drive. Previous studies using electrical nerve stimulation support this assumption by showing enhanced spinal reflex excitability after strength training. This adaptation seems to be irrespective of the exact kind of strength training; i.e. increased H-reflexes were observed after ballistic (9), maximal isometric (6) and dynamic strength training (1). The most likely mechanism to explain this improved utilization of afferent Ia excitation is a reduction in presynaptic inhibition.

Adaptations on the efferent side are less well understood. Based on V-wave measurements, Aagaard et al. (1) assumed increased supraspinal drive after strength training. Although this seems plausible, it still has to be shown which part of the brain contributes to an enhanced drive. Strength training studies using transcranial magnetic stimulation (TMS) showed either i) reduced (5), ii) increased (3), iii) unchanged (2) or iv) task specific (8) modulation of corticospinal excitability. The differential outcomes were speculated to depend on the experimental condition, the tested muscle(s) and/or the training regime and were often taken as evidence for minor contribution of the motor cortex (M1) in adapting MVC after strength training. However, in a recently conducted study, the output of M1 was lowered during the performance of strength exercises by means of repetitive TMS (4). The authors speculated that if M1 was responsible for strength adaptations, inhibition of M1 would reduce strength gains. As this was actually the case it seems that increases in MVC after strength training rely on sufficient efferent drive of M1 during training. So far, little is known about neuroplasticity in other supraspinal structures.

In summary, strength training probably induces disinhibition at the spinal level leading to facilitation of spinal reflexes. On the other hand, motor cortical activity seems to be important during strength training but it is not clear whether increased MVC is dependent on facilitation of the corticospinal drive.

IS-BM07 Cycling

THE BIOENERGETICAL AND BIOMECHANICAL HISTORY OF CYCLING

MINETTI, A.E.
UNIVERSITY OF MILAN

Similarly to the evolutionary struggle towards global mobility observed in animal species on a much wider time scale, human ingenuity has worked to circumvent the inherent limitation of a given musculo-skeletal system to enhance mobility and speed. In about a century (1817-1890 CE) the very first individual means of transport moved just by human power, the bicycle and its precursors, has been invented and rapidly developed up to a standard design that was only refined successively. From the 'Hobby Horse' to modern bikes, a short time scale evolution in manufacturing technology has solved a progression of physiological and biomechanical problems related to how to make the best use of the same muscles in spite of an increasing progression speed. By arranging a set of experiment where the same group of subjects rode replicas of the most significant bicycle models appeared as breakthrough in the 19th century, it was possible to dissect the relevant components of the mechanical work as determinants of the metabolic energy required to travel at the same speeds. This resulted in a study (Minetti et al 2001) about the evolutionary improvement in bicycling economy and its biomechanical explanation. The total mechanical work has been calculated as the sum of the 'external' component, due to the need to overcome rolling resistance and air drag, and the 'internal work', related to the movement of the lower limbs with respect to the body centre of mass (BCOM) during pedalling. The general conclusion from that study was that each newly invented bicycle model, while changing the partitioning of the three work components associated to a higher travelling speed, allowed muscles to operate at the same, maximal contraction efficiency.
A later investigation (Minetti 2001) on the metabolic equivalent of the internal work in cycling seemed to confirm the validity of the model equation designed for the historical study. A more accurate biomechanical analysis suggested that, despite the minimal change in BCOM due to pedalling, most of the internal work is devoted to maintain constant the angular speed of the chain wheel. Another important and often neglected component of the internal work, namely the joint/tissue friction, could contribute to better explain the overall economy of cycling.

FACTORS AFFECTING CYCLING CADENCE CHOICE AND CADENCE INFLUENCE ON PERFORMANCE

HANSEN, E.A.
NORWEGIAN SCHOOL OF SPORT SCIENCES

A considerable interest among researchers, coaches, and cyclists for cadence choice during submaximal cycling dates nearly 100 years back (Benedict & Cathcart, 1913). The current knowledge of factors affecting the freely chosen cadence and of the influence of cadence choice on performance has been summarized recently (Hansen & Smith, 2009). In particular, within the past 10 years, a number of papers brought novel insight into the topic. For example, under the influence of central pattern generators, which are constituted of neural networks in the spinal cord, a robust innate voluntary motor rhythm has been suggested as the primary basis for rhythmic movements (Zehr, 2005) including freely chosen cadence (Hansen & Ohnstad, 2008). This might clarify the cadence paradox, which has been described as the freely chosen cadence during low to moderate submaximal cycling being considerably higher and thereby less economical than the energetically optimal cadence (Kohler & Boutellier, 2005). Despite that central pattern generators apparently are important for the robust and highly individual base of the freely chosen cadence during submaximal cycling, the possible influence of factors internal and external to the cyclist on the choice of cadence under certain circumstances should be acknowledged. Thus, a number of factors including for example age (Balmer et al., 2008), power output (Hansen et al., 2002), and road gradient (Lucia et al., 2001), have been reported to affect the choice of cadence to some extent. But, it is likely that, during unrestricted pedalling, sensory feedback of changes to external conditions as well as internal conditions merely fine-tunes the innate motor rhythm. Finally, as to cadence influence on performance; during high intensity cycling, close to the maximal aerobic power output, cyclists choose an energetically economical cadence (Brisswalter et al., 2000) that is also favourable for performance (Nesi et al., 2004). However, the choice of a relatively high cadence during cycling at low to moderate intensity is energetically uneconomical and could compromise performance during prolonged cycling (Hansen et al., 2006).

THE PULL UP ACTION IN CYCLING: IMPLICATIONS FOR PERFORMANCE AND TRAINABILITY

MORNIEUX, G.
UNIVERSITY OF FREIBURG

Introduction: The pull up action in cycling refers to the ability to apply an effective pedal force (i.e. tangential to the crank displacement and in the same direction than its rotation) during the upstroke phase. However, it is questionable to which extent this action would be beneficial for the performance. Takaishi et al. (1998) have reported lower oxygen uptake for elite than for recreational riders. They argued that lower oxygen uptake was associated with a greater pull up action. Hence, training this pull up action might be relevant. It has been showed that a feedback training (instantaneous representation of the pedal forces profiles while riding) would allow modifying the pedalling pattern (Sanderson and Cavanagh, 1990). Therefore the aim of this study was to determine i) to which extent the pull up action might be beneficial for performance in cycling and ii) how it could be trained.

Methods: Elite and recreational cyclists were measured on a SRM ergometer, instrumented with 2D pedal forces transducers (Powertec). Oxygen uptake and electromyography for different relevant muscles were recorded. Subjects rode either with single pedal, clipless, or clipless and the pedal force feedback. This feedback allowed subjects controlling their pull up action. Finally subjects participated to a training study with this feedback (2x a week/6 weeks).

Results: Results have showed no significant difference for all aforementioned parameters for both cyclist groups when cycling with clipless vs. without. However, using feedback enhanced significantly the effective pedal force during the upstroke while increasing also the oxygen uptake. With feedback, tibialis anterior, rectus femoris and biceps femoris activity increased significantly. Furthermore, timing parameters (on/off) for these muscles changed. After 6 weeks feedback training, subjects altered significantly their pedalling pattern. Indeed, pedal forces were higher during the upstroke and therefore lower during downstroke, whatever the power output tested (i.e. 100, 200 and 300Watts). The control group, which trained without feedback, did not show such changes.

Discussion: Clipless did not allow any pull up action during sub-maximal cycling. However, pedalling with feedback helped to achieve this pull up action and changed therefore the pedalling pattern. Unfortunately, this increase in pedalling effectiveness also impaired oxygen uptake, as reported by Korff et al. (2007). As a consequence, even if the pull up action seems to have benefits for pedalling mechanics, performance might rather be impaired, at least as long as subjects are not used to this action.

After a pull up action training, subjects had learned how to pull up on the pedal. Therefore it is possible to change the pedalling pattern and to enhance the pull up action.

IS-BM06 Biomechanics in Alpine Skiing

MEASURING TECHNOLOGY AND PHYSICS IN ALPINE SKI RACING

SUPEJ, M.
SWEDISH WINTER SPORTS RESEARCH CENTER, OSTERSUND, SWEDEN AND FACULTY OF SPORT, UNIVERSITY OF LJUBLJANA, LJUBLJANA, SLOVENIA

Evaluating performance in top level ski racing is crucial for improvement of the athletes. This is the area, which is normally covered by physics and/or technology. To use physics and technology to the highest extend, it is important to understand the scheme of approaching the problem. If one scale of the world is investigated, then one scale bellow should be understood. For example, when we would like to evaluate skier's velocity (kinematics), we should understand the acting forces (dynamics), which are the reason for the movement. This is "one scale bellow". To continue, the skier is affected by gravity, ground reaction force including the friction, air drag etc. To understand whether these are strong or weak, another "scale bellow" should be investigated, e.g. for air drag the fluid dynamics, for friction the turn and gliding principles, material and snow properties. The further we investigate, closer to the atomic or subatomic scale we come.

As an example of this approach in physics and technology, the consequence of carving entering WC races will be discussed. The changes occurred in the turning principles, i.e. carving instead of skidding, therefore basic physical parameter values several "scales bellow" were altered. Therefore, it was inevitable that the whole structure up to the racing technique was needed to be adopted. Basics steps of the mechanical modelling of the "new" single motion technique (Supej et al., 2002), its evaluation by computer simulation, forces measurements and performance measurements comparing to the "old" double motion technique will be presented.

The details in performance are important, even when the racing technique is known. There physical principles of mechanical energy can be used, more specifically: diff(e-mech) (Supej, 2008), which represents "one scale bellow" the velocity and time that are normally used to classify the racers. The latest technology, i.e. high end GNSS RTK system, can be used to measure and calculate diff(e-mech). But GNSS devices survey only the antenna position and not the skier's CG. The CG can be approximated by improved methodology of measurement and mechanical modelling (Supej et al., 2008).

There are also many other examples in alpine skiing, where physics and technology are working hand in hand. Beside that, most of the sensors work on physical principles. To conclude, physics and technology are deeply related.

MECHANICAL ENERGY DISSIPATION, MOVEMENT, AND PERFORMANCE CHARACTERISTICS IN COMPETITIVE ALPINE SKIING

REID, R., GILGIEN, M., KIPP, R., HAUGEN, P., SMITH, G.
NORWEGIAN SCHOOL OF SPORT SCIENCES

INTRODUCTION: In 2005, Supej et al. [1] introduced a method of computing the mechanical energy losses of a skier to his surroundings as a measure of turn quality. Characterizing how elements of technique influence energy loss may help our understanding of how technique and performance relate. The purpose of this study was to describe the time-course of ski and center of mass (COM) motion characteristics and their relationships to both mechanical energy dissipation (EDISS) and performance in slalom.
METHODS: Six members of the Norwegian men's national team were analyzed through 2 turns during race simulations on 2 courses set with 10 and 13 m distances between gates. 3-D positions were captured from 4 cameras and control points distributed near the course [2]. Skier mechanical energy was determined knowing COM velocity and altitude. EDISS was calculated by differentiating mechanical energy with respect to altitude [1]. Pearson product moment correlation coefficients (r) were calculated to assess the relationship of instantaneous measures of COM fore/aft position and outside ski attack angle (γSKI) with EDISS. Average fore/aft position, fore/aft range of motion, amplitude of COM vertical motion and average initiation phase γSKI were compared to performance time using Spearman rank correlation coefficients (ρ).
RESULTS: Skier fore/aft position correlated strongly with both performance (ρ=1.0) and EDISS (r=.73, p<.001) on the 10 m course but less strongly on the 13 m course (ρ=.72, p=.10 & r =.54, p<.001, respectively). Significant correlations were observed between the amplitude of COM vertical motion and performance on both the 10 (ρ=.83, p=.04) and 13 m (ρ=.79, p=.06) courses, with the faster skiers having smaller amplitudes. Initiation phase γSKI was not significantly correlated to performance on either course (ρ=.26 and .34 for the 10 and 13 m courses, respectively). Correlations between instantaneous γSKI and EDISS were r=.29 and .01 for the 10 and 13 m courses, respectively.
DISCUSSION: While the time correspondence of skier fore/aft position and EDISS was high on the 10 m course, the relationship was less clear for the 13 m course. This may be related to the larger γSKI observed on the 10 m course. The strong correlations on both courses between vertical displacement and time suggest that vertical motion plays an important role in performance. Since it is the ground reaction force that turns the skier, excessive unloading from the snow surface due to increased vertical motion is likely to delay turning and thus be detrimental to performance during rapid turn transitions. The low correlations between γSKI and EDISS are surprising, and suggest that though skidding may influence EDISS, other factors may play a greater role.

TASK VARIATION AS A CRUCIAL POINT IN TECHNIQUE TRAINING OF ALPINE SKI RACERS

KRÖLL, J., BIRKLBAUER, J., MÜLLER, E.
UNIVERSITY OF SALZBURG

Variability, which traditionally (and from traditional motor learning perspectives) has been considered to be noise and detrimental to normal function, has more recently been considered to be an essential element to offer flexibility in adapting to perturbations (Hamill et al 1999). Therefore a crucial point of modern methods in motor learning is a high degree of task variations.
According to Bernstein (1967) our central nervous system has a compensation function between necessary movement forces and reactive phenomena (gravitation, inertia, forces stored in muscle-tendon-unit). Altering these reactive phenomena requires different neuromuscular patterns for an appropriate movement outcome. In Alpine ski racing we have movements which have constantly cyclic components (turn by turn), but, compared to other cyclic movements (e.g. running), external circumstances which alter reactive phenomena in a distinct amount (e.g. snow conditions).
With regard to technical training of elite alpine skiers our aim is to find task variations which additionally alter those reactive phenomena, but not exceed the solution space for ski racing. Therefore the interpolation ability to adequately adapt to new situations should be improved. To fulfill these requirements, two specific training devices were developed and evaluated by comparing some task variations to normal ski racing.
The first device is a ´see-saw´ based plate between the binding and the ski (Sensowip, Kröll et al 2006). The plate can be cushioned by springs or fixed with an inclination in sagittal plane. The second device is a system based on elastic cords fastened between joints acting as constraints to increase the degree of freedom and consequently the alteration of reactive phenomena (Tendybelt). This device is not exclusively designed for alpine skiing as studies on running and volleyball were performed recently with similar theoretical background (e.g. Haudum et al 2008).
In the current presentation, kinetic variations of several settings (3 SensoWip tasks; 3 Tendybelt tasks) compared to the normal situation (case studies) and the influence on runtimes during a training session (n=7) will be presented. Strong effects in all six tasks were found for the force distribution in sagittal plane (up to 25%, eta2=.74), while the overall force distribution between inside and outside was only marginally influenced (up to 3%, eta2=.09). The influence on runtimes was in 4 tasks significant but in all cases lower than 6%.
It can be concluded that the use of the two devices alters substantially the reactive phenomena, while the solution space for ski racing technique is not exceeded. Hence, the devices generate movement variations similar to that recommended for modern technical training.

OP-MB02 Molecular Biology 2

ALTERATION OF MUSCLE FIBRE COMPOSITION IN MALE JUNIOR ELITE ROAD CYCLISTS OVER THE COMPETITION PERIOD

FRESE, S., LOOSER, P., GEHLERT, S., BOELCK, B., BLOCH, W.

GERMAN SPORT UNIVERSITY COLOGNE

The cellular specialization of skeletal muscle fibres enables remodeling of the muscle's structural makeup according to alterations in functional demand. The capability to load-dependent muscle fiber type specific adaptations demonstrates the enormous plasticity of human skeletal muscle and the specificity of the adaptive response.

Close to the annual road cycling exercise planning we focused on the competition period to investigate the chronic skeletal muscle response to endurance exercise after the repeated impact of stimuli that occurs with competition and training performance.

The aim of this study was to investigate the activity-dependent muscle plasticity allowing for phenotypic stimuli and consequent muscular modifications.

Ten male elite cyclists (18.1±0.57yr) participated in this study. They had a history of >5yr of race experience and were part of competitive cycling teams at national level. In february (Pre) before beginning of the competition period and at the end in october (Post) the subject's performances have been tested by an incremental cycling step test to exhaustion. There was a spirometry and lactate survey. After the following two days each with a moderate cycling endurance exercise (~60-65% of subject's V˙o2peak;~90-120min) standardized muscle biopsies were taken of vastus lateralis muscle by needle biopsy the third day. The analysis of fibre composition was effected by histochemical ATPase-staining.

The muscular monitoring over the competition period illustrates no difference in mean value of the absolute ratio of fast twitch (Pre:36.29±2.56%;Post:41.14±9.99%) and slow twitch fibres (Pre:63.71±2.56%;Post:58.86±9.99%). But remarkable is the individual big range of relative remodelling of fibre types IIA and IIX within the fast twitch fibre spectrum.

Estimable is the fibre pattern of two subjects with a reduction of fatigue-resistance phenotype decreased by 31% and an accession of fibre type II increased by 59% compared with Pre ($p<0.05$).

However the analysis of fibre composition shows muscular modifications of the fast twitch fibre distribution-the rate of slow twitch fibres remains nearly constant.

In conclusion, the profile of muscle perturbation exerts essential control over the muscle phenotype. After execution of the extensive endurance winter training the subjects have a divergent fibre spectrum from the competition period. The chronic response to high intensity sessions over the competition period shows the cellular specialization that allows the recruited muscle fibres to adjust its metabolic and contractile makeup in response to alterations in functional demands. Thus we have to think about the extensive winter exercise regime and an improvement of exercise regulation that pass into the competition period.

THE REGENERATIVE CAPACITY OF SKELETAL MUSCLE IN EXPERIENCED ENDURANCE RUNNERS

COLLINS, M., RAE, D.E., VIGNAUD, A., LINSTRÖM, M., THORNELL, L.E., BUTLER-BROWNE, G.S., SINCLAIR-SMITH, C., DERMAN, E.W., LAMBERT, M.I.

SOUTH AFRICAN MEDICAL RESEARCH COUNCIL, UNIVERSITY OF CAPE TOWN (SA), RED CROSS CHILDREN'S HOSPITAL (SA), UNIVERSITY OF PARIS (FRANCE), UMEÅ UNIVERSITY (SWEDEN)

Purpose: The muscle of distance runners has presumably sustained numerous cycles of exercise-associated damage and regeneration or remodelling. Whether this interferes with the finite regenerative capacity of the skeletal muscle in asymptomatic runners is not known. To assess the chronic effects of a large exposure to running on muscle, this study compared markers of remaining regenerative capacity in the muscle of experienced endurance runners to that of sedentary controls.

Methods: Biopsies of the vastus lateralis muscle from 19 experienced endurance runners (ATH) (mean age: 43±7 years) were compared to those of 19 sedentary individuals (SED) (mean age: 39±10 years). The runners had covered approximately 50 000 km in training and racing over 15 years. Laboratory analysis determined the proportion of satellite cells present, terminal restriction fragment (TRF) lengths and morphology of the muscle samples.

Results: The proportion of satellite cells (number of satellite cells per number of myonuclei) present in the muscle of the runners was similar to that of the controls (ATH 3.8 ± 1.5 % vs CON 3.0 ± 0.7 %, $p=0.377$). There were also no differences in the minimum TRF lengths (ATH 6.9 ± 0.9 kbp vs CON 7.0 ± 0.8 kpb, $p=0.805$), in the muscle of both groups. The minimum TRF length of the runners was, however, inversely related to their years in distance running ($r= -0.63$, $p=0.007$) and hours spent training ($r=-0.51$, $p=0.034$).

Conclusion: The remaining regenerative capacity of the muscle of experienced runners was no more compromised than that of sedentary individuals despite the increased demand for skeletal muscle repair, regeneration and adaptation. Skeletal muscle appears to be a robust organ with sufficient capacity to tolerate large exposures to endurance running.

ULTRA-ENDURANCE EXERCISE AND DNA STABILITY: ROLE OF INFLAMMATORY AND ANTIOXIDANT RESPONSES

NEUBAUER, O., REICHHOLD, S., KÖNIG, D., KNASMÜLLER, S., WAGNER, K.H.

1. UNIVERSITY OF VIENNA, 2. FREIBURG UNIVERSITY HOSPITAL, GERMANY, 3. INSTITUTE OF CANCER RESEARCH, MEDICAL UNIVERSITY OF VIENNA

Introduction: Exhaustive endurance exercise has been shown to induce both a systemic inflammatory response as well as DNA damage. Hypothetically, exercise-induced DNA damage might either be a consequence of inflammatory processes or causally involved in inflammation and immunological alterations after strenuous prolonged exercise. Nevertheless, experimental data regarding a direct relation-

ship are lacking (3). One primary aim of the present study was to test this hypothesis and whether there is a further interaction of oxidative stress (OS) and antioxidant (AO) responses following an Ironman (IM) triathlon.

Methods: Blood samples were taken from 42 male triathletes (mean±SD: age: 35.3±7.0 yr, cycling VO2 peak: 56.6±6.2 ml kg-1 min-1) 2 days (d) before an IM, then immediately, 1, 5, and 19 d post-race. Blood was analysed for inflammatory, immune-endocrine responses, muscle damage, OS markers, endogenous and exogenous AOs and plasma AO capacity (1, 2). 20 and 28 subjects were randomly selected for the assessment of DNA and chromosomal stability in lymphocytes measured via the cytokinesis block micronucleus cytome (CBMN Cyt) (4) and the single cell gel electrophoresis (SCGE) assays (including lesion specific enzymes), respectively. Correlation, one-factorial ANOVA and post hoc analyses were applied to assess potential associations.

Results: The IM induced a pronounced initial systemic inflammatory response (2). Concomitantly with a transient increase in most OS markers there were strong AO responses (1). Increased DNA instability was detected by the SCGE technique, but these changes were temporarily. Endpoints within the CBMN Cyt assay actually decreased post-race (4). No associations were found between endpoints of DNA stability and inflammation or muscle damage (3). Endonuclease III-sensitive sites correlated negatively with the oxygen radical absorbance capacity immediately ($r = -0.54$; $P<0.01$) and 1 d post-race ($r = -0.65$; $P<0.05$).

Discussion: The current results indicate that DNA effects in lymphocytes are not responsible for exercise-induced inflammation and, that inflammatory processes do not directly promote DNA damage. However, our data suggest that training- and/or exercise-induced responses in the AO defences might have prevented DNA damage through reactive oxygen species derived from inflammatory cells.

SEX DIFFERENCES IN MUSCLE PROTEIN SIGNALLING

HAWKE, E., EDGE, J., DENT, J., MUNDEL, T., SHORT, M.J., MCMAHON, C., COFFEY, V.

UNIVERSITY OF VERONA

The number of women participating in team-based sports is rapidly increasing and therefore, identifying sex differences in training adaptations warrants investigation. Repeated-sprint (RS) ability has been shown to be an essential fitness component in many team based sports, therefore training methods include RS training aimed at optimising the athletes ability to perform RS efforts. While the adaptive effects of endurance and resistance training have been well researched, the effects of RS training on muscle protein synthesis are not well known. Few studies to date have investigated these effects in females, despite clear gender differences in adult human muscle mass and possible substrate utilisation differences during exercise between males and females. The purpose of this study was to determine the effects of a RS bout on muscle signalling and blood measures in well-trained male and female footballers.

Eight female and seven male senior football players (Mean ± SD, age, 19±1 y, VO2peak 53.0±5.1 ml•kg-1min-1) and seven male senior football players (Mean ± SD, age, 19±3 y, VO2peak 59.0±6.6 ml•kg-1min-1) performed four bouts of 6 x 30m maximal sprints spread equally over a 40 minute period. Sprint time was measured at 30m for each sprint. Muscle biopsies (vastus lateralis) and venous blood samples were taken at rest, 15 min following exercise and 2 h into recovery. Venous blood samples were taken at the same time points as the biopsies.

There were no differences ($P > 0.05$) between the female and male athletes in blood lactate response to RS or HR attained at the end of each bout of RS or during recovery between sprints. No changes ($P > 0.05$) were recorded in blood insulin or total or phosphorylated Akt at any time point or between genders. While there were no sex differences in total 4E-BP1, the phosphor of 4E-BP1 was significantly higher at rest in males compared to females ($P < 0.05$). Following exercise, there was a significant reduction in phosphorylation of 4E-BP1 in the males but not the females. By 2 h post-exercise phosphorylation of 4E-BP1 had returned to resting levels for both males and females.

While there were no differences in the resting or post-exercise muscle Akt or other physiological measures such as HR, blood lactate or blood insulin, the females had a reduced phosphorylation of 4E-BP1 at rest compared to the males. Additionally there was no significant change in phosphorylation of 4E-BP1 in the females following exercise. However, similar to studies using males and performing resistance exercise, the males in the present study had a reduction in phosphorylation of 4E-BP1 post exercise, which returned to basal levels by 2 h. These results indicate there may be small sex differences in the translational machinery regulating muscle mass. The lack of change in phosphorylation of 4E-BP1 following exercise in females may be due to sex differences in activation of AMPKinase, previously reported following intense exercise.

THE AKT-DEPENDENT ENDOTHELIAL NITRIC OXIDE SYNTHASE (ENOS) PHOSPHORYLATION IS NOT THE PRIMARY MOLECULAR MECHANISM UNDERLYING THE BENEFICIAL EFFECT OF LONG-TERM EXERCISE ON ATHEROSCLEROSIS

PELLEGRIN, M., MIGUET-ALFONSI, C., BOUZOURENE, K., AUBERT, J.F., BERTHELOT, A., MAZZOLAI, L., LAURANT, P.

SERVICE OF VASCULAR MEDICINE AND EXERCISE PREVENTION INNOVATION AND TECHNICO-SPORTING WATCHING DEPARTMENT

Introduction: Exercise reduces atherosclerosis extension in humans and animal models (Niebauer et al., 1997; Pellegrin et al., 2007). However, the precise anti-atherosclerotic molecular mechanisms of exercise are still unclear. Exercise-induced increase of vascular eNOS phosphorylation through the protein kinase Akt has been regarded as a vasculoprotective mechanism in patients with coronary artery disease (Hambrecht et al., 2003). Therefore, the aim of this study was to assess whether this regulatory pathway underlie the beneficial effect of exercise in experimental atherosclerosis using Apolipoprotein E-deficient mice (ApoE-/-) mice.

Methods: Hypercholesterolemic ApoE-/- mice were subjected to 24-week swimming exercise (50 min/day; 5 days/week). A group of sedentary animals were used as controls. Morphometry and characteristics of plaque stability were assessed in plaques from aortic sinus by immunohistochemistry. Expression of eNOS, eNOS phosphorylation at Ser1177, Akt, and Akt phosphorylation at Ser473 were measured in aortas by western blot.

Results: Morphometric analysis revealed that swimming significantly reduced by 30% the surface of atherosclerotic lesions. Moreover, plaques from exercised mice showed a more stable phenotype than that of sedentary ones: decreased layering, macrophage content ($p<0.05$), increased fibrous cap thickness and smooth muscle cells ($p<0.05$). Levels of eNOS, eNOS phosphorylation at Ser1177, Akt, and Akt phosphorylation at Ser473 did not differ significantly between exercised and sedentary ApoE-/- mice.

Discussion: Long-term exercise prevents atherosclerosis extension and promotes plaque stability in ApoE-/- mice. This anti-atherosclerotic effect is independent of changes in Akt/eNOS phosphorylation pathway. Exercise represents an essential non-pharmacological tool for the prevention of atherosclerosis-mediated cardiovascular events.

COOPERATION OF NKT CELLS AND TREG CELLS IN REGULATORY EFFECT ON TH1/TH2 IMBALANCE AFTER OVERTRAINING IN RATS

RU, W., PEIJIE, CH.

SHANGHAI UNIVERSITY OF SPORT

Purpose: At present, the exercise immunology field is becoming increasingly interested in the relationship between T helper (Th) lymphocyte subsets and immunosuppression during overtraining, excessive exercise, or fatigue[1]. We have recently found that defective NKT cell function is related to the emergence of exercise-related immunosuppression [2,3]. The unique features of NKT cells are reminiscent of another T regulatory (Treg) cell population: CD4+CD25+ Treg cells. CD1d-restricted NKT cells and CD4+CD25+ regulatory T (Treg) cells are thymus-derived subsets of regulatory T cells that have an important role in the maintenance of Th1/Th2 lymphocyte balance. Whether NKT cells and Treg cells cooperate functionally in the regulation of exercise-related immune imbalance is not known. We have explored this possibility in overtrained Sprague-Dawley rats. Methods: Eight-week-old female Sprague-Dawley rats were trained with a progressively increasing load for 9 weeks. At 36 h and at 7 d after training, groups of rats were euthanized. The whole blood was used to detect hemoglobin(Hb) , plasma was analyzed for hormones testosterone(T) and corticosterone(C), and spleen was harvested for detecting NKT cells, CD4+CD25+ cells and IFN-γ and IL-4 producing cells. We have demonstrated whether activation of NKT cells by a synthetic glycolipid activator of NKT cells, α-galactosylceramide (α-GalCer), inhibits the development of exercise-related immune imbalance. Results: The results indicated, at 36h after training, that the decrease in Hb, T and C concentration reflected overtraining or excessive exercise. At 7 d after training, NKT cell populations and CD4+CD25+ cells populations decreased, and a Th1/Th2 lymphocyte imbalance occurred. α-GalCer was found to enhance NKT cell numbers by 69% and CD4+CD25+ cells numbers by 1.2 time. In addition, α-GalCer shifted the Th1/Th2 lymphocyte imbalance by increasing the frequency IFN-γ secreting cells, while concomitantly decreasing IL-4 secretors. Conclusion: α-GalCer-activated NKT cells can induce expansion of CD4+CD25+ Treg cells, which in turn mediate the therapeutic effects of exercise-related immune imbalance. Induced cooperation of NKT cells and Treg cells may serve as a superior strategy to treat overtraining-induced immune imbalance.

EFFECTS OF INTERMITTENT HYPOBARIC HYPOXIC EXERCISE ON CARDIOVASCULAR RESPONSES DURING MODERATE EXERCISE IN POST MENOPAUSAL WOMEN

OGITA, F., NISHIWAKI, M., KAWAKAMI, R., TAMAKI, H., TANAKA, T., HAMAOKA, T.

NATIONAL INSTITUTE OF FITNESS AND SPORTS

Introduction: Cardiovascular diseases remain the major cause of mortality in postmenopausal women. Although hormone replacement therapy improves some of these risk factors, no overall cardiovascular benefit has been noted with it. Recently, we have reported that aerobic exercise under a hypobaric hypoxic condition could reduce more effectively total peripheral resistance (TPR) and blood pressure inducing the increase in vasodilaive capacity of adult men (Ogita 2008). Therefore, the present study aimed to examine whether intermittent hypobaric hypoxic exercise bring also comparable cardiovascular adaptations in postmenopausal women.

Methods: The subjects were 16 postmenopausal women (56±3 yrs). They were matched for physical fitness level into two groups and then randomized to normobaric normoxic exercise group (N, n=8) and hypobaric hypoxic exercise group (H, n=8). The aquatic exercise training was done in swimming pool located in a chamber where atmospheric pressure could be regulated. The exercise was performed at the intensity of 50%VO2max level for 30 minutes/training session, 4 days/week, for 8 weeks. H had the exercise in the hypobaric condition corresponded to 2000m above sea level, and was exposed to the condition for 2 hours/session. Before and after the training period, VO2max and cardiovascular responses such as heart rate (HR), stroke volume (SV), cardiac output (CO), and systolic (SBP),

diastolic (DBP) and mean blood pressure (MBP) during cycling exercise at the intensity of 50%VO2max, which was determined before the training, were measured. In addition, the diameter of the popliteal artery was measured at rest and during reactive hyperemia after release of 5-minute arterial occlusion.

Results: After the 4 weeks of training, VO2max did not change significantly in both groups. In cardiovascular responses during the moderate exercise, no significant changes were observed in N. On the other hand, SV and CO in H significantly increased, furthermore, SBP (pre: 174±22, post: 155±15 mmHg), MBP (pre: 114.0±14.9, post: 103.3±11.2 mmHg), and the calculated TPR (MBP/CO) significantly decreased ($P<0.05$). The diameter of popliteal artery at rest did not change significantly in both groups, however, peak diameter during reactive hyperemia significantly increased only in H (pre: 5.4±0.5, post: 6.0±0.7 mm) ($P<0.05$).

Discussion/Conclusion

These findings suggest that exercise in hypobaric hypoxic condition could induce more effectively beneficial cardiovascular adaptations, such as a reduction of TPR and BP with an increase in vasodilative capacity, for postmenopausal women as well as adult men when compared to the exercise under normal condition.

THE EFFECTS OF 70 DAYS OF SKIING ACROSS GREENLAND ON BODY COMPOSITION, COLD- AND ALTITUDE TOLERANCE AND WORK PERFORMANCE IN TWO ELDERLY MEN

SCHAGATAY, E., HUBINETTE, A., KLOCKERVOLD, I., BJÖRKLUND, G., ENQVIST, J., HOLMBERG, H.C.

DEPT OF ENGINEERING AND SUSTAINABLE DEVELOPMENT; SWEDISH WINTER SPORTS RESEARCH CENTRE; 3 DEPT OF HEALTH SCIENCES

Introduction: The physiological effects of a 70-day ski expedition across the Greenland ice-cap on two men, 59 and 60 years old, were studied. They started in May 2008 and covered 1550 km, from Thule to Cape Morris Jessup, on skis pulling sledges of 170 kg. Mean altitude was 2000 m. Work typically consisted of 8 bouts per day of 50 min low to medium intensity work with 10 min pauses and a longer lunch break. The diet was fat enriched but with a negative energy balance for most of the duration.

Methods

The men were tested on two consecutive days for body composition, cold and altitude adaptation, upper and lower body work performance and hematologic status. The tests were executed 10 days before and 5 days after the expedition, using both standardized and specially designed tests as specified below. No statistical analysis was done but a response identified substantial changes with the same trend in both men. Individual data are presented.

Results: Measurements with an iDXA body scanner revealed that the men had lost body weight (8.3 and 4.3 kg), entirely due to a loss of body fat (14.7 and 7.2 kg), while lean body mass increased (6.5 and 2.9 kg). Cold-induced vasodilation (CIVD, laser Doppler) and manual dexterity during cold exposure (pegboard and finger tapping test) were unchanged after the expedition, but a subjective rating of cold discomfort indicated improved tolerance. Spleen contraction was seen (ultrasonic imaging) after 20 min simulated 3000 m altitude exposure (15% and 37%), and this response was attenuated after the expedition (12% and 28%). Baseline SaO2 and apneic ability after 20 min altitude exposure was unchanged. Reticulocyte count had increased by 80% and 84% but Hb was unchanged. Aerobic capacity increased in both arms and legs (A: 16 and 14%, L: 6 and 2%), while anaerobic capacity had decreased. Blood cholesterol (LDL and HDL) increased, but the LDL/HDL ratio was lowered (by 21% and 11%) after the expedition.

Discussion: In response to the long-lasting, low-intensity work with a negative energy balance, fat mass decreased in accordance with previous studies on younger subjects (e.g. Helge et al 2003), but an increase in lean body mass has not previously been reported for such long term exposure. Hand cold-acclimation may have been prevented by gloves, but subjective rating suggested some habituation. Decrease in spleen contraction at altitude exposure may suggest adaptation to altitude (Richardson and Schagatay 2007), which accords with the increased reticulocyte count. Training prior to the expedition mainly involved the legs, explaining why the arms' aerobic capacity increased more. The decrease in anaerobic capacity was probably related to the low intensity of the work. The fat enriched food may explain the increased LDL and HDL while the decreased LDL/HDL ratio may reflect the low intensity work. We conclude that men in their 6th decade adapt to long term endurance work and environmental stress in a similar way as the younger men previously studied, except for the increased muscle mass.

SPLEEN CONTRACTION AND ERYTHROCYTE RELEASE IN ELITE APNEA DIVERS DURING SUBMAXIMAL AND MAXIMAL EFFORT APNEAS

LODIN-SUNDSTRÖM, A., RICHARDSON, M., SCHAGATAY, E.,2

1. DEPT OF ENGINEERING AND SUSTAINABLE DEVELOPMENT, 2. SWEDISH WINTER SPORTS RESEARCH CENTRE

Introduction: Spleen contraction has been observed in humans during e.g. apnea (Schagatay et al 2001) and simulated altitude exposure (Richardson et al 2008). The resulting autotransfusion of erythrocytes enhances gas storage capacity (Schagatay et al 2001). It was observed in non-divers that serial apneas evoke a more powerful spleen contraction than a single apnea, with a plateau after 3 apneas. Our aim was to reveal if time-limited, medium effort serial apneas in elite divers induce a maximal response, or if the response is further enhanced by a maximal effort apnea.

Methods: Eight female and 14 male elite apnea divers of mean(SD) age 29(7) years volunteered during two different international apnea competitions. After 20 min of prone rest and a 2 min countdown, the subject inspired deeply and held the breath for 2 min. After the first apnea (A1) the subjects breathed spontaneously for 2 min until the next apneic episode. Three apneas of 2 min duration were performed in this manner, each terminated by a 10 s countdown. The fourth apnea (Amax) was a relaxed maximal effort apnea performed after an additional 2 min rest, without prior hyperventilation. Arterial oxygen saturation (SaO2) was recorded continuously (Nonin pulse oximeter) while venous blood samples were drawn before and after the four apneas for hemoglobin (Hb) values (Hemocue). Spleen diameters were measured in 3 axes on ultrasonic Doppler images, for volume calculations. A pilot study revealed that maximum spleen contraction occurred at apnea termination both at 2 min and maximal apneas, and we therefore focused on measuring spleen volume at this point for the apnea response.

Results: An increase in Hb with concomitant spleen contraction occurred after A1, and the responses increased further after A2, while no further increases occurred with A3. There was, however, a further increase in both Hb and spleen contraction ($p<0.05$) after the maximal apnea, which had a mean (SD) duration of 4 (1)min. Mean spleen volume decreased from 311 to 247 mL across A1-3, and then to 223 mL

after A4. Mean Hb increased from 135 to 140 g/L across A1-3 and then to 142 g/L after A4. Both parameters had returned to baseline after 10 min. Nadir SaO2 after apnea was 94% for A1-3 and 81% for Amax.

Conclusions: We conclude that elite divers, with an extended apneic ability compared to non-divers, achieve further spleen contraction and red cell release during maximal effort apneas compared to medium effort apneas. This appears related to the lower SaO2. This information may be important when comparing responses between groups with different apneic ability, and for elite apneists when planning their warm-up.

CHANGES IN PACING STRATEGY IN RESPONSE TO AN ACUTE SHIFT TO AND FROM HYPOXIA

LINDSAY, T., ANSLEY, L., NEARY, J.P., HUNTER, A., ST CLAIR GIBSON, A., SKOWNO, J., NOAKES, T.D.

1. UNIV. CAPE TOWN, SOUTH AFRICA, 2. NORTHUMBRIA UNIV., NEWCASTLE, UK, 3. UNIV. REGINA, CANADA, 4. UNIV. STIRLING, UK, 5. RED CROSS WAR MEMORIAL CHILDREN'S HOSPITAL, CAPE TOWN, SOUTH AFRICA

Introduction: It is well known that hypoxia decreases exercise capacity but less is known about how acute changes in ambient oxygen concentration (FIO2) affect pacing profiles. The pacing profile during a time trial usually includes an initial surge, a middle plateau and an end-spurt (Amann et al. 2006; Noakes et al., 2008; Billat et al., 2006). The purpose of this study was to describe changes in pacing profile and physiology in response to a mid-exercise change in FIO2.

Methods: Eight male cyclists completed two 20 km time trials in random order. In one trial, the 1st 10 km was normoxic (FIO2=21%) and the 2nd 10 km was hypoxic (FIO2=15% ~2700 m). The order was reversed in trial two. Subjects were blinded to the conditions. The trials were done inside a chamber set at normobaric pressure. Subjects acclimatised to the initial FIO2 for 10 min before each trial. Expired gases (4, 14 km), cardiac output (Q) (continuous), and blood gases (0, 4, 9, 14, 19 km) were measured. Subjects used their own bicycles on an electrically braked cycle trainer. PO was averaged over 2 km. Analysis was by a Students' t-test and repeated-measures ANOVA with Bonferroni post-hoc.

Results: Power output (PO) was lower in hypoxia at every interval except 12 and 14 km ($p<0.01$). PO for the final 2 km was 116% of the mean PO for the 2nd 10 km in normoxia, but only 102% in hypoxia ($p<0.01$). VE during hypoxia was higher at 14 km ($p<0.05$) and pO2 during hypoxia was lower at every interval ($p<0.001$). Q for the final 2 km was lower in hypoxia ($p<0.001$).

Discussion: PO changed less than 210 sec after switching FIO2. Descriptively, pacing during the 1st 10 km was similar in both conditions, but absolute PO was lower in hypoxia. The attenuated hypoxic end-spurt was consistent with Amann et al. (2006). Q during the end-spurt was lower during hypoxia and thus was not limiting. Instead, the end-spurt seemed to be related to the altered VE and pO2. However, altered PO during the first 500 m (~60 sec) and a quick PO response after changing FIO2 (cf., Joseph et al., 2008) suggests that pacing changes are not merely a result of peripheral fatigue. Indeed, the initial PO was likely determined during the 10 min pre-trial equilibration period and/or from sensations in the first minute of exercise. Changes in PO with altered FIO2 may have involved a rapid oxygen sensing response. The data support the notion of an initial anticipatory component to pacing based on sensation.

VIGOROUS LATE-NIGHT EXERCISE AFFECTS CARDIAC AUTONOMIC CONTROL DURING SLEEP BUT NOT OBJECTIVE OR SUBJECTIVE SLEEP QUALITY IN PHYSICALLY FIT YOUNG ADULTS

MYLLYMÄKI, T., HOKKA, L., SAVOLAINEN, K., JAKONEN, R., JUUTI, T., MARTINMÄKI, K., KAARTINEN, J., KYRÖLÄINEN, H., KINNUNEN, M.L., RUSKO, H.

UNIVERSITY OF JYVÄSKYLÄ

BACKGROUND: Late-night exercising has generally been viewed as a typical symptom of a 24-hour society. This study was performed to solve whether a late-night exercise disturbs sleep – the most important time period for recovery.

METHODS: The sleeps of eleven physically fit young adults (7 males, 4 females, aged 26±3 yrs, VO2max 54±8 ml/kg/min) were monitored in a sleep laboratory in a counterbalanced order 1) after a day including vigorous late-night exercise and 2) after a control day without exercise. The exercise was an incremental cycle ergometer exercise until voluntary exhaustion. The exercise started at 21:00±0:28 hh:min and lasted for 28±3 min. The bed time was 2:13±0:19 h:min after finishing the exercise. ECG RR-intervals (Alive Heart Monitor) and polysomnography (BrainVision Recorder) were recorded during sleep. Cardiac autonomic control was analyzed with First-beat HEALTH Software (Jyväskylä, Finland), and assessed by HR and HRV as well as variables based on both HR and HRV (physiological stress-% and relaxation-%). Objective sleep quality was analyzed from sleep stages determined using a standardized scoring protocol. Subjective sleep quality was assessed by a question "how tired do you feel yourself physically right now?" asked in the evening and morning. The scale for the question was 1-10 (1 = not tired at all, 10 = very tired). Statistical differences were examined using Wilcoxon test and paired samples t-test.

RESULTS: During the whole sleep, the subjects' HR was significantly higher (54±7 vs. 51±7, $p<0.01$), stress-% higher (18±14 vs. 5±13 %, $p<0.01$), and relaxation-% lower (71±18 vs. 85±14 %, $p<0.01$) after exercise compared to control day. HR was higher during the first four hours of sleep after exercise compared to control day ($p<0.01$-0.05), while HRV tended to be lower during the first hour of sleep. However, the subjects tended to sleep more slow wave sleep (SWS), which is physiologically the most restorative sleep stage, after exercise than control day ($p=0.08$). Moreover, the subjects slept more non-REM-sleep after exercise than control day ($p<0.001$). Only two subjects spent more time awake while in bed after exercise compared to control day. After exercise day, the subjects seemed to be more tired in the evening than in the morning (5.7±2.0 vs. 3.7±2.1, $p=0.07$). However, after control day no such decrease in tiredness occurred from the evening to the morning (4.9±1.9 vs. 4.5±1.9).

DISCUSSION: The results of this study showed that vigorous but relatively short late-night exercise performed 2-2.5 hours before bed time affects cardiac autonomic control especially during the first hours of sleep. However, objective and subjective sleep quality may be even enhanced after exercise compared to control condition. We conclude that this kind of exercise procedure has minor effects on the essential recovery process during sleep.

ROLE OF STRENGTH TRAINING IN ENDURANCE RUNNERS DURING PREPARATORY, MAXIMAL VERSUS EXPLOSIVE, AND REDUCED STRENGTH TRAINING PERIODS.

TAIPALE, R.S., GITONGA, D., WALKER, S., NUMMELA, A., VESTERINEN, V., MIKKOLA, J., HÄKKINEN, K.

UNIVERSITY OF JYVÄSKYLÄ, KIHU-RESEARCH INSTITUTE FOR OLYMPIC SPORTS

Strength (STR) and endurance (END) training produce divergent adaptations and are often performed concurrently. An interference effect (1) between STR and END training is often related to high intensity/volume and long duration of training, but it is possible for concurrent training to lead to increased STR and END performances even in endurance athletes (2). A reduction in training stimulus leads to a reversal in adaptations as demonstrated by decreased activation and STR of detrained muscles (3).

Twenty-eight male recreational END runners (mean±SD, age 35.4±6.8yrs, height 180±5.3cm, body mass 79.3±7.5kg) were divided into three STR training groups: maximal (M=11), explosive (E=10) and circuit training (C=7). Within these groups, subjects completed 6 weeks of common preparatory STR training (PRE) and then a specific 8-week STR training intervention (STI) followed by 14 weeks of intentionally reduced strength training and increased endurance training (RST). STR training (including at least two exercises for leg extensors) occurred on average 1.3±.02, 1.5±.03 and 0.5±.03 times per week in each training period, respectively, while END training volume (running km) increased progressively throughout the study. Concentric leg press strength (1RM), jumping power (CMJ), muscle activation (EMG of VL + VM) and END performance (vVO2, VO2MAX, running economy (RE)) were measured prior to PRE (-6), at 0, 4 and 8 weeks of STI and after RST (+14).

During PRE and STI, 1RM improved significantly in all groups peaking at 4 (7.7, 3.2 and 6.4% in M, E and C from -6, respectively), while significant gains in CMJ peaked at 8. Gains in 1RM were accompanied by increased EMG of VL+VM in M and E (p=0.027 and 0.002) but not in C. VO2max increased only in M from -6 to 8 (4.3%), vVO2 improved significantly in all groups from -6 to 8 and RE in E improved significantly by 2.4%. Following RST, progressive decreases were observed in 1RM, CMJ and EMG which were significant in 1RM and EMG of M (p=0.002 and 0.038). However, significant increases in vVO2 of M and E (4.7 and 2.4%), RE of M (7.7%) as well as some gains (n.s.) in VO2max continued in M and E.

Both M and E STR training performed concurrently with high volume END training led to increases in 1RM, CMJ and EMG but strength development plateaued indicating some interference over a prolonged period. Nevertheless, these neuromuscular improvements were accompanied by progressive gains in VO2max, vVO2 and RE. RST resulted in decreases in 1RM, CMJ and EMG; however, vVO2 and RE continued to improve in M and E. Adaptations to ST were maintained to some extent, since 1RM, CMJ and EMG did not fall below starting values. Thus, improved neuromuscular performance and increased preparedness for an increase in running volume due to STR enabled subjects to improve END performance.

EFFECT OF NSAID ON HUMAN SKELETAL MUSCLE SATELLITE CELLS FOLLOWING ECCENTRIC EXERCISE

MIKKELSEN, U.R., MACKEY, A.L., HELMARK, I.C., SKOVGAARD, D., KJÆR, M., LANGBERG, H.L.

INSTITUTE OF SPORTS MEDICINE COPENHAGEN, BISPEBJERG HOSPITAL, DK-2400 COPENHAGEN NV, DENMARK

Introduction: Satellite cells – the stem cells of skeletal muscle – are essential for skeletal muscle adaptation to exercise and for muscle regeneration. They contribute to hypertrophy by providing new myonuclei and assist in repair of damaged muscle fibre segments. Non-steroidal anti-inflammatory drugs (NSAIDs) are widely consumed by athletes when faced with injuries and by rheumatic patients, but the influence of these drugs on muscle satellite cells and adaptation is not fully understood. Following a 36 km run the observed increase in satellite cell number (27%) was blunted by ingestion of NSAIDs (Mackey et al., 2007) pointing towards a negative influence of NSAIDs on satellite cell proliferation in vivo in humans. The aim of the present study was to investigate the effect of local NSAID infusion on satellite cells in vivo in human muscle.

Materials/Methods: Eight healthy male subjects (unaccustomed to leg resistance exercise) performed 200 maximal eccentric contractions with each leg. NSAID (Indomethacin) was infused via a microdialysis catheter into one leg (NSAID leg) before, during and for 5 hrs after exercise, the other leg being working control (unblocked leg). Biopsies were sampled from m.vastus lateralis before and 8 days post exercise. Satellite cells were analyzed by immunohistochemistry using antibodies against the transcription factor Pax7, and neural cell adhesion molecule (NCAM). Cell proliferation was analyzed using an antibody against the cell cycle marker Ki67.

Results: The number of Pax7+ cells per myofibre was increased by 75 % on day 8 post exercise in the unblocked leg (mean 0.13, SE 0.03) compared with pre exercise (mean 0.08, SE 0.02, P=0.03), while levels were unchanged in the NSAID leg (mean 0.06, SE 0.01, P=1.0). On day 8 post exercise the number of Pax7+ cells (per myofibre) tended to be lower (P=0.06) in the NSAID leg compared to the unblocked leg.

Very few proliferating (Ki67+) cells were found with no effect of NSAID, on average only one Ki67+ cell was found per 100 myofibres on day 8 post exercise.

Conclusion: The results indicate that NSAIDs may negatively affect satellite cells and muscle adaptation following eccentric exercise. This is clinically relevant given the widespread consumption of NSAIDs among athletes and rheumatic patients.

ISOKINETIC QUADRICEPS AND HAMSTRINGS MUSCLE STRENGTH AND THE ACL INJURY IN FEMALE HANDBALL PLAYERS

ESTRIGA, M., CARVALHO, J., BERNARDES, J., MASSADA, L.
UNIVERSITY OF PORTO

A disproportionate rate of ACL injuries between sexes is frequently reported in high-risk sports involving plant-and-cut movements. The ratio of female risk to male risk is generally between 2 and 3, depending on sport specificity and level of practice. The seriousness of the ACL injury stresses the need to improve the management of its risks and causes. As the knee flexor musculature is important on active knee stabilization, it's normalized value (hamstrings/quadriceps peak torque ratio - H:Q) has been suggested as an ACL injury risk indicator.

Purposes: to characterize the muscular force adaptations over the players' handball career; and to investigate a possible epidemiological correlation between lower limb isokinetic strength and previous or subsequent ACL injuries.

Sample: 100 elite Portuguese female handball players, 19±4 years old, practicing handball for 7±4 years. The players were evaluated about 3 months after the beginning of the sport season and any sequent knee injury was registered. They were further subdivided into 3 groups: those with no previous history of ACL injuries (91 players), those with previous or chronic ACL injury (9 players) and those that in the following season suffered an ACL injury (4 players). The isokinetic torque-angle curves were obtained with a Biodex 2 dynamometer at 90º/s (concentric). A clinic evaluation was performed to identify any previous knee injuries and a screening questionnaire was used to assess some vital and sports related information.

Results: in players with healthy knees the measured H:Q ratio (45%±7%) is lower than several publish desirable values.

In injured players, the knee where reconstructive surgery was performed showed, about 4 years later, approximately 10% reduction of the extension peak torque and no significant reduction on the extension work capability, an indicator of a change in the shape of the torque-angle curve.

A small linear neural network (one layer, two node) was trained with half the available isokinetic data. With an optimized turnover point (A=0.981), the model was applied to the full size sample, miss-predicting only 4 cases (4 false-positive ACL ruptures). It even predicted all 4 cases of ACL ruptures that occurred about 1 year after the isokinetic evaluation. A total squared correlation of 62.6% was obtained, with the hamstrings peak torque (36%) as the most powerful single factor.

An odds ratio analysis on the logistic regression showed that an improvement of a single N.m on the peak knee flexor torque improves the chance of not having an ACL injury by a factor of 1.27 on average, although the 95% confidence interval contains unity.

Conclusions: we could not substantiate the importance of the H:Q isokinetic peak torque ratio as a risk indicator but a more complex model like this may be of some real value. It will improve with all additional evaluations but it already suggests the importance of the knee flexor musculature in the ACL rupture prevention.

COMPARISON BETWEEN RESISTANCE TRAINING PROTOCOLS ON MARKERS OF GLYCEMIC CONTROL IN TYPE 2 DIABETES MELLITUS

EGGER, A., DIEM, G., NIEDERSEER, D., LEDL-KURKOWSKI, E., MÜLLER, E., FORSTNER, R., HERGAN, K., GRAF, S., PIRICH, C., WEITGASSER, R., NIEBAUER, J.
UNIVERSITY INSTITUTE OF SPORTS MEDICINE, PREVENTION AND REHABILITATION, PARACELSUS MEDICAL UNIVERSITY SALZBURG, INSTITUTE OF SPORTS MEDICINE OF THE STATE OF SALZBURG, AUSTRIA

Introduction: Despite the fact that exercise training has been shown to be very effective in type 2 diabetes mellitus (T2DM), it still remains elusive, which protocol of resistance exercise training is most effective in improving glycemic control.

PURPOSE: It was the purpose of this study to compare two different protocols of resistance training, i.e. hypertrophy versus endurance strength training, on various metabolic markers in T2DM.

Methods: Thirtytwo patients with T2DM (mean age 64,8 +/- 9,0 years, 13 men and 19 women) were randomized between hypertrophy strength training (HST: n=16; 2 sets of 10-12 repetitions at 70% of the one-repetition maximum (1RM)) or endurance strength training (EST: 2 sets of 20-25 repetitions at 40% of 1RM) twice a week for eight weeks on a multi gym weight-lifting machine (Nautilus® nx200). In addition submaximal ergometer based aerobic training (Daum®Ergometer Fitness3; 60-70% of heart rate reserve) was performed by all patients.

Results: Systolic blood pressure at rest (HST: 131.3 +/- 17.2 to 125.3 +/- 17.6 mmhg, p=0,001; EST: 135.3 +/- 16.4 to 128.4 +/- 14.3 mmhg, p=0,008); aerobic exercise capacity (HST: 121.0 +/- 26.8 to 142.4 +/- 29.9 W, p=0,001; EST: 127.6 +/- 22.5 to 140.1 +/- 23.3W, p=0,008); muscle mass of both arms (HST: from 4825 +/- 1233 to 5077 +/- 1333g, p=0,003; EST: from 5231 +/- 1284 to 5475 +/- 1461g, p=0,01); upperarm strength assessed during chest-press (HST: p<0.001; EST: p<0,001); and back-pull (HST: p<0.001; EST: p<0,001) all improved significantly in both groups. Furthermore hemoglobin A1c improved significantly in EST (from 7.5 +/- 1.2 to 7.2 +/- 1.0%, p=0,04) but not in HST (from 6.9 +/- 1.2 to 6.8 +/- 0.8%, p=0,2). Intraabdominal fat remained unchanged in both groups (HST: p=0,1; EST: p=0,5). HDL (from 53.6 +/- 16 to 58.6 +/- 13,4mg/dl, p=0,02), fastening insulin, and urea acid significantly improved in EST only.

Discussion: Both hypertrophy and endurance strength exercise training performed on top of an ergometer-based aerobic exercise program led to a similar increase in muscle strength. In addition, endurance strength training led to superior reduction in important glycemic parameters like hemoglobin A1c (p=0,04), fructosamin (p=0,002), LDL (p=0,02), urea acid (p=0,04) and fastening insulin (p=0,001). Thus, we conclude strength training in general is a beneficial addition to aerobic exercise training. However, endurance strength training appears superior to hypertrophy strength training, since it not only improves strength, but also exerts beneficial effects on patients' cardiovasular risk profile.

EXERCISE IMPROVES THE MITOCHONDRIAL ANTIOXIDATIVE DEFENSE CAPACITY IN ADIPOSE NON-DIABETIC AND DIABETIC MEN

GEISLER, S., SCHMIDT, U., KREUTZ, T., LENZEN, E., SCHIFFER, T., GRAF, C., BRIXIUS, K., BLOCH, W.
GERMAN SPORT UNIVERSITY COLOGNE

Diabetes has been shown to be accompanied by an increased generation of reactive oxygen species and a depression of the antioxidant defense capacity. The present study investigated whether a three months exercise intervention is able to improve the oxidative stress situation in non-insulin dependent adipose male diabetics (age: 40-60 yrs, n=13). Half of the patients were taking place in an endurance and the other half in a strength endurance training. Non-diabetic adipose men, who participated in a 3 mo strength training, were investigated for comparison (age 40-60 yrs, n=7). Before and after the 3 mo-exercise, biopsies were taken from the M. vastus lateralis. Immunohistochemical stainings were performed for gluthathion peroxidase 1 (GPX1) and superoxide disutase 2 (SOD2), two mitochondrial antioxidative enzymes, as well as for HSP70, an oxidative stress/hypoxia signalling molecule.

Under basal situations (i.e.before the training), GPX1 was slightly decreased in the M. lateralis of diabetic compared to the non-diabetic men (7.01.8 arbitrary Units (ArU) vs. 9.33.9 ArU, p=0.096). The regular participation in exercise resulted in a significant increase in the GPX1 protein expression in the diabetic men (+16%). GPX1 protein content was not changed by exercise in the non-diabetic group. SOD2 and HSP70 were similar in the non-diabetic and diabetic group before the exercise program. Exercise significantly increased SOD2 in both non-diabetic and diabetic participants (+18%). The exercise-induced HSP70 protein content was only significantly increased in the diabetic persons (+16%).

Conclusions: Diabetes depresses the mitochondrial antioxidative defense regulation/signaling of H2O2 at very early stages of the disease. This situation can be improved by regular physical activity. The regulation of the protein expression of the SOD2 seems to be differentialy regulated from that of GPX1 under both physiological (exercise) and pathophysiological (diabetes) situations.

CASE REPORT: SEVERE IRON DEFICIENCY ANAEMIA AND REDUCTION OF VO2MAX IN AN ELITE ROWER

TREFF, G., SCHMIDT, W., STEINACKER, J.M.
UNIVERSITY OF ULM, UNIVERITY OF BAYREUTH

Introduction: An elite rower experienced a dramatic decrease of physiological performance in an incremental rowing exercise test and VO2max was decreased. Subsequently, iron deficiency anaemia was detected. As the rower was regularly evaluated physiologically, time course of iron status, erythropoesis and physical performance can be reported.

Material and Methods: Measurements included 4 pre-anaemia values that were averaged (PRE). 2nd measurement was 6 months later during peak of anaemia (ANM). 3rd measurement (POST) took place 10 months later, 8 months after normalization of [Hb]. Blood Volume (BV), Red Cell Volume (RCV), total Haemoglobin mass (tHb) were determined using the optimised CO-rebreathing method, VO2max was measured breath-by-breath. Ferritin and soluble transferrin receptor (sTr) were measured in serum.

Results: The anaemia caused a dramatic decrease of tHb from 1267 g (PRE) to 917 g (ANM) (-27.6 %), RCV (-20.9 %), [Hb] (-30.8%). VO2max decreased from 5.8 to 4,8 l/min (-17.5 %). This was accompanied by an increase of PV from 4359 ml (PRE) to 5254 ml (20.5 %) resulting in a normovolemic BV-situation. At POST, haematological values increased compared to PRE: tHb 1377 g (8 %), BV (6.2 %), EV (2 %) and PV 4820 ml (9.6%). VO2max was 6.0 l/min. Ferritin values were (PRE – ANM - POST): 38 - 24 - 41 mg/l. sTr were 1.7 - 3.5 - 1.6 µg/l.

Discussion: The diagnosis revealed a hp-negative gastritis, possibly induced by intake of non-steroidal antiphlogistics due to back pain. Subsequently, gastritis was treated with a protone pump inhibitor and iron was substituted intravenously after ANM. The PRE values showed a critical iron status. When gastritis induced

blood loss and iron resorption disturbance occurred, erythropoiesis failed. Despite the decrease in VO2max and performance, ferritin levels barely decreased below clinical relevant values. Only sTR and direct tHb-measurement definitely indicated iron deficiency anaemia. The increase of PV at ANM did not compensate the loss of oxygen transport capacity. After successful treatment, tHb and BV were 8%, and VO2max was 3 % higher compared to PRE. The VO2max-levels at PRE and POST support the finding, that a change of 1g tHb in healthy conditions is associated with a change in VO2max of 4.4 ml. The borderline sTr in POST may indicate again increased iron demand.

Conclusion: Ferritin-levels are of limited value for diagnosing iron deficiency in highly trained athletes, since ferritin behaves also as an acute phase protein and may be elevated by training related acute phase reactions. [Hb] may be falsely negative influenced by hemoconcentration. The anaemia was definitely detected by sTr level and tHb-measurements. After successful treatment of anaemia, tHb increased to the highest level observed in this athlete.

RELATION OF PHYSICAL ACTIVITY INTENSITY AND ENERGY CONSUMPTION – PRELIMINARY RESULTS

VAßE, V., BRANDES, M.
INSTITUTION OF SPORT SCIENCE

To counteract the decrease of physical activity in most western civilizations, common recommendations intend to increase daily life activities of the subjects in order to enhance energy expenditure. Mostly, cycling, varying walking speed and stair climbing are addressed (e. g. Crouter et al. 2003; Harrell et al. 2005). The amount of physical activity and energy expenditure is measured by pedometers, accelerometers or oxygen consumption analyzer (Crouter et al. 2003; Fudge et al. 2007), but little is known about the relation of energy expenditure and the intensities of the activities. Therefore, the aim of the present study is the computation of equations to convert steps into energy consumption taking age, sex and frequency of steps into account.

Thus, 300 subjects divided into six age groups (children to seniors) are to be measured. A local ethics committee approved of the study.

This abstract includes preliminary data for the age groups >60 (53.0 ± 5.9 years, 167.3 ± 5.3 cm, 66.7 ± 9.0 kg) and 40-60 years (66.4 ± 4.1 years, 170.2 ± 8.2 cm, 66.8 ± 11.2 kg). All subjects were healthy and gave written informed consent. Equipped with a step-activity-monitor at the right ankle, storing gait cycles in 1-min intervals [cycles/min], and a mobile oxygen consumption analyzer calculating energy consumption [MET] breath-by-breath, the subjects completed a parcour consisting of resting and walking at varying speed. Mean values of the last three or one and a half minute of each activity were computed, whereas resting oxygen consumption was subtracted from the activity values.

No significant differences were found between age groups. Thus, square regression analysis revealed Y=-0.662x2+9.359x+34.767, R2=.54 ($p<0.01$) for the necessary step frequency to meet given MET values for all subjects.

The results show that the increase of energy expenditure is non-linear to an increase of walking intensity. If physical activity is measured with devices allowing for a calculation of walking intensity, a more solid estimation of energy expenditure is possible. Furthermore, recommendations regarding an increase of physical activity can be rephrased taking walking intensity into account.

Further investigations will show if the equation has to be altered for different sex and age groups.

PE AND HEALTH - THE FRAME FACTOR THEORY FOR ANALYSING EDUCATIONAL SETTINGS

LUNDVALL, S., MECKBACH, J.

GIH, SWEDISH SCHOOL OF SPORT AND HEALTH SC.

On a normative level as a subject Physical Education and Health (PEH) seems to adjust rapidly to changes in society, whereas on the practical level it seems receptive to limiting factors like time, facilities and dominating inherited practices. What choices and determinants of options do teachers have and use, and how are students involved in the framing of PEH?

The purpose of the study has been to investigate the process between the transmission of curriculum and the realisation of content as viewed by teachers and students of PEH in secondary schools in Sweden. Bernstein's concepts of classification and frames together with Linde's work defining the arenas of formulation, transformation and realisation. are used as analytical tools. The empirical material consists of quantitative data from questionnaires administered to teachers (n=61) and students (n=380, aged 15–16 years) within a national multi-disciplinary project entitled School-Sport-Health (SIH).

Results From the formulation arena of a broad given content the content given seems to become narrowed in the process of transformation, transmitting and realisation of content. Limiting factors as time and facilities are not strongly influencing the content provided. Lack of perceived subject matter knowledge is not mentioned at all as limiting the teaching objectives. When organising and conducting lessons, teachers mostly address the entire group of students and seldom give instruction in smaller groups. Just over half the students responding to the questionnaire expressed doubt about whether the teacher was aware of their previous experiences/knowledge.

Discussion: By using Bernstein's principles of classification and framing for understanding the results of the study, PEH in secondary schools in Sweden emerges as a weak subject, where the framing of subject is not strongly bound to limiting factors as time and facilities. It seems to be more influenced by the boundaries set by other agencies and the process of transforming and transmitting of legitimate knowledge by teachers. In some respects students active in organised sport seem to act as a steering group in terms of how PEH teaching is addressed.

COMPARATIVE INVESTIGATION IN CREMONA AND PROVINCE AMONG DIFFERENT SPORT DISCIPLINES AT 12 YEARS

ANNA, A.

UNIVERSITÀ CATTOLICA SACRO CUORE

INTRODUCTION: In these last years the sporting practice to juvenile level, represents a social phenomenon of great interest and constitutes a privileged context, inside which young people enhance an harmonic, motor, technical and psychological development. This research wants to verify how important is the education and the development of the motor abilities, before improving the executive techniques of the sport.

MATERIALS AND METHODS: The research, made in 2008, has been directed into 6 different sport disciplines and it has interested motor test and one questionnaire. The tests have been administered to 150 athletes of 12 years old, practising 3 individual sport and 3 team sport and 100 students (control group) attending the middle school. The practising young males trained 3 times per week and at school they attend to 2 h of Physical Education per week; the control group attends to 2 h of Physical Education at school per week and during the leisure time did not practice any motor activity.

RESULTS: The trends are the following: 60 m fast run, basketball, track and field, basket obtained best data results compared to control group and the other sport disciplines. In the 1200 m run test, the control group and the karate athletes obtained worse results compared to the athletes of other disciplines. In the stick test, the athletes of volleyball and basketball obtained worse results compared to athletes of others discipline; in the sit & reach, the athletes of soccer obtained worse results compared to the athletes of others discipline. In the forward throw of medical ball test, the athletes of basketball, swimming obtained better results compared to the control group and to athletes of others discipline. In the long standing jump, the athletes of basketball, volleyball and track and field obtained better results compared to athletes of other sport discipline; relativity to feet rapidity the data of basketball, volleyball and karate are superior to the other sport. The analysis of the questionnaire outlined that athletes start some sports at the age of 5 or 6 years old too early and that coaches dedicated much more time on teaching the sport technique than on developing motor sport abilities.

CONCLUSION: From the results obtained by the administered test and by the proposed questionnaire, the following tendency emerges: during the training sessions, coaches work few on the development of the motor abilities and very on the technique, in individual sporting disciplines the analytical work.The start of teaching technique and selection are preponderant. This research offers very important data in order to reflect about the formulation of a correct methodology of training when a boy or a girl is going to practice a sport.

INTERNATIONAL COOPERATION IN PHYSICAL EDUCATION HIGHER EDUCATION: THE CASE OF THE PALESTINIAN TERRITORIES.

FERES, A.

BRASILIA UNIVERSITY

Background: In June 2008 the Brazilian Ministry of External Relations organized a multidisciplinary mission to the Palestinian Territories. I was responsible for the areas of Physical Education and Leisure. The first step of the cooperation took place in Ramallah and East Jerusalem. The main goals were to gather information of the Palestinian higher educational system in the areas above and establish contacts with the local authorities in order to set a frame of cooperation between the two national entities. This qualitative study has been carried out through interview and participant observation. Meetings were set with the Palestinian representatives from June 2nd to the 6th. The most important meeting was with Mr. Ibrahim Sabbah, the Minister of Sports and Youth. I also had meetings with leaders from related institutions, such as a youth center in the Al-Amari refugee camp located in Al-Bireh, north of Jerusalem, and representatives from Birzeit and An-Najah Universities. The An-Najah University is located in Nablus, north of Ramallah. I was able to find out that this university was the only one in the Palestinian Territories to offer a Physical Education undergraduate curriculum but has no graduate courses yet. Right away, we went to this university and were hosted by Dr. Kherieh Rassas-Kharouf, President Assistent for International Affairs. After visiting the university facilities, including those specifically related to the Physical Education field, we talked about the possibility of creating a graduate course in this area, since they already had nine professors with PhD involved in it. Birzeit University, located on the outskirts of the West Bank town of Birzeit, about 20 kilometers north of Jerusalem and 7 kilometers north of Ramallah, was the next place visited. The campus has very good facilities in Leisure and Sports, used mainly for community physical activities. It could very easily offer an undergraduate course in P.E., in the short term, and a graduate one with the cooperation of the university, concerning the building of labs and invitation for visiting professors from countries that have structured graduate courses in P.E. and related areas. These findings suggest that the improvement of the Physical Education and Leisure higher educational system in the Palestinian Territories could lead to a more qualified and professional approach towards public policies. This would create important possibilities for the population that has been suffering severe constraints in the context of the Israeli occupation, as well as the international financial embargo, since 2006. One of the conclusions of this study is that the Palestinians have already a good infrastructure in P.E and Leisure, and also universities that could highly benefit from international cooperation initiatives in its higher educational system in the fields above.

PHYSICAL EDUCATION AND GLOBALIZATION: COMPARISON OF PHYSICAL SKILLS DEVELOPMENT IN MULTIETHNIC CLASSES IN ITALIAN SCHOOL

CAZZOLI, S.

UNIVERSITY OF TORINO, ITALY

Introduction: The 10% of scholastics population in Italian school is multiethnic, from east Europe and north Africa. PE is a compulsory subject from the primary to secondary school for two hours per week.

Aims: The survey wants investigate the physical skills in the multiethnic PE class and understand if there is a different development in the Italian, east Europe and north Africa students attending the Italian school.

Methods: the physical skills development is analyzed with long standing jump thank to quality test (Test Gross Motor, Dale A. Ulrich) and a quantity test (Motor FIT- AAHPERD). The data analyses is descriptive and use percentile and percentage comparison for differences ethnic groups in the scholastic from years 2007-2009.

Results: the data come from 30 PE physical education classes. The students involved in the survey are 750, the PE teachers are 30. The complete data will be 1500.

Discussion: The heterogeneity ethnic culture has been influence by the physical skills development in the multiethnic Italian PE classes. The culture of the body, the religion believes, the socioeconomics status are important factor for participation at the PE lessons and the physical skills development.

Conclusion: In the multiethnic PE class the cohesion is going towards difference and the inclusion and integration of difference based on exchange between people of difference culture, country, religion, economic status

THE 'SWITCHING' WORK LIVES OF HONG KONG PRIMARY SCHOOL PHYSICAL EDUCATION TEACHERS

SUM, K.W., DIMMOCK, C.

THE CHINESE UNIVERSITY OF HONG KONG

The aim of this study is to investigate the work lives of Primary School Physical Education Teachers (PSPETs) in Hong Kong. The central research questions are how do PSPETs describe their work and how do they feel about their typical daily work lives.

The study carried out through the inductive development of a theory, based on grounded theory methods. The researchers employed theoretical sampling in order that data collection be purposively directed towards informants and towards situations thought likely to provide data that promised to be relevant to and able to develop and build the emergent theory. PSPETs in Hong Kong have been defined by the researchers as professionals who specialize in teaching physical education in primary schools in Hong Kong.

Through snowball sampling, the researchers identified suitable participants for study. Participants for this study were from a variety of backgrounds and were able to enrich the contexts for analysis. The researchers used semi-structured interviews, together with documentary sources (diaries) for conducting data collection. Eleven PSPETs were participated. Data collection was conducted over a 11-month period and ceased upon data saturation, which was when nothing new could be added to the data. The transcribed interviews were analyzed using open coding, axial coding and selective coding procedures. Member checks, audit trails and triangulation were used to ensure trustworthiness.

The concepts of (1) multi-dimensional knowledge, (2) acclimatization to the organization, (3) reconcilable scope of work, (4) multi-level job specification, and (5) irregular work hours and workloads are clustered into the Switching (Work Lives) category, which describes the PSPETs' work and their feelings toward their daily lives.

Switching (work lives) refers to how PSPETs must equip themselves with infra-structural abilities in order to tackle their everyday challenges and routines. PSPETs have to adjust to a broad scope of work that has multiple levels of job specifications and that demands possession of multi-dimensional knowledge. Irregular work hours and workloads also have a great influence on their working lives. To acclimatize to the ever-changing organizational environment, from time to time, PSPETs must "switch" their scope of work effectively and efficiently.

ATTITUDE TO PHYSICAL EDUCATION AND PARTICIPATION IN ORGANIZED YOUTH SPORTS DURING ADOLESCENCE RELATED TO PHYSICAL ACTIVITY IN YOUNG ADULTHOOD: A 10-YEAR LONGITUDINAL STUDY

KJONNIKSEN, L.

TELEMARK UNIVERSITY COLLEGE

Abstract

We examined the relationship between participation in organized youth sport and attitude to physical education (PE) during adolescence and physical activity in young adulthood. The sample comprised 630 subjects who completed questionnaires from age 13 and over a 10-years period. Analysis of variance and regression were used to examine the relationship between attitude to PE and participation in organized sport at age 13 years and physical activity at age 23 years. Both genders had a consistent and positive attitude toward PE at age 13–16 years. More boys participated in organized youth sport, and participation rates declined from age 13 to 16 years. Participation in organized sport was the strongest predictor of physical activity at age 23 years in males, whereas attitude to PE was the strongest predictor in females. Participation in sport and physical activity in different arenas during adolescence may affect participation differently in young adult men and women.

"NORMAL" BODY MASS INDEX DOES NOT NECESSARILY INDICATE A HEALTHY BODY COMPOSITION IN ELITE FEMALE ATHLETES AND NONATHLETES

TORSTVEIT, M.K., SUNDGOT-BORGEN, J.

1. UNIVERSITY OF AGDER, KRISTIANSAND, 2. NORWEGIAN COLLEGE OF SPORT SCIENCES, OSLO

Introduction: Body composition and body weight may impact health and performance. While the most used classification of body composition in non athletes is the Body Mass Index (BMI), no studies have assessed the relationship between BMI and body fat percent (BF%) in elite female athletes and compared with normal-active controls. Therefore, the aims of this study were to assess the relationship between BMI and BF% in elite female athletes representing several sports, and to compare with non-athlete controls.

Methods: This two-phase study included: 1) a questionnaire regarding training patterns, menstrual-, dietary-, and weight history, nutritional factors, oral contraceptive use, pregnancy, stress fractures, and disordered eating behaviours, and 2) measurement of body composition with dual-energy X-ray absorptiometry using a full body scan on a LUNAR-Prodigy. In part I, all female athletes representing the national teams of Norway at the junior or senior level, aged 13-39 years (n=938) and a same-age random sample control group (n=900) were invited.. The questionnaire was completed by 88% of the athletes and 70% of the controls. Based on these initial data, a random sample of athletes (n=300) and controls (n=300) were selected and invited to participate in part II. A total of 186 athletes (62%) and 145 controls (48%) participated in part II. Overfatness was defined as a BF% ≥33% (Ode et al. 2007).

Results: The athletes had a significantly lower BMI (21.7 ± 2.4 kg/m2) and BF% (24.2 ± 7.2%) compared with the controls (24.0 ±4.2 kg/m2 and 35.5 ±7.1%) ($p<0.001$). The correlation between BMI and BF% was 0.671 ($p<0.01$) for athletes and 0.813 ($p<0.01$) for controls. Of those athletes with normal BMI values (n=150), 6,7% were classified as overfat. Seven athletes were classified as overweight based on their BMI values, but not overfat. For the controls with normal BMI values (n=96), 50,0% were classified as overfat. A total of 63,4% of the controls had a BF ≥33%, a level several times higher than that of the athlete group (11.3%) ($p<0.001$).

Discussion: As expected, the athletes had lower BMI and BF% than the controls. The correlation between BMI values and BF% is acceptable for both athletes and controls. However, of those athletes and controls with normal BMI values, 7% and 50% of the sample respectively, had a BF ≥33%, and were classified as overfat. On the contrary, 4% of the athletes were classified as overweight without being overfat. Thus,BF% should be preferentially used over BMI as a tool for validly classifying body composition in young female athletes and in the general female population. We recommend future studies to develop a classification of BF% values for health status and ranges of BF%. Furthermore, recommended levels of BF% for different sport groups are needed.

WEIGHT RULES, WEIGHT REDUCTION, PERFORMANCE AND ATHLETE'S HEALTH. - A REVIEW OF THE LITERATURE.

STORNÆS, A.

NORWEGIAN SCHOOL OF SPORTS SCIENCE

Purpose: The aim of the project was 1) to evaluate current weight rules (weight categories, weight-in schedule) in sports, 2) to review studies aiming to examining the prevalence of weight loss methods practised by elite and national team athletes, 3) to determine health and performance related outcomes related to use of weight loss methods 4) should weight-rules be changed in any of the sports?

Methods: The literature search was conducted in PubMed, Sport Discus and EMBASE Ovid. 25 studies from 1993-2007 were included. The studies included elite/national level athletes, surveys of weight loss methods, health and performance related aspects of weight loss methods and possible effects of changing the weight-rules.

Results: 1) The weight rules vary in the different sports. 2) Most (64-94%) athletes are dieting and losing weight prior to competition. The average weight reduction is 5-9% of their body weight. Gradual, energy restriction and increased exercise, and rapid weight reduction methods such as sauna, fluid restriction, and sweat suit are reported (by athletes who reduce weight prior to competition).

3) Most studies aiming at examining the health aspects of weight reduction methods have methodological limitations. Rapid and significant weight reduction seems to have negative health effects, and weight regain seems to reverse the negative effects.

The performance related effects seems to be related to the weight loss methods reported and the recovery strategies between weigh-in and competition. The results indicate that rapid, one week or less, or short 6-8 weeks, and a significant weight loss (>5%) is associated with a decrease in performance. However performance level seems to be maintained in those athletes practising longer weight reduction strategies (16-17 weeks), adequate rehydration strategies after weigh-in and by following a diet that is well planned. Finally, this review also indicates that athletes competing in weight class sports more often than other athletes suffer from eating disorders.

4) Rule changes with the intention to be in the benefit of the athletes health is done only in high school/college wrestling in USA and ski jumping. The rule change in ski jumping indicates positive health effects since the number of underweight athletes with BMI <18.5kg/m² were reduced from 22.8% in 2002 to 8.7% in 2004/2005.

Conclusions: Research investigating the short and long term health effects of using different weight loss techniques to meet the requirements in their sports is needed. Athletes who consider weight reduction should receive close guiding related to optimal strategies to meet the requirements. Considering a higher weight class should be discussed with athletes. The weight categories in some sports should be changed. Also the weight rules needs to be further considered, such as weigh-in the same day as competition for all the "Weight-rule sports".

PHYSICAL ACTIVITY AND AEROBIC FITNESS IN A SAMPLE OF CHILDREN LIVING IN TIBET

BERNTSEN, S., BIANBA, ANDERSEN, L.B., LUOBU, O., BJERTNESS, E.

NORWEGIAN SCHOOL OF SPORT SCIENCES

Background: The physical activity and aerobic fitness levels in children living in Tibet are largely unknown. The present study aimed to determine objectively measured physical activity levels and aerobic fitness using direct measurements of peak oxygen consumption in a sample of children living in Lhasa, Tibet.

Methods: Forty-six 9-10 yr old children (20 boys) living in Lhasa (3658 metre above sea level), Tibet, performed maximal cycling on an electronically-braked cycle ergometer with oxygen consumption measurements. Peak oxygen consumption was defined as aerobic fitness. The participants also wore an activity monitor, SenseWear*TM* Pro2 Armband (BodyMedia, Inc., Pittsburgh, PA, USA) for six consecutive days.

Results: All children fulfilled the physical activity recommendations which recommend children to be daily physically active for at least 60 minutes. Moderate physical activity was significantly higher (p=0.001) in boys (Mean and 95%CI; 5.46 (4.24, 6.68) hours per day) vs. girls (3.40 (2.96, 3.84) hours per day). Also vigorous physical activity was significantly higher (p=0.003) in boys (0.83 (0.38, 1.28)) hours per day) vs. girls (0.24 (0.13, 0.35) hours per day). The boys had significantly higher (p<0.001) aerobic fitness compared to the girls (46.5 (43.2, 49.8) vs. 39.5 (37.5, 41.6) ml/min/kg. Vigorous physical activity was positively associated with aerobic fitness and explained 17% of the variability in aerobic fitness (p=0.02).

Conclusions: The children living in high altitude included in the present study were fit and physically active.

RECOVERY METHODS FOR ELITE TEAM ATHLETES-ARE WE ADDRESSING THEIR NEEDS?

VENTER, R.

STELLENBOSCH UNIVERSITY

Introduction: Recovery is seen as an essential component of athletic training, and it is often stated that elite performance is only achievable if athletes balance training and competition stress with adequate recovery. A diversity of means to recover have been suggested throughout sports literature due to the supposed physiological and psychological benefits for the athlete. Although the implementation of recovery strategies has become popular amongst athletes, no information exists on the actual reasons why elite team athletes would want to use recovery methods. Therefore, the aim of this study was to determine the main reasons why elite team athletes use recovery methods during the competitive phase of the year.

Methods: A total of 890 club-, provincial- and national-level players from field hockey (n=214), netball (n=213), rugby union (n=317) and soccer/football (n=145) participated in the study. Data were collected once-off by means of a questionnaire specifically compiled for the study. Players had to indicate their main reasons for using various recovery methods after training and after matches.

Results: Although physical recovery methods (such as cryotherapy and contrast temperature therapy) are often emphasised more, results indicated that the team athletes rated methods relating to their social and emotional recovery as more important. A number of reasons why the athletes used physical recovery methods also became clear, such as relieve from muscle soreness, pain and inflammation. Results showed statistically signicifant differences between players from the various sport codes, as well as players from different levels of participation.

Discussion: Two main issues with regard to recovery methods for team athletes are raised. Firstly, team athletes train and compete under unique circumstances and have specific needs with regard to recovery. Are we really addressing their needs in terms of social and emotional recovery? Secondly, controversy surrounds the use of many of the physical recovery methods for the physiological complaints athletes have. Are the use of these methods in a team setting worth the money, time and effort?

HOW DOSE TIMING TRAINING AFFECT GOLF PERFORMANCE?

SOMMER, M., RÖNNQVIST, L.
UMEÅ UNIVERSITY

Introduction: Timing in terms of intra- and inter-limb coordination and control is an important factor for motor skills. It's also a well-built belief in the golf branch that timing is crucial for optimal golf performance. However, it is surprisingly few empirical studies investigating the timing properties of the golf swing and its effect on the outcome accuracy. Hence, the main purpose of this study was to investigate if training by means of synchronized metronome training (SMT), do affect golf performance accuracy. An additional purpose was to investigate the effect of a task-specific swing training method (Explanar®) in comparison with the non-task specific SMT training method.
Methods: Twenty-six experienced male golfers (mean age 27 years; mean golf hcp 12.6) completed pre- and post-test of golf performance. Investigations were made by use of a P3ProGolf simulator and measurements made from the outcome of golf shots and by use of three different golf clubs (investigating the overall accuracy, length versus direction accuracy and outcome variability). The golfers were randomized into two groups: one non-task specific metronome training group, and one task-specific swing training group. Golfers in the metronome group completed a 4-week intervention (Interactive Metronome, 2008) designed to improve their timing/rhythmicity by reducing the latency in their response to a synchronized metronome beat. Golfers in the swing group completed training designed to improve their golf swing characteristics during the same period.
Results: It was found that he golfers' in the non-task specific metronome training group showed a significant effect of SMT training by means of improvements in their motor timing and synchronizations. Additionally, they significantly improved their scores on selected golf accuracy variables and with evidently decreased variability after the 4-week training period. No such improvements were found for the golfers in the swing training group.
Discussion: In agreement with previous findings by Libkuman et al. (2002), this study provides further evidence that timing training leads to improvements in golf performance accuracy. One possible explanation is that SMT increased accuracy because the temporal properties of the golf swing were improved. An alternative explanation is that SMT training does improve the golfers' ability to concentrate and stay in focus. The online motor correction based on feedback may contribute to optimization of timing and organized actions. Thus, IM training seems to affect the person's abilities to inhibit irrelevant stimuli and distracters. These findings have interesting implication for developing complementary "timing training methods" also associated to other sports than golf.

CARDIOVASCULAR RISK FACTORS ASSOCIATED WITH SOCIO-GEOGRAPHIC ENVIRONMENT IN AFRICAN CHILDREN AND YOUTH FROM MOZAMBIQUE

PRISTA, A., DAMASCENO, A., MAIA, A., NHANTUMBO, L., SARANGA, S., SEABRA, A., WILLIAMS-BLANGERO, S., BEUNEN, G.
FACULTY OF PE AND SPORTS SCIENCES, UNIVERSIDADE PEDAGÓGICA

Associated with abrupt changes in lifestyle, the importance of cardiovascular disease in morbidity and mortality in Africa is increasing, which recommends surveillance in school-age children and youth. The aim of the present study was to describe, interpret and establish age, sex and socio-geographic trends for cardiovascular risk factors in school age population from Mozambique. Three cross sectional surveys were carried out in the year 1992, 2000 and 2005. Studies were done in an urban and a rural area from Mozambique. Sample's includes a total of 1 939 boys and 2 037 girls , aged 7 to 17 years, classified in 4 socio-geographic groups namely ELITE, URBAN, PERYPHERY and RURAL. Cardiovascular risk factors include BMI, % of FAT, Blood pressure (BP), Cholesterol (CHOL), Cardiorespiratory fitness (CRF) were measured at the three studies using the some standard protocols. Standard criteria for risk classification were used for each variable. Physical activity (PA) was measured by a questionnaire. Prevalence of risk was: BMI =5.4%, FAT=9.6%, CHOL=1.2% and CRF=9.6%. Higher prevalence was in BP (SBP = 16.4; DBP = 11.8). Patterns of CVRF were different according to age, gender and socio-geographic groups and variable. Trend from urban sample's from 1992 to 2000 indicates increasing risk for excess of FAT, BP and low CRF while no changes in CHOL have been observed. PA were significantly associated with CRF and FAT although interacting with socio-geographic position. It was conclude that CVRF are already present in this young age group of sub-Saharan African country, indicating that a rapid epidemiological transition is taking place.

LOW CORE BODY TEMPERATURE DURING ENDURANCE CYCLING: ASSOCIATED NON-OSMOTICALLY REGULATED CHANGES IN URINARY OUTPUT

PETERS, E.M., PILLAI, P.
UNIVERSITY OF KWAZULU-NATAL

Introduction: Our previous field study identified the possibility of different mechanisms contributing to hydration status when cycling in hot and cold environmental conditions (Rose and Peters, 2008). This cross-over laboratory study therefore examined selected vasopressin-induced cardiovascular and renal adaptations to differences in core body temperature during endurance cycling when serum osmolality remained constant.
Methods: After voiding their bladders, 13 well-trained male road cyclists (age: 29.2 ± 6.5 yrs) completed two 90-minute trials at 60 - 65% VO2 max in warm (28.2°C), humid (72.1% relative humidity) and cool (18.3°C), windy (4- 5 m/s) conditions. Subjects were required to

maintain a constant power output in the two trials and ad libitum fluid intake was permitted. Body mass, serum osmolality and concentrations of sodium, potassium, cortisol and glucose as well as urine osmolality and volume were measured pre-and post-trial. During the trials, tympanic temperature, heart rate, blood pressure, blood glucose concentration and serum osmolality were monitored at 15 minute intervals.

Results: Mean power output was insignificantly different (247 ± 25.9 vs. 249 ± 26.2W; $p > 0.05$) between warm, humid and cool, windy trials. Mean post-trial serum osmolality (283 ± 3.8 vs. 285 ± 6.1 mOsm/L), body mass (72.8 ± 9.8 vs.73.5 ± 9.3 kg), haematocrit (45.6 ± 2.6 vs. 46.1 ± 2.8%) and circulating concentrations of sodium (138.4 ± 2.6 vs. 140.9 ±2.7 mmol/L), potassium (4.4 ± 0.4 vs. 4.6 ± 0.4 mmol/L) and glucose (5.2 ± 0.9 vs. 5.1 ± 0.9 mmol/L) were not different between the trials ($p > 0.05$). Mean peak tympanic temperature (38.8 ± 0.7 vs. 35.2 ± 0.8°C), heart rate (174.2 ± 15.3 vs. 149.0 ± 11.3 b/min) and post-trial serum cortisol (717 ± 144 vs. 306 ± 147 nmol/L) were higher in the warm trials ($p < 0.05$). During the cool trials, elevations in systolic and diastolic blood pressure did not differ from those in the warm trials, but urine volume after the trials was significantly greater (488 ± 301 vs. 57 ± 31 ml) and more dilute (osmolality: 435 ± 269 vs. 832 ± 191 mOsm/L), despite a lower fluid intake during these trials ($p < 0.001$).

Discussion: The unchanged body mass, haematocrit and serum electrolyte concentrations and osmolality following both 90-minute trials indicate that euhydration was maintained during the trials. Of greatest interest is the association between the decrease in urine osmolality from pre- to post-trial, the increase in free water excretion and lower serum cortisol concentrations after the cold trial. This suggests possible thermal and/or cortisol–induced non-osmotic regulation of urinary volume and concentration, but not blood pressure. The potential effect of core body temperature on vasopressin release and the likelihood that vasopressin-2 receptors are implicated in the non-osmotic regulation of vasopressin during exercise, require further examination.

NO EFFECT OF A DOPAMINE/NORADRENALINE REUPTAKE INHIBITOR ON FIXED INTENSITY AND SELF-PACED CYCLING PERFORMANCE IN THE HEAT.

ONUS, K.J., MARINO, F.E., LIBERTS, E., CANNON, J.

CHARLES STURT UNIVERSITY

Maintaining central neurotransmission is essential in providing the required drive to motoneurons during exercise performance. Recent evidence indicates that inhibiting dopamine and noradrenaline (DA/NA) reuptake by the use of Bupropion (BUP) improves power output during cycling in the heat with an augmented core temperature (Tcore) and similar perception of effort and thermal stress compared to placebo (1). The purpose of this study was to examine the effect of a DA/NA reuptake inhibitor during fixed and self-paced exercise in HOT (32.04±1.1°C, 65.8±1.7% relative humidity) and COOL (20.09±0.5°C, 47.9±2.7% r.h.) conditions. Eight healthy, active male subjects (22.1±5.4 years) completed a 30 min fixed power cycling trial with 30 s sprints at each 9.5 min interval, followed by a 30 min self-paced time trial (TT) with 30 s sprints at similar intervals. The study was single blind, placebo controlled, crossover design with groups referred to as: Bupropion (BUP) or Placebo (PLA) in a single blind fashion.

There was no significant difference in distance cycled for the fixed power output trial (16.09 – 17.03 km, $p > 0.05$) nor for the self-paced performance trial (12.36 – 13.0km, $p > 0.05$) among conditions. Tcore increased significantly over time for each condition during the fixed-power trial. However, Tcore was significantly higher for BUP in both the HOT and COOL condition during the fixed power trial compared to PLA. Tcore continued to rise during the subsequent TT for BUP only in the HOT condition, whereas Tcore declined for BUP in the COOL condition, to values similar to pre-exercise. Skin temperature increased significantly during HOT to ~ 35.5°C and was significantly different from COOL (~31°C, $p > 0.05$). Rating of thermal sensation increased over time for both fixed-power and TT but was significantly higher for the HOT condition. Heart rate increased similarly for each condition during the sprints in both the fixed-power and TT. Perceived exertion (RPE) increased in each condition and peaked during the sprints but was significantly higher for BUP at the end of the TT in the heat.

These findings suggest that the use of a DA/NA reuptake inhibitor alters thermoregulation, but this alteration does not provide for enhanced performance either in HOT or COOL conditions and that performance at least over 30 min in a self-paced mode is possibly independent of thermoregulatory responses.

UTILITY OF THE PHYSIOLOGICAL STRAIN INDEX WHEN APPLIED TO OUTDOOR DISTANCE RUNNING IN A WARM-HUMID ENVIRONMENT

BYRNE, C., LEE, J.K.W., LIM, C.L.

UNIVERSITY OF EXETER

The physiological strain index (PSI) based on core temperature (Tc) and heart rate (HR) has been proposed as a universally acceptable means of quantifying, on a scale of 0-10, the combined load on the thermoregulatory and cardiovascular systems during exercise in environmental heat (Moran et al., 1998). The aim of this study was to quantify and assess the utility of the PSI during outdoor mass-participation distance running in a warm-humid environment. Twenty four heat-acclimatized professional soldiers competing in the Singapore Army half-marathon volunteered with informed consent to participate in this ethics committee approved study. The runner's mean (SD) age, stature, body mass, and maximal oxygen uptake were: 26 (3) y; 1.72 (0.05) m; 65.4 (6.3) kg; and 59 (5) ml/kg/min, respectively. Each runner wore a heart rate monitor and ingested a telemetric temperature sensor for the continuous measurement of HR and Tc, respectively. The PSI was calculated at minute intervals by the standard formula: $PSI = [5(Tct - Tc0) / (39.5 - Tc0)] + [5(HRt - HR0) / (180 - HR0)]$; where Tct and HRt are simultaneous measurements at any time and Tc0 and HR0 are the initial measurements. Ambient temperature and humidity during the race were 26.4 (0.4)°C and 81 (1)%, respectively. All volunteers finished the race asymptomatic of heat illness in a duration of 107 (10) min, corresponding to a mean velocity of 11.7 (1.0) km/h. Peak Tc was 39.7 (0.5)°C, with 66% of runners experiencing Tc greater than the PSI formula maximum of 39.5°C. Peak HR was 186 (6) beats/min with 83% of runners experiencing HR greater than the PSI formula maximum of 180 beats/min. The PSI was 6.9 (0.7) at 15 min and increased significantly (up to 90 min) and progressively throughout the race i.e. 8.3 (0.9) at 30 min ($P<0.001$), 9.1 (1.4) at 60 min ($P=0.003$), 9.8 (0.3) at 90 min ($P=0.011$), and 10.3 (1.8) at race finish ($P=0.067$). Fifty eight percent of runners experienced a PSI greater than the theoretical maximal value of 10. Our results suggest the Tc and HR constraints of PSI (i.e. 39.5°C and 180 beats/min) are too low for the current application involving trained heat-acclimatized distance runners competing in environmental heat. Calibration of the PSI formula with an individual's true maximum HR and

a more realistic maximal Tc is likely to improve the utility of the index. For the latter, a value of 41°C represents a more realistic maximal Tc for trained and acclimatized distance runners competing in environmental heat (Byrne et al., 2006).

EFFECT OF A LOWER BODY COMPRESSION GARMENT ON RUNNING PERFORMANCE IN COLD AND HOT ENVIRONMENTS

GOH, S., NOSAKA, K., DASCOMBE, B., LAURSEN, P.

EDITH COWAN UNIVERSITY

Introduction: Lower body compression garments (LBCG) are popular attire worn amongst high performance athletes and the general sporting population. Only two previous studies have investigated the effect of LBCG on endurance running performance. One study [1] showed improvement in running economy with LBCG; the other [2] did not find an effect on 10 km running performance. Due to the potential insulatory and thermal effects that LBCG could have during exercise, LBCG should be examined under different ambient temperatures. The purpose of the present study was to investigate the effect of LBCG on sub-maximal and maximal running performance in hot and cold environments.

Methods: Ten male recreational runners (19 - 44 y, VO2max: 56 - 64 ml/kg/min) performed 4 running performance tests (20 minutes at first ventilatory threshold [VT1], followed immediately by a run to exhaustion at VO2max running speed [v.VO2max]) under 4 different conditions (10°C with LBCG, 10°C without LBCG, 32°C with LBCG, 32°C without LBCG) in a random order. Changes in oxygen consumption (VO2), heart rate, rating of perceived exertion (RPE), blood lactate and skin and rectal temperature were compared with (LBCG) and without LBCG (CONTROL) for each temperature separately using a two-way repeated measures ANOVA. Time to exhaustion (TTE) was compared between conditions with a paired t-test. Significance was set at $p<0.05$.

Results: TTE was not significantly different between LBCG and CONTROL at either 10°C (158  74 vs. 148  73 s) or 32°C (115  40 vs. 97  33 s). Most physiological parameters examined during sub-maximal and maximal running were not significantly different between conditions for both ambient temperatures. However, RPE during sub-maximal running at 32°C was significantly lower for LBCG (13.8  2.0) compared with CONTROL (14.5  2.7), and skin temperature following the 10°C maximal running trial was significantly higher ($p=0.007$) in the LBCG (27.9  0.8°C) versus CONTROL (26.4  1.2°C) condition.

Discussion: The present study found no significant influence of LBCG on TTE and running economy irrespective of ambient temperature. The lower RPE found for the LBCG condition is difficult to explain, as we hypothesized that LBCG would have an adverse effect in a hot environment as a result of an assumed insulatory effect. It is possible that athletes might 'feel better' when wearing LBCG, even in the heat. In conclusion, LBCG had no beneficial or adverse effects on maximal or sub-maximal running performance in hot or cool environments.

URINARY EXCRETION OF 8-HYDROXY-2´-DEOXYGUANOSINE <8-OHDG> AS A BIOMARKER OF OXIDATIVE STRESS IN ULTRA-MARATHON RUNNERS

WESSNER, B., VIDOTTO, C., GRIBITZ, L., ATAMANIUK, J., BACHL, N., TSCHAN, H.

UNIVERSITY OF VIENNA, CENTRE OF SPORTS SCIENCES AND UNIVERSITY SPORTS

Introduction: During the resting state the human body continuously produces reactive oxygen species (ROS), but in healthy individuals these ROS are produced at levels well within the capacity of the body's antioxidant defence system. Strenuous physical activity increases oxygen uptake which may result in the production of ROS at rates that exceed the body's capacity to detoxify them. DNA, proteins and lipids are known to be the biological targets of oxidative damage [1]. In a recent study we have shown that mRNA levels of cell protective (Hsp70 and Hsp32) as well as pro-apoptotic (Bax) genes increased whereas Bcl-2 mRNA (anti-apoptotic) decreased in monocytes of ultra-endurance runners. Levels of cell-free plasma DNA were significantly increased immediately post race [2]. The present study was designed to investigate whether the stress of a six hours ultra-marathon running event can induce oxidative DNA damage in trained runners as assessed by comparing urinary 8-hydroxy-2´-deoxyguanosine (8-OHdG) pre- and post race.

Methods: Resting and post-exercise spot urine were sampled from 13 healthy hobby ultra-endurance athletes, all non-smokers (age: 47.5 ± 5.5 years) that had been engaged in endurance training and competition for 10.5 ± 6.4 years before submitted to the trial. Urinary 8-OHdG was measured by an enzyme-linked immunosorbent assay according to the assay kit instructions provided by the manufacturer (Japan Institute for the Control of Aging, Fukori, Japan).

Results: Baseline urinary levels of 8-OHdG were within the normative range of healthy people and increased significantly from pre- to post-race (pre-race: 4.5 ± 1.4 nmol/mmol creatinine; post-race: 6.3 ± 1.4 nmol/mmol creatinine; $p<0.001$). In 12 out of 13 subjects, post-race elevations were within the physiological reference range as provided by the manufacturer.

Conclusion: Strenuous endurance exercise in middle-aged recreational runners induces a significant elevation of urinary 8-OHdG indicating the challenging of the body's antioxidant defence system. Although elevated, 8-OHdG levels did not exceed the normal physiological range.

DOES EXERCISE IN HOT ENVIRONMENTAL CONDITION IMPAIR DETECTION OF ERYHROPOIETIN DOPING?

CAILLAUD, C., TROUT, G., HOWE, C., SIMAR, D., FATSEAS, G., KAZLAUSKAS, R.

THE UNIVERSITY OF SYDNEY

The abuse of recombinant erythropoietin to stimulate red blood cells synthesis and to improve physical performance is a major concern and improving rHuEPO detection is a real challenge. The current detection method approved by the World Anti-Doping Agency (WADA) is based on the analysis of erythropoietin (EPO) isoforms distribution in urine. A concern has recently been raised as whether strenuous prolonged exercise performed in hot environmental conditions may or not alter native EPO synthesis, EPO excretion or urine isoform distribution. This study was designed to test whether intense exhaustive exercise performed in hot condition will: change haematological parameters; modify EPO isoforms distribution in urine; impair rHuEPO detection via increased excretion of basic isoforms and/or increased protein concentration.

After an initial maximal exercise test, 6 highly trained cyclists (26.5 (5) yrs, VO2max:61.1 (4) ml/kg/min) performed 1 hour's cycling at 70% VO2max in the heat (35oC, 40% rh). The participants then started the acclimatisation period: during 6 consecutive days they did 60 min of cycling exercise at 70% VO2max in hot condition. Blood and urine samples were collected pre and 1hr post exercise during the first and the last exercise session. Haematocrit (Hct), Haemoglobine concentration ([Hb]), EPO were measured and ON-hes and OFF-hre models were calculated. Urine was analysed for EPO isoforms according to current recommendations by wada and updated by wada technical document TD2007EPO. Pre acclimatisation, exercise did not significantly changed [Hb], Hct or models scores ([Hb]: 149.7 (13.6) vs 150.8 (7.5) g/l; Hct: 0.459 (0.04) vs 0.461 (0.03); ON-hes: 171 (22) vs 173 (22); OFF-hre: 84.5 (9) vs 86.3 (4). Post acclimatisation all variables declined post exercise ([Hb]: 148.2 (11.4) vs 141.2 (11.6) g/l; Hct: 0.452 (0.04) vs 0.426 (0.03); ON-hes: 171 (17) vs 163 (13); OFF-hre: 78.8 (5) vs 74.1 (9)). None subjects reached critical cut off levels for identification of EPO doping. Our haematological data support previous reports and demonstrate that 6 days of intense exercise in hot condition do not significantly change variables used in the indirect detection of rHuEPO doping. Some of the changes observed are opposite of those expected to be induced by rHuEPO abuse. Results from urine samples were analysed using both the current peak ratio criteria (B2:E) and the older criteria consisting in the percentage of basic isoforms. We did not find any sample approaching the criteria required for the identification of rHuEPO. The results do not support a hypothesis that acute or chronic exercise in hot environment might impair rHuEPO detection through shifts in the distribution of EPO isoforms. In conclusion this study shows that vigorous aerobic exercise performed in the heat for several consecutive days does not lead to false positive cases of EPO doping.

FREELY CHOSEN CADENCE AN GROSS EFFICIENCY DURING ERGOMETER AND FREE BICYCLING

LEIRDAL, S., ETTEMA, G.

HUMAN MOVEMENT SCIENCE, NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY.

Introduction: Freely chosen cadence (FCC) may be regarded a fixed parameter, robust for many conditions. The effect of work rate on FCC is unclear: Some studies provide evidence for a modest increase, while others report FCC not to change with work rate. Many laboratory studies are performed on a bicycle ergometer, using a fixed work rate that is independent of the cadence that is chosen. The mechanism that links cadence and work rate differs from the mechanism that applies in free cycling, where both cadence and gears can be used for attaining a certain work rate. The purpose of this study was to examine the effect of the type of regulation of work rate on the relationship between this work rate and FCC and gross efficiency.

Methods: 18 male well trained cyclists participated in the study. One group, free cycled (FC) on their own competition bike mounted on an electromagnetic roller, could use gearing and cadence to achieve each power output level, imitating outdoor cycling. The other group (EC) performed the same protocol on an ergometer with a computer controlled electro-magnetic brake mechanism that generates a constant work rate, independent of cadence. Subjects performed an increasing work rate protocol from 100W up to exhaustion, with a 50W increment every 2 minutes. Pedal rate, oxygen consumption, and heart rate were measured continuously.

Results: Statistical analysis showed a strong interaction between group and work rate on cadence ($p<0.001$). In the FC group work rate affected cadence ($p<0.001$), cadence increasing from 72 rpm at 100W to 106 rpm at 350W. For the EC group, no work rate effect was present (average FCC 92 rpm). Gross efficiency increased with work rate for both groups. The efficiency-cadence relationship was strongly affected by the protocol. At a given work rate, very similar efficiency values was obtained at highly different cadences.

Discussion: The discrepancy in the FCC-work rate relationship between the EC group and the FC group in the present study may be related to the manner in which one can regulate work rate. FCC does not only depend on work rate but is affected considerably by the manner work rate can be (or not) controlled by cadence. This finding may have important implications for the interpretation of the preferred pedaling rate, especially how this is related to optimizing metabolic cost. Thus, a mismatch between the most efficient and preferred cadence, as found in some studies, may be caused by the way cadence on work rate are controlled. Some suggest that the most efficient cadence increases with work rate and that the preferred one does not. Thus, at relatively high work rates, when metabolic costs become a critical factor, the preferred cadence may be similar to the most efficient. However, this hypothesis is based on results mainly from ergometer studies. The present study indicates a different situation for free cycling: cyclists may prefer a higher than most efficient cadence also at high intensity.

THE KINETIC OF QUADRICEPS MUSCLE FATIGUE DEVELOPMENT DURING CONSTANT-LOAD CYCLING

VERGES, S., DECORTE, N., LAFAIX, P.A., MILLET, G., WUYAM, B.

JOSEPH FOURIER UNIVERSITY AND GRENOBLE UNIVERSITY HOSPITAL; JEAN MONNET UNIVERSITY, SAINT-ETIENNE

Introduction. Exercise-induced muscle fatigue has been Introduction. Exercise-induced muscle fatigue has been mostly investigated at exhaustion, i.e. reporting the reduction in force immediately after exercise compared to resting measurements. The kinetic of fatigue development during exercise remains however unclear and may help to better understand the mechanisms of fatigue and task failure. To study the kinetic of quadriceps fatigue development, we used the magnetic stimulation techniques we recently validated (1) during an intermittent constant-load cycling exercise performed until exhaustion.

Methods. Thirteen subjects cycled at 80% of maximal power output with, every 6 min of exercise, a 4 min break to assess quadriceps fatigue with maximal voluntary contractions, single (1Hz), paired (10 and 100Hz) potentiated and interpolated stimulations of the femoral nerve. Electromyographic signal (EMG) of the quadriceps was recorded during stimulations and during cycling. Handgrip strength as well as ventilation, gas exchange, blood lactate and rate of perceived exhaustion during cycling were also measured.

Results. Subjects cycled for a total of 31.2 ± 7.5 min. The force ratio of stimulations at 10/100Hz was significantly reduced after the first 6 min of cycling compared to rest (0.84 ± 0.14 vs 1.03 ± 0.16; $p < 0.001$) while it did not decrease significantly anymore until exhaustion (0.74 ± 0.14). Maximal voluntary activation was significantly reduced compared to rest at exhaustion only (86.3 ± 6.5% vs 92.3 ± 4.2%; $p < 0.001$). Handgrip strength did not change significantly throughout the protocol ($p > 0.05$). Root mean square of the vastus lateralis EMG was significantly increased compared to the first minute of cycling from the end of the second 6 min bout (last min of second bout: +63 ± 101%; last min of exercise: +91 ± 100%; $p < 0.001$). The amplitude of force decrement and EMG increases during cycling did not correlate throughout the protocol.

Conclusion. We concluded that peripheral low frequency fatigue mainly developed early during constant-load intense exercise, while central fatigue seems to be rather associated with task failure.

HEART RATE RECOVERY AS A GUIDE TO PREDICT FATIGUE AND CHANGES IN PERFORMANCE PARAMETERS.

LAMBERTS, R., SWART, J., CAPOSTAGNO, B., NOAKES, T.D., LAMBERT, M.I.

UNIVERSITY OF CAPE TOWN

Background

Determining the optimal balance between training load and recovery is part of achieving peak performances in well-trained and elite athletes. In the process of monitoring this balance, the measurement of heart rate recovery (HRR) after exercise has shown to be responsive to recently applied training loads (1,2). However, the link between a decrease in HRR, fatigue and an impairment in performance, has not been confirmed. Therefore, the aim of this study was to monitor HRR and cycling performance in a group of well-trained cyclists who participated in a 4 week high intensity training (HIT) program.

Methods: Fourteen well-trained cyclists participated in a 4 week program consisting of 8 HIT sessions. Before and after the training period peak and endurance parameters were measured. HRR was measured after each HIT session (HRRHIT) and expressed a relative change compared to after the first HRRHIT. Retrospectively cyclists were assigned to a group that continuously increase their HRRHIT (GIncr) or a group that showed a decrease in HRRHIT (GDecr).

Results: The relative peak power output improved in both groups had (GIncr; $P = 0.001$ and GDecr; $P = 0.016$, respectively), as did parameters of endurance performance ($P = 0.001$ and $P < 0.048$, respectively). A significant interaction effect of Group X Time was found for 40-km TT power ($P = 0.010$), indicating that GIncr improved significantly more than GDecr after the HIT period. Improvement in 40-km TT time showed a similar tendency and although effect size statistics showed a "moderate" to almost "large" chance that this difference is clinically meaningful, this effect was not statistically significant ($P = 0.059$).

Conclusions:

This is the first study show that a decrease in HRR after exercise, during a HIT training period, is associated with a blunted improvement in endurance performance. However, changes peak performance seem initially to be unaffected. This suggests that a decrease in HRR, which possibly reflects accumulative fatigue (3,4), initially compromises endurance performance rather than peak performance. Therefore, HRR has the potential to monitor changes in endurance cycling performance and contribute to a more accurate prescription of training load in well-trained and elite cyclists.

RELATION OF MYOELECTRIC AND OXYGENATION CHANGES DURING FATIGUING ISOMETRIC CONTRACTIONS

COTUK, B., SAYLI, O., BICER, B., BESTING, A., UZUN, S., PELVAN, O., TATAR, Y., PERLITZ, V., AKIN, A.

MARMARA UNIVERSITY (TURKEY), BOGAZICI UNIVERSITY (TURKEY), RWTH AACHEN (GERMANY)

Introduction: Near infrared spectroscopy (NIRS) allows to study local muscle oxidative metabolism in a noninvasive way. By combining NIRS measurements with surface EMG data, we investigated the relation of electromyographic and oxygenation changes during isometric contractions in various muscles.

Methods: 33 athletes from three different sport disciplines (rowing, volleyball and karate) participated in the study. The athletes were asked to perform isometric exercises with different muscles at 50% of maximal voluntary contraction force as long as possible. Task failure was assessed by visualization of force output level on a computer screen. NIRS and EMG recordings were obtained from the flexor digitorum superficialis, biceps brachii and vastus lateralis muscles. For evaluation of the lower back muscles a modification of the Bier-

ing-Sorensen muscular endurance test with 15 degrees forward bend was used: NIRS and EMG were recorded bilaterally from the center of the erector spinae muscle at the level L3.

For analysis of the NIRS data, least square regression lines were computed and inflection points between different slopes were identified. For analysis of the EMG the median frequency (MDF) of the power spectrum was computed by the Fast Fourier Transform on sequential epochs. Additionally, we used a novel nonlinear approach by tracing the changes of the instantaneous frequency with maximum power (MPF) in the Morlet wavelet based time-frequency distribution (mTFD).

Results: An identical pattern was found in all NIRS and EMG measurements. Muscle oxygenation showed an initial rapid decrease (RD) followed by a long lasting plateau (LP). During the RD phase both MDF and MPF remained constant on a high frequency level. During the LP phase both MDF and MPF showed a linear decrease, mostly beginning at half time of the entire contraction. The time ratio of RD/LP was significantly correlated to the frequency decrease.

Discussion: Our results contradict studies reporting coincidence and correlation of the decay of oxygenation during the RD phase and decrease of MDF in the EMG (1). In our study, during this first phase (RD) the decay of oxygenation was not correlated with myoelectrical activity. Only during the second LP phase of the fatiguing isometric contractions the EMG power spectrum shifted to lower frequencies. Although the local tissue oxygen content now remained constant, the developing fatigue was characterized by this myoelectrical alteration. Thus, we strongly recommend the use of nonlinear time series analysis, e.g. wavelet power spectrum, for tracking the instantaneous frequency changes in the EMG.

EFFECTS OF INCREASED EXTRACELLULAR POTASSIUM AND LACTIC ACID ON DYNAMIC MUSCLE CONTRACTIONS IN ISOLATED RAT SOLEUS MUSCLES

OVERGAARD, K.

UNIVERSITY OF AARHUS

Introduction: It is well known that in muscles, increased extracellular potassium concentration ([K+]o) reduces excitability and isometric force. [K+]o is, therefore, considered an important factor in muscle fatigue. The effects of [K+]o on dynamic muscle function parameters such as maximal power or maximal unloaded velocity (Vo) are, however, not extensively studied. Knuth et al. (2006) observed that a reduction in muscle fiber pH to 6.2 gave a larger decrease in maximal power than expected from the loss of isometric force. This was explained by pH affecting maximal unloaded velocity (Vo) and the curvature of the FV relation. In contrast, the effects of high [K+]o on muscle isometric force and excitability have been shown to be alleviated by lowering pH with lactic acid (LA) (Nielsen et al., 2001). The present study was undertaken to investigate the effects of [K+]o and combinations of [K+]o and LA on dynamic muscle function.

Methods: Soleus muscles from 4 wk old Wistar rats were isolated and incubated in standard K.R. buffer at 30°C initially containing 4 mM K+ and equilibrated with 95% O2/5% CO2 (pH 7.4). Muscles were mounted on a force/length controlled dynamometer (305B, Aurora inc., Canada) at Lo. Muscles were stimulated every 10 min with 1.5 sec pulse trains (60 Hz) to obtain tetanic activation. Muscles were held isometric until force was fully developed, where after the resistance was reduced to preset force levels in brief steps (0.2s sec) and length changes were recorded over time. Data points for force and velocity were used to construct FV curves by fitting to the Hill equation. Maximal power was calculated from the Hill plots. During the experiment [K+]o was increased from 4 to 9 mM and subsequently 20 mM LA was added (reducing buffer pH to 6.9).

Results: Increasing [K+]o from 4 to 9 mM reduced maximal power by 64±7% (mean±sd), which was significantly more than the 50±10% reduction seen in isometric force ($P<0.05$, n=4). The Vo obtained from extrapolation of the Hill curves was not significantly changed by increased [K+]o (18,4±2,0 mm/s vs 19,0 ±2,1 mm/s, $P>0.05$). When 20 mM LA was added to the 9 mM K+ buffer, the isometric force and maximal power recovered completely to the level initially obtained in 4 mM K+. LA did not significantly affect Vo.

Discussion: Maximal power was substantially decreased by increasing [K+]o and this decrease was relatively larger than the reduction in isometric force. Since Vo was not reduced by 9 mM K+ the relatively large reduction in power may be due to an increased curvature in the FV relation. The effect of 20 mM LA added to muscles in 9 mM K+ was a complete recovery of dynamic contractile function. At the concentrations used here, LA protects dynamic muscle function against the deleterious effects of high [K+]o, and no fatiguing effects of LA were found in muscles contracting dynamically.

TRAINING INDUCED CHANGES IN TENDON MECHANICAL AND MATERIAL PROPERTIES ARE RELATED TO MUSCLE HYPERTROPHY, NOT TO STRENGTH GAINS.

SEYNNES, O.R., ERSKINE, R.M., MAGANARIS, C.N., NARICI, M.V.

MANCHESTER METROPOLITAN UNIVERSITY

The design of tendinous structures determines their interaction with the muscle (2) and the coordination of the changes occurring in both structures is critical to the preservation of muscle-tendon unit function. To get a better understanding of the effect of chronic overloading on human tendon, we investigated the relationships between the structural and mechanical adaptations of the patellar tendon and of the quadriceps femoris muscle in response to strength training.

Fifteen healthy male subjects (20 ± 2 yrs) underwent 9 weeks of knee extension resistance training. Tendon load-deformation properties were measured with ultrasonography during a ramp maximal isometric contraction, and tendon cross-sectional area (CSA) was determined along the entire length of the tendon by using magnetic resonance imaging (MRI). Maximal isometric force was measured at the optimal knee joint angle of force production. The physiological CSA (PCSA) of the quadriceps femoris muscle group was obtained by combining measurements of muscle volume (MRI) and architecture (ultrasound).

Following training, muscle force and PCSA increased by 31% ($P < 0.0001$) and 7% ($P < 0.01$), respectively. Increases in tendon CSA were observed in regions corresponding to 20%, 30%, 60%, 90% and 100% of the tendon length (5-6%, $P < 0.05$), and tendon stiffness and modulus increased by 24% ($P < 0.001$) and 20% ($P < 0.01$), respectively. None of the changes in tendon mechanical properties or CSA were related to the increase in maximal force. However, we observed a positive correlation between the increase in quadriceps PCSA

and the increases in tendon stiffness (r = 0.68, P < 0.01) and Young's modulus (r = 0.75, P < 0.01). Unexpectedly, the increase in muscle PCSA was inversely related to the mean increase in tendon CSA (r = -0.64, P < 0.05).

These data show that patellar tendon hypertrophy is prominent near but not limited to osteo-tendinous junctions. The positive relationships between increases in tendon stiffness and modulus and muscle PCSA, but not with maximal force, suggest that changes in tendon mechanical and material properties to overloading are closely related to the loading history, rather than to the increase in maximal stress that can be exerted upon the tendon. The inverse correlations between changes in tendon mean CSA and in muscle PCSA, or lack thereof, implies that the mechanisms underlying acute tendon hypertrophy are different than those responsible of the increase in tendon dimensions with development (1).

IS-SS10 Physical Education, Obesity and Health - Critical Perspectives

GOVERNING BODIES: BIO-PEDAGOGIES AND THE OBESITY EPIDEMIC

WRIGHT, J.

UNIVERSITY OF WOLLONGONG

The idea of an 'obesity epidemic' has taken hold internationally with widespread media attention, government health initiatives and interventions at a range of levels (from health to education) and changes in school policies and practices. In this presentation I will make the argument that the 'obesity epidemic' and associated practices depend on a range of pedagogies that affect contemporary life at both the level of the individual and the population. The concept of 'bio- pedagogies' will be introduced as a means to conceptualise how these pedagogies function. The notion of bio-pedagogies is drawn from Foucault's (1987) concept of 'biopower', the governance and regulation of individuals and populations through practices associated with the body. Bio-pedagogies not only place individuals under constant surveillance, but also press them towards increasingly monitoring themselves, often through increasing their knowledge around 'obesity' related risks/issues, 'instructing' them on how to eat healthily, and stay active and contributing to affective investments in the ways children and young people come to think about themselves and their bodies. The presentation will report on the first steps in the theorising of the results of a joint UK, Australian and New Zealand project, which investigated the impact of the new 'health imperatives', or as we have come to call them 'biopedagogies', associated with the rhetoric of the 'obesity epidemic' on schools and school students. The shared purpose of the project is to explore how schools have taken up and recontextualised the new health imperatives within their policies and practices, and how this has impacted upon students' lives.

SAVING YOUNG PEOPLE FROM OBESITY - FOR THE GOOD (?) OF THE SOCIETY

QUENNERSTEDT, M.

ÖREBRO UNIVERSITY

Over the past two decades there has been a worldwide reappearance of interest in health education and the health of young people both from educators and from politicians. In the light of the western world's growing population of aging people and the difficulty with obesity and other health problems, focus has been given to education as a tool for creating healthy citizens in terms of ready-made lifestyles and healthy behaviours.

Although the evidence about young people's health and participation in physical activities is inconclusive, young people, as "the coming future", have become a principal target of government initiatives aimed at countering the perceived trend of increasing ill-health.

In the presentation media texts, video games (exergaming), school curricula and research on health education is used to illustrate a possible shift towards a more individualistic, instrumental, biomedical, but also a more morally normative health approach directed towards behavioural change, disease prevention, individual lifestyle choices and in that sense teaching young people to be healthy. The consequences of this is now revealing itself in schools regarding running 'fat laps' for overweight children (Australia), special PE for overweight students (Sweden), governmental health surveillance through BMI (USA, UK) and daily physical activity in schools using unfounded walks without content where energy in/out constitute the central rationale for the implementation of the activity.

However, an alternative to conceiving good health as something that can be defined by politicians, researchers, public health policies, sport federations and the media, set up as an aim for young people to achieve, is instead to conceive health in the context where they live, learn and flourish in terms of learning health. Learning health, then, is something you continuously do, as a practice and not as an outcome. To overcome individualism and instrumentalism in health education we need to discuss learning as situated in young peoples lives as well as in a wider social, cultural, political context. In this way health is also regarded as a societal responsibility in terms of that the wider context provides opportunities to be healthy and to learn healthy living. This way of conceiving health and health education is clearly supported by school curricula in several countries (e.g. New Zealand and Sweden). However, the national curricula also opens up for health education reduced to consumerism practices where we turn over the health messages to young people to private enterprise, media, sports organizations, fitness people and TV programs like 'down size me'.

In research, if we are to understand the construction of school health knowledge, we have to go beyond the instrumentalism and individualism of health education and health policy and as researchers take an interest in how young people learn health and in what ways they have the possibility to be healthy and to develop health.

WHAT MESSAGES ARE YOUNG NORWEGIANS LEARNING ABOUT HEALTH AND FITNESS IN SCHOOL PE?

DOWLING, F., ASPEN, K.T.H.

NORWEGIAN SCHOOL OF SPORTS SCIENCES

In 2005, the Norwegian government launched an action plan designed to increase the population's physical activity levels due to evidence that Norwegians are "succumbing to the health-impairing lifestyle of post-modern society …that among other things involves a decrease in the level of activity"(NM, 2005:2). The strategy document was the product of eight ministries' efforts to produce a "national mobilisation in order to promote improved public health through increased physical activity" (NM, 2005:3), not least with the intention of reducing incidents of coronary heart disease and an acknowledgement of the World Health Organisation's declaration about a global obesity epidemic. Schools were seen as prime sites for providing knowledge about, and influencing attitudes towards, regular physical activity because they represent an arena in which children and adolescents participate irrespective of socio-economic inequalities, which are known to affect activity levels. As the action plan states, "Society is able to affect individual decisions … and it should indeed exploit every opportunity of positive persuasion" (NM, 2005:6). A revised national curriculum for Physical Education (PE) was passed the following year, echoing many of the sentiments of the action plan. PE lessons should provide all pupils with positive experiences of play, sport, dance and outdoor pursuits with the aim to nurture lifelong active lifestyles, and from aged 13 years, pupils should in particular learn (both theoretically and practically) about how to get fit and remain fit, as well as learning about the relationship between physical activity, lifestyle and health. Indeed, one third of curricular time should be allocated to learning about training and lifestyle.

This paper will explore how a sample of young people has experienced the teaching of health and fitness in the upper secondary school system. It draws upon qualitative data generated from in-depth interviews with ten pupils, which were tape-recorded and later transcribed verbatim. Using a critical discourse analysis approach (MacLure, 2003) it aims to problematise the taken-for-granted nature of the 'truths' about physical activity and health which are described above, because as critical pedagogues we fear that the dominance of exercise science and neo-liberal individualist discourses in the texts, together with a lack of socio-cultural perspectives, can too easily result in young people being exposed to so-called 'perfection codes' which stress autonomy, self-responsibility, self-surveillance and control, rather than nurturing 'good' health.

PHYSICAL EDUCATION AND HEALTH IN SWEDEN – A TENSION BETWEEN PUBLIC HEALTH DISCOURSES ABOUT PHYSICAL HEALTH AND SCHOOL DISCOURSES ABOUT LEARNING OUTCOMES

LARSSON, H.

THE SWEDISH SCHOOL OF SPORT AND HEALTH SCIENCES

In Sweden, as in several countries world wide, the school subject Physical education and health (PEH) is often viewed as a part of a strategy to solve acute public health problems, such as the alleged emerging obesity epidemic (for an overview, see Wright [Ed.] 2008). As such, a PEH lesson is primarily viewed as successful from the point of view of the duraton and intensity of the physical activity.

At the same time, Swedish school policy is emphasising knowledge and (assessable) learning outcomes in all school subjects – also in subjects that were conventionally seen as practical-asthetical. This creates a tension between the public health discourse, where a 'good pupil' participates – and preferably gets sweaty with a smile in his/her face – and the school discourse, where a 'good pupil' is supposed to learn something.

Of course, there is no 'natural' opposition between public health discourses and school discourses. Pupils learn certain things from being physically active, and being physically active also, arguably, promotes learning. However, recent research within the research program School-Physical education-Health (SIH-program; Larsson & Redelius 2008) show that a rather one-sided emphasis on physical activity in terms of public health has made it very difficult for physical education teachers and pupils to engage with the issue of formulating what learning is supposed to come out of being physically active during a PEH lesson.

A preliminary interpretation of this situation is that the public health discourse 'works well' with both a physiology discourse and a sports discourse – ways of reasoning about physical activity within PEH that used to dominate the subject during the latter part of the 20th century – in a way that is not significant for the relation between public health discourses and school discourses of learning. While the latter embraces constructivist perspectives on pupils (the body) and learning (movement, physical literacy), the former all embrace positivist notions about the body and physical activity.

OP-ST04 Sports 4

THE EFFECT OF BODY ORIENTATION ON CYCLING TECHNIQUE

ETTEMA, G., MCGHIE, D., OLSEN, K.K., LILLEMARK, K.

NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY

The present study was undertaken to test the hypothesis that the pedal technique in cycling is unaffected by body configuration and orientation factors like seat position and climbing conditions. To test this idea, we performed two cycling protocols with well trained

cyclists at constant submaximal work rate on a bicycle ergometer. It was hypothesised that crank cycle characteristics at joint level (i.e., relationship between crank position and joint power and - moment) would merely shift according to the rotation of the lower extremity with regard to a fixed coordinate system.

1. Level and uphill cycling (11% or 6.3 degrees) were compared at three different cadences: self chosen preferred (PR), PR-10 rpm, and PR+10 rpm. In this protocol, the entire system (bicycle and rider) was rotated relative to gravity. That is, the rider position with regard to the bicycle was unaltered.

2. Seat and handlebars were repositioned around the preferred seat position, such that the lower extremities were rotated around the crank with regard to gravity, whereas the upper body's orientation was unaltered (only translated with the hip joint). Three positions, preferred (0 degrees), 3 degrees backward, and 3 degrees forward were tested in the self chosen cadence at the preferred position.

Pedal force and kinematics of lower extremity and trunk position were recorded for at least 45 crank cycles during steady state cycling at 80% of maximal heart rate (about 200W) in all conditions. Power and moment for hip, knee, and ankle joint were calculated with inverse dynamics. Crank angle phase shifts between conditions were calculated by means of cross-correlation adapted for circular data.

For both protocols, the phase shift of joint power and moment was in accordance with the systems' rotation. In other words, when rotating the lower extremity backward a certain number of degrees, be it in uphill cycling or by moving the seat backward, the power (and moment) profile shifts with the same amount of degrees, when analysed in a fixed coordinate system. Generally, the cross-correlations amounted to very high values (often well above 0.9), indicating that the crank cycle profile was very similar among conditions. These findings were similar for all cadences explored in the first protocol on uphill cycling.

Even though the present data confirm the main hypothesis in general terms, i.e., that the crank cycle technique is invariant and does not depend on body orientation with regard to gravity, a more detailed analysis revealed some small differences between joints: in level-uphill cycling, the knee joint showed a larger phase shift, particularly for the moment characteristic. Furthermore, the amplitude of the hip power crank cycle profile was higher in uphill cycling than in level cycling. This may be explained by that the dynamic interaction between pelvis-hip and seat is strongly affected by body orientation, thereby influencing the power generated at the hip.

A PRELIMINARY INVESTIGATION INTO THE INFLUENCE OF RECOVERY DURATION ON SPRINT CYCLING PERFORMANCE FOLLOWING HEAVY RESISTANCE EXERCISE

THATCHER, R., GIFFORD, R.

ABERYSTWYTH UNIVERSITY

Introduction: Chatzopoulos et al. (2007) highlighted acute adaptations following Prior Heavy Resistance Exercise (PHRE) may improve subsequent performance during sprint activities via a transient increase in muscle contractile performance known as postactivation potentiation (Sale, 2002). The majority of research has focused on jumping activities and to date there is little research that has addressed the influence of PHRE on sprint performance. The aim of the current study was to examine the influence of recovery duration following PHRE on sprint performance.

Methods: Seven healthy male participants gave informed consent to participate in the study which was given clearance by the institutional ethics committee. Following 3 familiarisation visits during which 1 repetition maximum (1RM) was determined for the deadlift exercise (visit 1) and 30 s Wingate sprints performed on a cycle ergometer (visits 1, 2 and 3) participants performed 5 experimental trials. Trials involved performing 5 deadlifts at a pace of 1 repetition every 10 s at 85% of 1RM. Participants then rested for 5, 10, 20 or 30 min before performing a 30 s Wingate sprint, a control trial was also included which did not involve any lifts. Expired air was collected for the duration of the 30 s sprint and blood sampled for lactate prior to the warm-up and 7.5 min following completion of the sprint (LPOST). Values were recorded for Peak Power (PP), Time to Peak Power (TPP), Mean Power Output for 5 s (MPO5), 10 s (MPO10), and 30 s (MPO30) and oxygen uptake (VO2). Statistical analyses were performed using repeated measure ANOVA and significant differences explored via paired t tests with Bonferroni correction.

Results: Following PHRE peak power increased to values of 104%, 108%, 101% and 101% of the control value following 5, 10, 20 and 30 min of recovery respectively, ($p>0.05$) while TPP was 94%, 89%, 94% and 103% of the control value ($p>0.05$). Mean power outputs for the first 5 s of the sprint were 95%, 108%, 104% and 96% ($p>0.05$), the first 10 s of the sprint were 104%, 110%, 104% and 103% ($p>0.05$) and the first 30 s of the sprint were 102%, 106%, 102% and 103% ($p>0.05$) of control values following 5, 10, 20 and 30 min of recovery respectively. Oxygen uptake increased to 115% ($p<0.05$), 122% ($p<0.05$), 106% and 106% of control value, while LPOST values were 113% ($p<0.05$), 107% ($p<0.05$), 103% and 89% of control value.

Discussion: These preliminary finding suggest that the use of PHRE is beneficial to performance in sprint activities inline with the suggestion by Chatzopoulos et al., (2007). Furthermore the significant changes in oxygen uptake and lactate suggest that the prior activity can change the energy pathways employed during sprint exercise possibly by changes to the oxygen uptake kinetics.

EFFECT OF LEG MASSAGE WITH DIFFERENT DURATIONS ON ANAEROBIC PERFORMANCE AND RECOVERY FROM HIGH INTENSITY CYCLING EXERCISE

KIN ISLER, A., KOSEOGLU, A.

BASKENT UNIVERSITY

Introduction: Sport massage, a manual therapy for muscle and soft tissue pain and weakness (Moraska 2005), is a widely used modality for recovery after intense exercise. In literature it is seen that sport massage is applied with a variety of durations and conflicting results was found (Robertson et al., 2004; Hemmings et al., 2000). Hence the purpose of this study was to determine the effects of leg massage applied with different durations on anaerobic performance and recovery from high intensity cycling exercise.

Methods: Ten male university students participated in this study voluntarily. Subjects were investigated on four occasions with a massage therapy (10 or 20 minutes) or passive recovery (10 or 20 minutes) in random order. Subjects participated in Wingate anaerobic power test (WAnT) before and after the recovery interventions. In addition heart rate and blood lactate responses were determined at rest, after the first WAnT, at 10th and 20th minutes of recovery periods and after the subsequent WAnT.

Results: 2 (pre/post) x 4 (recovery interventions) ANOVA with repeated measures indicated significant time x recovery intervention interaction in average power (F(3,27): 5.297, p=.032) and follow up one way ANOVA with repeated measures indicated that there was a significant difference in average power between 20 minutes of massage intervention and 10 minutes of passive recovery. No significant differences or interactions were observed in other measured anaerobic indices (p>.05). Results also indicated no significant differences among resting heart rate and blood lactate levels measured before four testing occasions (p>0.05). Significant differences were found in heart rate at the end of recovery interventions (F(3,27)=6.875; p=.001) and bonferroni post hoc analysis indicated this significant difference was as a result of 20 minutes of massage intervention. In addition results also revealed significant differences in lactate levels at the end of recovery interventions (F(3,27)= 4.734; p=.009) and post hoc analysis showed that this difference was due to 20 minutes of massage intervention. No significant differences were obtained in other measured recovery indices (p>.05).

Discussion: Our results indicated that 20 minutes of leg massage was effective in improving average power and recovery from high intensity cycling exercise. Given that many of researches have found no effect of leg massage on subsequent performance (Robertson et al., 2004; Goodwin et al. 2007), these findings suggest that in determining the effects of leg massage on various performance indices, duration of massage should be taken into account.

EVALUATION OF A FIELD TEST TO ASSESS AEROBIC ENDURANCE AND PERFORMANCE IN ELITE CYCLISTS

NIMMERICHTER, A., WILLIAMS, C., ESTON, R.

UNIVERSITY OF EXETER (EXETER, UK), AUSTRIAN INSTITUTE OF SPORTS MEDICINE (VIENNA, AUSTRIA)

Introduction: The assessment of endurance performance is usually conducted during laboratory ergometer tests. In field tests, time to complete a given distance is often the chosen performance measure. Since external conditions can largely influence these measures, the aim was to evaluate the reliability of power output in a field test and validate performance measures obtained from a traditional laboratory ergometer test.

Methods: Fifteen competitive male cyclists (age: 25.6 ± 5.2 y; height: 180.6 ± 4.5 cm; weight: 70.6 ± 4.4 kg; VO2max: 67.1 ± 5.0 ml/min/kg) completed an incremental graded exercise test (GXT) to determine ventilatory threshold, respiratory compensation point (VT, RCP) and lactate turn points (LTP1, LTP2) and two maximal aerobic power 4-min (MAP 4) and 20-min (MAP 20) time-trials, during which power output was measured with mobile power cranks (SRM).

Results: Power (W) was 263 ± 37, 344 ± 38, 243 ± 27, 344 ± 37 and 440 ± 38 W, for LTP1, LTP2, VT, RCP and Pmax, respectively. Average power during the 4-min time-trial (412 ± 53 W) was significantly higher ($p < 0.001$) than during the 20-min time-trial (347 ± 42 W) and was correlated with ($r = 0.791$ to 0.878, $p < 0.001$) but significantly different from ($p < 0.001$) performance markers obtained during GXT. No significant differences were observed between the 20-min time-trial, LTP2 ($p = 0.946$) and RCP ($p = 0.853$). Strong test-retest correlations for MAP 4 (ICC = 0.976, $p < 0.001$) and MAP 20 (ICC = 0.985, $p < 0.001$) were observed.

Discussion: The test-retest reproducibility was in agreement with the results of a 40-km outdoor time-trial reported by Smith et al. (2001). The reliability of a 3-min laboratory all out test has been published by Burnley et al. (2006) where typical error was found to be ± 7 W or 3 %, which is similar to the results of the 4-min time-trial (± 8 W or 2.2 %). Measures of aerobic performance explained 65 % - 77 % of the variance in MAP 4 and MAP 20. The 4-min time-trial was on average 93 % of Pmax from GXT, reflecting the ability of high-level athletes to tolerate intensities of 95 % - 105 % over 4-15 min. Average power during 20-min time-trial was 79 % of Pmax, which is in accordance with exercise intensities during time-trials in professional cyclists (Lucia, et al., 2001). In conclusion the 4-min and 20-min time-trials are reliable measures of aerobic endurance. The 20-min time-trial is valid to predict RCP and LTP2.

CAN CYCLING PERFORMANCE IN AN EVENING LABORATORY-BASED CYCLE TIME-TRIAL BE IMPROVED BY EXERCISE OR HABITUATION THE DAY BEFORE?

EDWARDS, B.J., GEORGE, C., WATERHOUSE, J., REILLY, T.

LIVERPOOL JOHN MOORES UNIVERSITY

The normal circadian rhythm of performance can be altered by the habitual timing of performance. Whether this is due to a resetting of the body clock or due to a habitualisation of the time of training is unknown. Therefore, we investigated if evening time-trial performance was affected by the time at which moderate exercise was performed the previous day (at 12:00 or 18:00 h) or by the subjects attending the laboratory at 18:00 h with the intention of exercising but, in fact, just sitting on the ergometer for 30 minutes. Eight male cyclists (Mean±SD: VO2 peak = 54.7±7.7 ml.kg.min-1, age = 19±1 years, body mass = 77.7±8.2 kg and height = 183.7±5.2 cm) took part in the study. The local Ethics Committee of the University approved the study. The subjects completed three familiarisation trials to the best of their ability at a self-selected pace. The subjects then completed three separate pre-time-trial sessions of sub-maximal cycle ergometry (60% VO2 peak for 30 minutes) on the day before the time trial: at 12:00 h and 18:00 h, and a condition of no exercise at 18:00 h (where the subjects were told that no exercise was to be undertaken after having completed the resting part of the experiment and spent the same amount of time sitting on the cycle ergometer). The time trials themselves were 16.1 km and always took place at 18:00 h. The design of the study was such that the pre-time-trial sessions were counterbalanced in order of administration and a standardised 5-min warm-up at 130 W was completed prior to each time-trail. Heart rate, power output, ratings of perceived exertion, RPE, and rectal temperature were measured at rest, every 5-min in the pre-time-trial exercises, and every 1.61 km (split times) during the time trials. Fingertip blood samples were taken at rest and immediately after the time trials for estimations of haematocrit, haemoglobin and lactate. The 95% ratio limits of agreement for the 16.1 km time-trial performances were */÷ 0.46, assessed in a prior test-retest study. Data were analysed

using an analysis of variance model (condition [3 levels]) for performance times and blood lactate. A two-way analysis of variance model (condition [3] x pre-post [2]) was used for blood variables and (condition [3] x time-trial distance [10]) was used for RPE, rectal temperature, heart rate, power output and split times. There was no statistical difference in the finishing times for the time trials (P=0.253); the time trial performed after the 12:00 h pre-time-trial exercise was completed in 1714±113s (95% CI=1619-1808s) compared to 1756±137s (95% CI=1641-1870s) and 1723±124s (95% CI=1619-1827s) for the time trials performed after the pre-time trials at 18:00 h and when no exercise was undertaken, respectively. None of the variables during the time trials showed a main effect for condition or a condition by time or distance interaction. In summary, unlike morning time-trial performance, no advantage is gained by performing exercise or being prepared to undertake exercise at the same time as evening competition on the previous day.

EFFECT OF WARM-UP ON MUSCLE OXYGENATION AND METABOLISM IN SUPRAMAXIMAL CYCLING

WITTEKIND, A., COOPER, C.E., ELWELL, C.E., LEUNG, T.S., ANGUS, C., BENEKE, R.

UNIVERSITY OF ESSEX AND UNIVERSITY COLLEGE LONDON

The effect of a warm-up induced increase in blood lactate prior to performance is unclear and may be unwarranted in severe exercise where a reduced glycolytic rate may compromise performance. PURPOSE To examine the effect of warm-ups which raised blood lactate concentration (BLC) to different levels on muscle oxygenation and metabolism in a supramaximal cycling sprint test. METHODS 8 trained male cyclists undertook a 30s sprint test from stationery seated start (load 0.09 x body mass (kg)) preceded by one of 3 warm-up protocols: WE 6 min at 40% peak aerobic power (PAP); WM 5 min at 40% PAP + 1 min at 80% PAP; WH 5 min at 40% PAP + 1 min at 110% PAP – each followed by 10 min seated recovery. Pulmonary oxygen uptake (VO2p), and muscle oxygenation as measured by near infrared spectroscopy (oxyhemoglobin (O2Hb), deoxyhemoglobin (HHb), total hemoglobin (Hbtot) and tissue oxygenation index (TOI)), were measured throughout. The responses of HHb and TOI during the sprint were analysed using a monoexponential model with time delay. The off kinetics of VO2p were analysed using a biexponential model. Blood lactate kinetics of the sprint were analysed with a biexponential model predicting extravascal lactate generation. RESULTS Mean power during the sprint was reduced in WH compared to WE (WE 672±54 WM 666±56 WH 655±59 W $p<0.05$) and was primarily due to lower mean power during the first 5s. BLC was different prior to the start of each sprint (WE 0.9±0.4 WM 1.9±0.6 WH 4.4±0.9 mmol.L-1 $p<0.05$) and extravascal lactate generation during the sprint was reduced by each increment in warm-up (WE 12.4±1.7 WM 11.0±1.5 WH 9.5±1.8 mmol.L-1 $p<0.05$). VO2p was higher than rest prior to each sprint but not different between conditions and with no difference in mean VO2p during the sprint (WE 1.5±0.2 WM 1.5±0.2 WH 1.5±0.3 L $p>0.05$). There was no difference in the area under the fast component of VO2p off kinetics though this tended to be higher for WH compared to WM and WE (WE 2.2±0.4 WM 2.3±0.4 WH 2.6±0.6 L). NIRS data indicated that oxygen delivery was increased prior to sprints but not different between conditions. There was no difference between warm-ups for the on kinetics of HHb or TOI. However there was a tendency for the TOI time delay for WH to be shorter (WE 3.7±1.6 WM 4.0±0.5 WH 2.9±1.2 s $p<0.06$). CONCLUSION An apparent increased PCr hydrolysis as indicated by the higher area under the fast component of VO2p off kinetics could not fully compensate for the reduced glycolytic rate in the sprint following WH which was itself indicated by a reduced extravascal lactate generation. All warm-ups increased muscle oxygenation to the same extent prior to the sprint and there was no difference in oxygen delivery/utilisation or VO2p during the sprint despite WH tending to increase apparent PCr hydrolysis. It appears that warm-up may reduce glycolytic rate and for harder warm-ups other energy sources may not be able to fully compensate in severe intensity exercise.

PS-PL04 Sport and the Environment: Towards an Environmentally Sound Movement Culture

CAN SPORT BECOME ECOLOGICALLY SOUND?

BREIVIK, G.

NORWEGIAN SCHOOL OF SPORT SCIENCES

The debate about global warming has brought new fuel to the discussion of an environmentally sound lifestyle and a sustainable development of human societies. Sport is certainly a part of the problem and also of the solution, since "with few exceptions, sport as it is practiced is not sustainable" (Chernushenko, 1994:4). The winter Olympic Games at Lillehammer 1994 and the summer Olympics in Sydney 2000 focused on "green ideals", but without much lasting effects. The goal of the presentation is to show how environmental concerns need to be addressed in the future. I will raise the following questions:

1) Gregory Bateson (1973) thought that the ecological crisis was due to three root causes: a) technological progress, b) population increase, c) hubris: man against nature. The systemic interaction of these three factors constitutes the threat to a sustainable future. How is modern sport involved in this interaction?

2) Modern sport is built on a combination of three ideas: a) competition, b) progress, c) ethical values, like fair play. International elite sport has seen a decrease in ethical focus and an increase in hard competition and quest for records. Supported by advanced technology and economic growth elite sport, according to some, has become the spearhead of a reckless consumer culture that is going in the opposite direction of sustainability. Other would succinctly respond that the concept of 'sport' includes not only elite sport but also more sustainable sports like jogging, hiking, eastern martial arts, fitness, lifestyle sport. The movement culture has many faces and not all of them are environmentally ugly. I will present examples of this diversity.

3) Arne Næss (1973) distinguished between shallow and deep ecology. Without doubt shallow ecology focusing on a mild redressing and ecological haul over of present consumer culture can be useful for most sports. Sport is tapping ecological resources and polluting the environment in many ways (travel, equipment, facilities). How could sport organizations contribute to a 'greening of sports' in all these areas?

4) A more radical solution would be to go to the roots of the problem and develop a form of sport that was built on "richness in ends, simpleness in means" (Næss, 1990). Such sports would not focus on relentless record-setting, winning at all costs and with the most

cutting-edge equipment. The question is whether the deep ecological attitude is a realistic one. How far can "homo oecologicus" (Seewald, Kronbichler, Groessing, 1998) be developed in sport settings?

CLIMATE CHANGE AND OUTDOOR SPORT – A DISCUSSION OF IMPACTS AND ADAPTATION STRATEGIES

PRÖBSTL, U.

BOKU UNIVERSITY OF NATURAL RESOURCES AND APPLIED LIFE SCIENCES

Introduction: Climate Change is perceived as one of the major challenges to tourism on a local and global scale. In the case of winter tourism with its crucial reliance on snow and ice, climate change effects are obvious; however, the phenomenon may also affect lake tourism, recreational fishing, and even hiking and many other forms of summer or all season tourism. In the meantime, many studies have investigated the effects of climate change on such tourism activities, and also explore adaptation strategies. An overall pattern indicates that these adaptation strategies follow similar principles. In this overview paper, results from several studies using social science research methods to investigate user reaction to and acceptance of several tourism related adaptation strategies are analysed in order to determine similarities and differences.

Methods: The presentation will focus on downhill-skiing, cross-country skiing in Austria and Finland, summer tourists in the alpine Area, water related sport activities at the step lake Neusiedlersee in Austria, hikers and climbers in high mountainous areas with respondents from Austria, Germany and other European countries. The presented results are summarizing the findings of several studies (see Unbehaun et al 2008, Landauer and Pröbstl 2008, Pröbstl et al. 2008, Pröbstl and Jiricka 2007).

Results: Already in all analysed activities we found impacts due to climate change. There are less hours suitable for artificial snow making, the level of the step lake is reduced in hot summers and the danger of rockfall and other forms of erosion for hikers and climbers in the high mountains has increased as well. The sport and tourism offers are already reacting on these changes. Overall, adaptation strategies in out door sport may take one of these three directions:

1)Focussing on technical solutions involve aspects such as artificial snow in the case of winter sport destinations, man-made ponds in the case of the lake tourism, or skiing tunnels in case of cross country skiing.

2)Adding service improvements and new offers like indoor sport and alternative entertainment

3)Shifting to new products and activities also in other seasons.

Discussion: The results show that the reaction on climate change is not predominantly affected by the change itself and natural shifts but the motives and desired experiences of the sportsmen and tourists. More than the financial adaptation capacity the societal acceptance as well as tradition and local habits are mainly influencing the possible future development.

THE EFFECTS OF TWO DIFFERENT STRENGTH TRAINING MODALITIES ON SATELLITE CELLS, MYONUCLEI AND MYOFIBER SIZE IN ELDERLY – PRELIMINARY DATA FROM A RANDOMISED CONTROLLED TRIAL.

CUMMING, K.T., KVAMME, N.H., KOSKINEN, S., HALLÉN, J., RAASTAD, T.

NORWEGIAN SCHOOL OF SPORT SCIENCES

Introduction: Muscle mass and strength decline with age (sarcopenia). This reduction in muscle mass is mainly due to the atrophy in myofibers, especially the type 2 myofibers (Andersen, 2003). Since its discovery in 1961, the satellite cell has been shown to play a key role in myofiber repair, maintenance and growth (Hawke & Garry, 2001). Physical exercise is a potent activator of the satellite cells, both in the young and elderly (Kadi et al., 2005), and thus thought to be an effective inhibitor of sarcopenia. The aim of this study was to investigate the effect of two different strength training modalities on satellite cells, myonuclei and myofiber size in elderly.

Methods: 11 healthy elderly women and men (70-88 yrs) were randomised into two training groups; functional strength training (FT) or strength training (ST). The groups exercised 3 times a week for 12 weeks. The ST group followed a strength training program that included 8 exercises (3 leg exercises) each consisting of one to three 4-12 RM sets. The FT group performed 8 exercises (4 leg exercises) with one to two 12-15 RM sets simulating everyday activities (e.g. stair climb). Muscle strength was assessed before and after the training period through the determination of the one-repetition maximum of knee extension. Biopsies were obtained from m. vastus lateralis, immediately frozen and later analysed with fluorescence microscopy with antibodies against NCAM (satellite cells), dystrophin and myosin heavy chain II (SC71). DAPI was used to identify myonuclei.

Results: At the end of the 12 week training period, the ST and FT groups had increased their maximal strength significantly by 36 % and 24 %, respectively. The preliminary analyses signaled an increased number of satellite cells from 0.06 to 0.08 cells per myofiber in the ST group; and an increased number of myonuclei in type 2 myofibres in the FT group (2.26 to 2.49 p=0.06). No changes were observed in the myonuclear number in type I myofibres in either group.

Discussion: The preliminary data indicate increased number of satellite cells in the ST group and a tendency to increases myonuclear number in type 2 myofibres in the FT group. In addition to these preliminary data we will further analyse the data to show the possible changes in myofiber size and myofiber type specific changes in the satellite cell pool within the training groups.

EFFECTS OF AGING AND LONG-TERM RESISTANCE TRAINING ON TESTICULAR TESTOSTERONE PRODUCTION CAPACITY

AHTIAINEN, J.P., HELSTE, M., NYMAN, K., RANNIKKO, A., HUHTANIEMI, I., KRAEMER, W.J., PARVIAINEN, T., HÄKKINEN, K.
JYU (JYVÄSKYLÄ, FINLAND), CENTRAL FINLAND HOSPITAL (JYVÄSKYLÄ, FINLAND), UH (HELSINKI, FINLAND), UTU (TURKU, FINLAND), UCONN (STORRS, CT, USA)

Introduction: Testosterone production is regulated by the function of the hypothalamic–pituitary–testicular (HPT) axis. The hypothalamus releases gonadotrophin-releasing hormone (GnRH), which in turn stimulates pulsatile release of luteinizing hormone (LH) from the anterior pituitary gland, and this subsequently, induces testicular testosterone production. The HPT axis can be assessed using exogenous GnRH agonist as well as human chorionic gonadotropin (hCG) that mimics the normal surge of LH. Previously it has been shown that acute and chronic endurance training induces suppressed testosterone responses to GnRH agonist and hCG (1,2,3). However, the effects of resistance training on the HPT axis have not been examined. Therefore, GnRH and hCG stimulation were used to investigate training-induced changes in testicular production of testosterone before and after long-term systematic resistance training.

Methods

Healthy untrained young (28.0 (2.9) yrs., n = 5) and old men (69.5 (2.3) yrs., n = 8) volunteered to the study. Before and after the 1-year resistance training (2-3/wk) the nasal solution of GnRH agonist (Synarela 200 mikrog) or hCG injection (Pregnyl 5000 IU) were dosed in a randomized order with a two week interval. Basal serum total testosterone (T) and sex-hormone binding globulin (SHBG) concentrations were measured before and 24h after the administration of GnRH as well as before and 48h, 72h and 96h after the administration of hCG.

Results: Serum free androgen index (FAI; T/SHBG) was greater ($p<0.01$) in young than older men before the hCG and GnRH tests. The hCG tests induced significant increases (mean of 48h, 72h and 96h, $p<0.05$) in T and FAI before and after the training period in both young and old men. The GnRH tests induced increases ($p<0.05$) in T and FAI before the training period in young and older men, but after the training period T and FAI increased significantly ($p<0.05$) only in old men. The relative T and FAI responses to hCG were greater ($p<0.05$) in young than old men after the training period. No significant changes were observed in hCG and GnRH induced T and FAI responses due to resistance training in young or old men.

Discussion: The main finding of the present study was that the exogenous stimulated testicular production of testosterone is suppressed in older men compared to young men. Furthermore, the present results indicate that the function of HPT axis of old men was impaired in the testicular rather than in pituitary component. It could be speculated that this age related attenuation in testosterone production may have an effect on muscular characteristics and training-induced muscular adaptations. However, the present results showed that training-induced adaptations did not occur in testicular capacity to secrete testosterone neither in young nor in older men.

THE EFFECT OF TWO DIFFERENT TRAINING MODALITIES ON MUSCLE STRENGTH, MUSCLE MASS AND POWER MEASURES IN ELDERLY – PRELIMINARY DATA FROM A RANDOMIZED CONTROLLED TRIAL

KVAMME, N.H., ANDERSEN, V., CUMMING, K., SOLBERG, P.A., RAASTAD, T.
NORWEGIAN SCHOOL OF SPORT SCIENCES

Introduction: When we grow older, strength and muscle mass will decline. This might make it more difficult to perform different activities of daily living. It is well documented that strength training can counteract these changes (Hunter et al. 2004), but there have been few studies on how functional strength training affect strength and muscle mass. The aim of this study was to investigate the effects of a functional strength training program compared to a more traditional resistance program on muscle strength, muscle mass and power measures in elderly.

Methods: 11 elderly men and women (age 70-88) were divided into a resistance training group (RTG) and a functional strength training group (FTG). The RTG trained a progressive resistance program consisting of 8 exercises (three leg exercises) with one to three 4-12 RM sets three times a week for 12 weeks. The FTG trained 8 exercises (four leg exercises) simulating everyday activities with additional loading in one to two 12-15 RM sets. All subjects were tested in isokinetic and isometric strength in knee extension, and counter movement jump (CMJ). Rate of force development (RFD) was also calculated in the knee extension. The thickness and fascicle pennation angle of m. vastus lateralis were measured by ultrasound in the mid-portion of the muscle belly, and fascicle length were calculated. The cross sectional area (CSA) of the quadriceps was measured by MRI.

Results: Isometric strength increased significantly in the FTG at 90˚ (1.8%) and in the RTG at 30˚ (8.1%). Isokinetic strength increased significantly in the FTG at 240˚/s (29%) while both groups had a non significant increase at 60˚/s (RTG: 9%, $p=0.11$, FTG: 7%, $p=0.07$).

No statistically significant changes were observed in RFD and CMJ. Both groups increased thickness (RTG: 21%, FTG: 14%) of m. vastus lateralis and pennation angle increased in the FTG (20%). Fascicle length remained unchanged in both groups. The CSA of quadriceps in the mid-portion of the thigh increased in FTG (4.1%), but the increase in the RTG was not statistically significant (2.9%). There was no significant difference between the two groups in any of the variables measured.

Discussion: Both groups increased strength in some of the strength measures, and had a tendency to increase in the other. When it comes to the explosive strength measures we did not observe any significant increase. This might be due to the training not being done in an explosive manner. However, the measures of CSA and muscle thickness show that both groups increased muscle mass. Both resistance and functional training improved strength and muscle mass, but did not have any detectable impact on explosive force production measures in this study.

EFFECTS OF THE CROSS SECTIONAL AREA ON PASSIVE LEG RAISING AFTER EXERCISE

YOSHIOKA, A., NISHIMURA, K., MATSUMOTO, N., ONODERA, S.
GRADUATE SCHOOL, KAWASAKI UNIVERSITY OF MEDICAL WELFARE

Purpose: We demonstrated that the cross sectional area of inferior vena cava during passive leg raising after high intensity ergometric exercise was less than that of at rest with passive leg raising (European College of Sports Science, in Lisbon, 2008). We implied that inferior vena cava after high intensity exercise was regulated by the some modulation system, in order to maintain the blood flow to the atrium. We hypothesized that the cross sectional area of inferior vena cava during passive leg raising after exercise change in according to exercise intensity. The purpose in this study was to clarify the effects of cross sectional area of inferior vena cava on passive leg raising after ergometric exercise at the low and high intensities. Methods: Seven healthy young Japanese males volunteered to participate in this study. All subjects signed the informed consent forms prior to participation in this study. The age, height, body weight and body fat of subjects were 21 (SD:2) years, 172.3 (SD:6.6) cm, 66.0 (SD:6.4) kg and 16.6 (SD:3.3)%, respectively. Each subjects performed ergometric exercise after the rest in the supine position with passive leg raising. Moreover, each subjects maintained the supine position with passive leg raising for 15 minutes after exercise. The exercise intensity in high intensity condition was 80% of peak oxygen uptake, and that in low intensity condition was 40% of peak oxygen uptake, respectively. The exercise duration were 15 minutes in high intensity condition, and 10 minutes in low intensity condition. We measured the cross sectional area of inferior vena cava using ultrasound, at rest and every five minutes during recovery period after exercise. We determined the cross section of inferior vena cava at the level of processus xiphoideus. After recording the images of the cross section of inferior vena cava to a computer, we calculated the cross sectional area of inferior vena cava using a computer. Furthermore, we measured heart rate throughout experiment. Results and Discussion: The cross sectional area of inferior vena cava in low intensity condition was no difference between at rest and after exercise. But, cross sectional area of inferior vena cava after exercise in high intensity condition was significantly less than at rest ($P<0.05$). These results suggested that the cross sectional area of inferior vena cava change in depending on the exercise intensity, and this change contribute to the modulation of blood flow. Furthermore, we imply that the inferior vena cava is regulated partially by autonomic nervous system because the cross sectional area of inferior vena cava is depending on the exercise intensity.

ROLE OF CENTRAL COMMAND IN THE RENAL ARTERIAL BLOOD FLOW RESPONSES DURING SATIC ELBOW FLEXION

SADAMOTO, T., SATO, K., HIRASAWA, A., SASAHARA, C., SHIBUYA, K., SAITO, M., KAMO, M., OSADA, T., KAGAYA, A.
JAPAN WOMEN'S COLLEGE OF PHYSICAL EDUCATION

PURPOSE. The role of central command in the renal flow regulation has remained elusive. A prior study reported that central command was not essential for producing the renal vasoconstriction during exercise because the renal vascular resistance was almost identical during voluntary and electrically induced (involuntary) contractions (3). However, the studies in conscious animals demonstrated a significant role of central command during voluntary static and dynamic exercises (2, 4). One reason for the discrepant data was due to insufficient works studying this topic "non-invasively" during exercise in humans. The magnitude of involvement of the central command during exercise can be non-invasively decreased without altering the muscle mechanoreflex activation by tendon vibration to assist an exercising muscle in developing a given force (1, 5). Using this manipulation, we examined in the present study whether a decreased involvement of central command resulting from applying the tendon vibration produced a concomitant decrease in renal flow responses during exercise.

METHODS. Ten healthy female volunteers whose mean age was 22 (SD=3.3) yr participated in the present study. After 10-min resting, the subject performed a 2-min static elbow flexion at a constant load of 30% of maximum voluntary contraction with vibration (EX+VIB) and without vibration (EX). The vibration (frequency, 100Hz; amplitude, 0.8 mm) was applied to the distal tendon of the biceps brachii in the exercising arm. Time-averaged mean blood flow velocity (MBV) in the renal artery (RA) was measured by using Doppler method. Muscle fatigue sensation of the subject, as an index of the magnitude of central command (6), was monitored. Heart rate (HR: ECG) and arterial mean blood pressure (MAP: Finometer) were continuously measured. The conductance in RA was calculated as MBV/ MAP.

RESULTS. Muscle fatigue sensation in the exercising arm and the increase in HR were significantly lower during EX+VIB than those during EX indicating the vibration manipulation substantially decreased involvement of central command during EX+VIB. The MAP responses during EX+VIB also tended to be lower than those during EX. In contrast, the conductance in RA was identical during both EX+VIB and EX suggesting that the decreased central command was not effective in the renal flow regulation.

CONCLUSION. It seems likely that central command was not essential for regulating blood flow responses in RA but the actual work load of force production was more important during static exercise in humans.

GENDER DIFFERENCE IN NITRIC OXIDE EMANATING FROM HUMAN SKIN

ITOH, H.
NAGOYA INSTITUTE OF TECHNOLOGY

Introduction: Recent study (Wangensteen et al., 2004) has reported gender difference in the role of endothelium-derived relaxing factors (EDRF) modulating smooth muscle tone. Nitric oxide (NO) is one of the most important EDRF (Moncada S. and Higgs E., 2006), however, no one has confirmed gendrer difference in NO emanating from human skin. Therefore, the present study examined gender difference in human skin-gas NO concentrations would exist or not.

Methods

Sixteen healthy male (21.8 ± 1.5 years; mean ± SD) and female students (21.5 ± 1.1 years) volunteered as the subjects. The skin-gas samples were obtained by the covering index fingertip for 30 sec with a polyfluorovinyl bag (Tedlar bag; GLScience, Tokyo, Japan) in which pure nitrogen gas was introduced, and collected in a sampling bag at rest. The skin-gas NO concentration was measured by a chemiluminescence analyzer (Pico-Device Co., Ltd., Nagoya, Japan). Forearm blood pressure was measured with a Vascular Screening System (VaSera VS-1000, Fukuda Denshi Co., Ltd, Tokyo, Japan).

Results: A significant higher ($p<0.05$) skin-gas NO concentration was observed in males (15.4 ± 2.7 ppb) than in females (13.4 ± 2.9 ppb). Systolic blood pressure and pulse pressure were significantly higher in males than in females, although there was no significant difference in diastolic blood pressure.

Discussion: Menopause is accompanied by a dramatic rise in the prevalence of hypertension in women, suggesting a protective role of endogenous female hormone on blood pressure (Ashraf and Vongpatanasin, 2006). In this study, higher blood pressure was found in males than in females. Jungersten et al. (1997) have suggested that NO is increased with increased cyclic wall stress associated with increased pulsatile blood flow. Therefore, gender difference in skin-gas NO concentrations may depend on the difference in endothelial NO production.

ENHANCED MYOCARDIAL PEAK SYSTOLIC CAPACITY IN ELITE ENDURACE ATHLETES DURING EXERCISE

CARLSSON, L., ISAKSSON, D., LIND, B., ANDERSSON, E., BRODIN, L.A., HOLMBERG, H.C.

MID-SWEDEN UNIVERSITY

Introduction: Conflicting theories discuss whether or not endurance training improves heart contractility, even though most studies have found no changes (Pluim et al., 1999) Traditionally, echocardiography has been used to show ejection fraction (EF) and fractional shortening (FS) to reflect myocardial contractility. However, the sensitivity of EF and FS has been debated, using the argument that these methods only provide indirect measurements of contractility, due to the influence of hemodynamic conditions. Tissue Velocity Imaging (TVI) has been developed in order to provide a more direct measurement of contractility. Based on measuring longitudinal myocardial systolic velocities (PSV), TVI has been found to reflect contractility better than EF (Bach 1996) and also provides analyses during exercise. As TVI has been found a more sensitive method for measuring contractility, this study attempts to investigate whether TVI can prove the Hypothesis that endurance trained athletes (ETA) have enhanced myocardial contractility, at rest and during exercise.

Methods: Ten elite male cross-country skiers and ten untrained subjects (US) (mean; age: 28 respectively 28 yr; body height: 180 resp.181 cm; body mass: 76 resp. 70 kg; VO2max: 72 resp. 46 ml kg-1 min-1) performed a progressive combined arm and leg (ratio 25:75) upright sitting cycle work to exhaustion. The protocol was designed to provide registrations at every 10% level from 50 to 100% of VO2max with continued work. In the last 30 s of each 3 min step, measurements were taking using echocardiography (GE vivid7 Pro; Horten, Norway), sphygmomanometer (TriCUFF WA DS55, AJ Medical, Stockholm, Sverige) and oxygen uptake device (Oxycon Pro, Jaeger, Würzburg, Germany). Statistical significance was set to $P<0.05$.

Results: No changes in PSV were found at rest between the two groups (7,6 cm/s vs. 7,4 cm/s). During exercise at 70% to 100% of VO2max ETA had a higher PSV than the US, a difference which increased continuously (from 18% to 36%). From rest through every level of exercise to maximal exhaustion, PSV increased continuously in the ETA. The PSV in US increased from rest to 60% of VO2max, followed by small but not significant increases between the levels. The ETA had 11% to 16% higher blood pressure from 60% to 100% of VO2max.

Discussion: TVI revealed that the ETA had higher PSV than that of the US during exercise at 70% to 100 % of VO2max, but not at rest and during mild exercise. PSV might be enhanced for two reasons, either increased contractile capacity or lower peripheral resistens. In view of the fact that the athletes' blood pressure was higher during exercise, this experiment indicates that endurance athletes may have enhanced contractile capacity, only observable during exercise.

SUB-MAXIMAL EFFICIENCY DURING ROLLER SKI SKATING

LEIRDAL, S., SANDBAKK, Ø., HOLMBERG, H.C., ETTEMA, G.

1. HUMAN MOVEMENT SCIENCE, NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY, 2. OLYMPIATOPPEN MIDT-NORGE, 3. SWEDISH WINTER SPORTS RESEARCH CENTRE, MID SWEDEN UNIVERSITY

Introduction: Movement economy and efficiency are regarded as important parameters for endurance performance. Whereas movement economy is used in movements where it is difficult to calculate external work rate (e.g., running), efficiency is often used in movements where the opposing forces can be measured and external work rate can be calculated (e.g., cycling, rowing). During roller skiing on a treadmill, the opposing forces can be measured. In present study we investigated the effect of gender, discipline (cross-country, biathlon and Nordic combined), level of performance (world class vs. national class) and technique (V1 and the V2 skate technique) on sub-maximal efficiency.

Methods: This study include 9 male and 8 female biathletes, 22 male and 6 female cross-country skiers and 14 nordic combined skiers. All subjects were skiers of high national and international level. Sub-maximal average efficiency was calculated for a multiple set of steady state 5 min workload steps below 4 mmol/l blood lactate, for which gas exchange was measured. V1 was tested at 12% incline and the V2 at 5-8% incline, on a large treadmill. Velocity was set to each individual's physical level in order to obtain sub-maximal measurements. External work rate was calculated using the roller friction forces, incline, subjects' mass, and velocity. Metabolic rate was calculated based on gas exchange data. Efficiency was calculated as the ratio of external work rate and metabolic rate. The results were statistically analyzed using ANOVA for repeated measures.

Results: We found a highly significant difference between the V1 and V2 for both men and women and for all disciplines (17.18% vs 15.63%, $p<0.001$). Overall, gender differences were extremely small and not significant. We found no discipline differences. Biathlon had a smaller difference in efficiency between techniques than cross-country and Nordic combined skiers ($p=0.031$). World class skiers had

significantly higher efficiency than national class skiers in V2 (16.28% vs 15.23%, p<0.001), and a trend in the V1 (17.58% vs 16.98, p=0.07). Furthermore, a strong inter-individual correlation was found between V1 and V2 efficiency (r=0.734, p<0.001).

Discussion: Efficiency is lower during roller ski skating than in bicycling (20-25%), but it is close to speed skating (16%) and slide board skating (15%). The higher V1 efficiency might be a result of this technique being slower and relying more on concentric muscle action, as well as being more continuous in power generation, than V2. Biathlon skiers have less difference between V1 and V2 efficiency which might be a result of training and technique differences. Efficiency seems to differ between performance levels in ski skating. Also, the inter-individual correlation shows that the two skating techniques are biomechanically and/or physiologically closely related.

MODEL-GENERATED DECOMPOSITION OF UNFUSED TETANI OF FAST AND SLOW MOTOR UNITS EVOKED BY STIMULATION AT RANDOM INTERPULSE INTERVALS

CELICHOWSKI, J.

UNIVERSITY SCHOOL OF PHYSICAL EDUCATION

During voluntary contractions active motoneurones generate successive action potentials at variable interpulse intervals. The importance of these individual potentials for the force generated by single motor units was analyzed. Unfused tetani of motor units (MUs) evoked by stimulation at variable interpulse intervals at mean frequencies of 20, 25, 33, 40 and 50 Hz were studied using fifteen functionally isolated fast and slow type MUs from the medial gastrocnemius muscle of adult Wistar rats. A previously proposed algorithm and computer program for mathematical decomposition of unfused tetani into a series of twitches, representing responses to individual pulses, were used (Raikova et al. 2007). Analysis of the parameters of the decomposed twitches showed considerable variability in force of successive contractions. These twitches were extremely variable with up to over 2-fold (fast MUs) or 6-fold (slow MUs) higher forces and considerably longer contraction times than a single twitch evoked by one stimulus. However, when the temporary stimulation frequency was decreased, the decomposed twitches became similar to the single twitch with respect to amplitude and contraction time. It was found that the basic contractile parameters of decomposed twitches could be predicted with high accuracy on the basis of the tetanus force level at which the next contraction begins. This analysis of the parameters of decomposed twitches demonstrated that the contractile responses of the muscle fibers to successive action potentials generated by motoneurons are highly variable and depend on the previous MU state.

EFFECTS OF 7-DAY DRY IMMERSION UPON CONTRACTILE PROPERTIES OF POSTURE AND DYNAMIC MUSCLES

NETREBA, A., KHUSNUTDINOVA, D., VORONOV, A., KOZLOVSKAYA, I.

SSC RF INSTITUTE OF BIOMEDICAL PROBLEMS RAS

INTRODUCTION: "Dry immersion" (head-out water immersion with waterproof fabric separating body from the water) is the effective method for ground simulation of microgravity conditions. It was shown that gravitational unloading induces in motor system an acute decrease of support afferentation, which in its turn triggers suppression of activity in postural extensor muscles. The dynamic muscles seem to be affected to a lesser degree. The calf muscles (ankle extensors) are of special interest as they include posture slow m.soleus and dynamic mixed m.gastrocnemius. Noteworthy, the contribution of these muscles into total ankle torque depends on the angle in knee joint: at an angle of 90˚ muscle effort is performed mainly by m.soleus, and at higher angles m. gastrocnemius is involved as well. Thus the discriminative analysis of force-velocity characteristics of these muscles is possible.

METHODS: 16 volunteers were exposed to 7 days dry immersion. The force-velocity characteristics of knee and ankle extensor muscles were determined under isokinetic (angular velocity of 30-300 °/s) conditions. Calf muscles were tested at two different knee angles (90º and 160º) for discrimination of the effects of m. soleus and m. gastrosnemius.

RESULTS: After 7 days immersion the decrease of force-velocity characteristics for knee extensors equaled 10% in the whole range of angular velocities. During testing of calf muscles with the knee angle 160º the decrease of force-velocity characteristics was similar to that – no more than 6% for all tested velocities. But when tested in the same movement with a knee angle of 90º the decrease of force was noticeably greater – about 20% of initial value.

DUSCUSSION: As was expected the maximal decrease of force-velocity properties was demonstrated for postural m. soleus (knee angle - 90º). The decline is apparently connected with reduced support afferentation affecting mostly posture soleus muscle with high content of slow muscle fibers. The decreases of force-velocity characteristics for ankle extensors as a whole group (knee angle 160º) and for knee extensors were less pronounced – 6 to 10%. This result may be connected with compensatory increase of dynamic muscles involvement in motor activity in response to essential decrease of contractile properties of posture synergists. Thus using special approach to evaluate force-velocity properties of mixed muscle group we confirmed the previous results obtained by different methods: the most pronounced decrease of contractile properties during simulated microgravity conditions is demonstrated by pure postural slow muscle.

EFFECT OF HISTORY OF MUSCLE FORCE PRODUCTION ON THE PASSIVE TORQUE

MURAOKA, Y.

MEISEI UNIVERSITY

Purpose: It had been clarified by animal studies that the passive mechanical properties in skeletal muscle were affected by not only muscle length but also the muscle's previous history of force production (Whitehead et al., 2001). The purpose of the present study was to investigate to what extent the muscle previous force production affect passive torque of plantarflexion in humans.

Methods: Five subjects (four males and one female) participated in this study. The subject's foot was fixed to the foot plate of an electrical myometer (VMP-004, VINE, JPN). The passive torque was measured in two conditions; the long condition (LC) and the short condition (SC). In both conditions, initial ankle joint angle was set at anatomical position (AP). First, the ankle joint angle was slowly changed from AP to 15 deg dorsiflextioned (15DF) by the tester in the LC, then the subject exerted maximum voluntary contraction (MVC). After MVC, joint angle was changed to AP again and kept 1min. Finally, joint angle was changed to 15DF and kept 1min. In SC, the MVC was exerted in AP. After the ankle joint angle was kept AP in 1 min, the joint angle was changed 15DF. Subjects maintained the relaxation except the exerted the maximum voluntary contraction (MVC). All sessions were repeated 5 times. Each of the trials was separated by 2min rest at 15DF of ankle joint angle. Surface electromyogram (EMG) was recorded from medial and lateral gastrocnemius, soleus and tibialis anterior using bipolar electrode (SX-230, DKH, Japan). The data of plantarflexion torque and EMG were stored on a personal computer by using an analog-to-digital converter (PowerLab/16sp, ADInstruments). Passive torque was measured at the end of 5sec in AP following MVC and in 15DF.

Results and Discussion: During measurement of passive torque, we confirmed that there was no significant EMG activity. The passive torque was different according to the ankle joint angle in which the MVC was exerted. Although the passive torque at AP was significantly smaller in LC than in the SC ($P<0.05$), the difference was relatively small (8% smaller than in the SC). There was no significant difference in the passive torque measured at 15DF between in the LC and the SC. The passive torque was significantly smaller when it was measured after MVC at longer muscle length than the shorter muscle length. However, this difference of passive torque did not remain after the following stretching. These results were in accordance with the results of animal studies. It was suggested that the history of muscle force production could change the passive torque in human. The change in the passive torque was relatively small, and hence might be practically ignored, for example, when measuring the passive torque as the reference of joint flexibility.

MECHANISMS OF MANAGEMENT OF SPORTS MOVEMENTS IN CONDITIONS OF DEVELOPING FATIGUE

GORODNICHEV, R., MOISEEV, S.

ACADEMY OF PHYSICAL EDUCATION AND SPORT

Introduction: Management of movements represents a complicated multi-level neuronal system functioning on hierarchical principle (G. Courtine et al,2007). Specific mechanisms of management of complete motor actions of a human depend on the level of skills of the motor response, its difference from natural locomotions, time and amplitude parameters of the performed movement, its particular parameters and other factors. Detection of mechanisms of coordination of sport movements is of considerable interest as their performance is connected with exact time and amplitude parameters, development of great muscle efforts and high speed of working muscle contraction.

Methods: 82 athletes-wrestlers (judo) participated in the research aimed at investigation of biomechanical and EMG parameters of skeletal muscles during motor actions of different coordination complexity. Besides, there were studied changes of the structure of a «leg grip» throw in the process of fatigue caused by two kinds of physical activities. The following loadings were applied: 1) technique - performance of techniques within 5 minutes; 2) competitive - 6 competitive fights with a 5-minute interval. Biomechanical parameters and electrical activity were registered by the programme complex Star Trace (Video Motion, 2005) and electromyography «Neuro- MBP-8» (Russia. 2006), correspondingly.

Results/Discussion: It is revealed, that performance of techniques of different biomechanical parameters is determined by specific EMG patterns of the working muscles which parameters depend on coordination complexity of the performed motor action, subjects' sports qualifica-tion, as well as the character of counteraction of a rival, using counter-attacking and defensive techniques. Developing of muscle fatigue was accompanied by natural changes of duration of the tested technique (a «leg grip» throw), its kinematic parameters - speed, acceleration, movements of an athlete's parts of the body, dynamics of angular parameters, and also specific electromyography signs - change of the sequence of working muscles involvement, duration and amplitude of their electric activity. The quantitative changes and direction of dynamics of kinematic and electromyography parameters depends on a kind of physical activity. The greatest changes of the parameters of a «leg grip» throw are registered under the influence of the muscle loading – a model of wrestling competitive activity.

Conclusion.

In the process of muscle fatigue development the efficiency of a performed technique is achieved by means of specific changes of its biomechanical parameters and those of electric activity of skeletal muscles.

COMPARISON OF THE DECREASE IN MUSCLE POWER AND RATIO BETWEEN HAMSTRINGS AND QUADRICEPS AFTER TWO DIFFERENT AEROBIC DANCE PROGRAMS

RADOVANOVIC, D., BÖHMEROVÁ, L., MARINKOVIC, M.

1. FACULTY OF SPORT AND PHYSICAL EDUCATION, UNIVERSITY OF NIS, SERBIA, 2. FACULTY OF PHYSICAL EDUCATION AND SPORT, COMENIUS UNIVERSITY BRATISLAVA, SLOVAKIA, 3. MILITARY ACADEMY BELGRADE, SERBIA

Introduction: Muscular power is one of the most important components of sport, both for high performance and for injury prevention. Fatigue represents a reduction in the capatibility of muscle to generate force. An imbalance in the agonist/antagonist ratio has been identified as a pathological factor. This study assessed the decline in power of the hamstring and quadriceps muscles with fatigue after two different aerobic dance programs and comparison of hamstring to quadriceps ratio.

Methods: Subjects from the first group (n=10, age 20,4yrs±1.3, body height 177.6cm±5.8, body weight 72.9kg±8.4) performed 45 min aerobic dance lesson for beginners with constant intensity of exercise during the main aerobic phase within the 60-75% of estimated maximal heart rate (HRmax). Subjects from the second group (n=10, age 20,6yrs±1.4, body height 175.8cm±6.2, body weight 71.2kg±7.7) performed 45 min aerobic dance advanced lesson with the rope. During the main aerobic phase the subject alternated 2-min high intensity intervals (80–90% HRmax) of rope jumping (5 times) and 2-min low to moderate intensity intervals (70–75% HRmax) of low-impact aerobics (5 times), 10 intervals in total. Muscle power of the knee extensors and knee flexors was measured by a specific tensiometer (Fitro, Slovakia) on two occasions. First measurement was done after warm-up and pre-stretching phase, and second after main aerobic phase and cool down phase in subjects of two different groups. Depending on a statistical marker, measurement scale

and type of distribution, the following tests were used: Student's t-test, Mann-Whitney U test, the Wilcoxon rank sum test, and the Wilcoxon test for paired samples.

Results: There was no significant difference in maximum muscle power of hamstring (224.8W±15.1 pre vs. 214.8W±15.4 post; p>0.05) and quadriceps (348.3W±31.8 pre vs. 343.4W±26.1 post; p>0.05) after lesson in the first group. Further, there was no significant difference in hamstring to quadriceps ratio (0.64 pre vs. 0.63 post; p>0.05). In the second group there was a significant difference in maximum muscle power of hamstring (311.3W±21.3 pre vs. 280.3W±20.9 post; p<0.05) and quadriceps (526.5W±32.6 pre vs. 472.4W±27.2 post; p<0.05) after lesson, but hamstring to quadriceps ratio (0.59 pre vs. 0.6 post; p>0.05) was not changed.

Discussion: Our findings suggested that although the more intensive exercise induced statistically significant decreases in maximal muscle power of hamstring and quadriceps, hamstring to quadriceps ratios were unaltered by the rope jumping and high-intensity exercise. We concluded that intensive aerobic dance lesson with the rope does not cause the imbalance in the agonist/antagonist ratio, so that it can be safely used in training.

PHYSICAL ACTIVITY LEVEL MAY AFFECT VOLUMETRIC BONE DENSITY AND BONE GEOMETRY OF PREPUBERTAL GIRLS

LEONTSINI, D., MICHALOPOULOU, M., MICHOPOULOU, E., KATRABASAS, I., SXINA, M., KREKOUKIA, M., SOVATZIDIS, A., TAXILDARIS, K., TOURNIS, S., LYRITIS, G., FATOUROS, I.

DEMOCRITUS UNIVERSITY OF THRACE

Introduction: Numerous cross-sectional studies suggested that intense physical activity (PA) is beneficial for the load-bearing sites of the human skeleton (1). Physical activity, specifically sporting participation during growth, seems to be effective in reducing

the prevalence of osteoporosis-related fractures (2). However, an increased sedentarism in children (3) has also been described, which is even more alarming in girls because they are usually less active than boys (4). Although, the impact of intense physical training on growth and pubertal development has been adequately studied (5), it is not clear whether various levels of PA affect positively or negatively prepubertal bone geometry as this is assessed by peripheral quantitative computerized tomography (pQCT). The goal of the present investigation was to study bone geometry in prepubertal girls exhibiting different PA levels.

Methods: This was a cross-sectional study. After completing a PA questionnaire (Μαρία βάλετο ερωτηματολόγιο), 60 prepubescent girls were assigned to one of three groups: high PA level (HA, n=20), moderate PA level (MA, N=20), and low PA level (n=20). Participants' tibias were scanned at midsite by using pQCT to determine volumentric bone density, periosteal circumference, pericortical circumference, cortical thickness, polar moment of inertia, strength strain index. Clinical evaluation included body composition (percent body fat assessed by skinfold measurement), body mass index (BMI), and breast and pubic hair assessment development according to Tanner's stages of prepubertal development. Skeletal maturation was determined by x-ray of the left hand and. Bone age was determined according to Greulich-Pyle standards (14). Data were analyzed with ANOVA (P<0.05).

Results: The three groups had comparable bone age and prepubertal development. There were no differences between groups in body composition and BMI. HA had higher volumetric bone density (8%), pericortical circumference (6%), cortical thickness (10%) polar moment of inertia (16%) and strength strain index (10%) than that of MA. MA demonstrated higher volumetric bone density (5%), pericortical circumference (4%), cortical thickness (7%) polar moment of inertia (10%) and strength strain index (8%) than LA.

Discussion: Data from the present study suggest that increased PA activity level affects positively the mechanical properties of prepubescent girls bone and this response may be related to adaptations of bone's geometry.

EFFECTS OF EXERCISE ON COGNITIVE FUNCTION

YUKAKO, I., KEIKO, T., YUKO, M., KARINA, A., MASASHI, K., SUNAO, U.

WASEDA UNIVERSITY

Introduction: There are many studies that investigate the effect of acute aerobic exercise on cognitive function. Tomporowski (2003) has reviewed these studies, and shown that submaximal aerobic exercise for periods up to 60 min facilitates specific aspects of information processing. However, most of these studies have only focused on the effect of cognitive function immediately after the exercise. Therefore, the aim of this study was to investigate the long-term effect on cognitive function after the exercise.

Methods: Ten subjects (23.0±2.4years; mean ± S.D) visited the laboratory at the same time of day on two separate occasions with more than six days between experimental conditions (exercise and rest). Subjects performed 3 tasks of cognitive functional tests (e.g.; Go-no/go, Stroop, Wisconsin card sorting) in pre-exercise session. In exercise condition, subjects again performed tasks immediately after and 3-, 6- and 9-hour after the 30-minute moderate (60% of VO2max) cycling exercise. In the rest condition, subjects rested quietly for 30-minute.

Results: Reaction time (RT) of the stroop task immediately after the exercise was faster than RT of pre-exercise ($p < 0.05$), and faster than after the 30-minute rest ($p = 0.07$). However, there was no difference between exercise condition and rest condition on 3-, 6- and 9-hour after the exercise. In Go-no/go and Wisconsin card sorting tests, no significant improvements were seen after the exercise.

Discussion: These findings suggest aerobic exercise improves cognitive processing temporarily but not for a long period in behavioral performance. This may be due to the relationship between exercise-induced arousal and cognitive performance improvement (Grego et al., 2004), thus effects of exercise may not last for a long period. In addition, these findings suggest effect of acute aerobic exercise on cognitive processing is sensitive to task variety and difficulty (Kamijo et al., 2007).

EXERCISING WITH RESERVE: EVIDENCE THAT THE CNS REGULATES PROLONGED EXERCISE PERFORMANCE.

SWART, J., LAMBERTS, R.P., LAMBERT, M.I., ST CLAIR GIBSON, A., LAMBERT, E.V., SKOWNO, J., NOAKES, T.D.
UNIVERSITY OF CAPE TOWN

Introduction: A central debate in the exercise sciences is the nature of the fatigue that determines exercise performance under different conditions. Two opposing theories are currently popular. The first holds that exercise is limited principally by metabolic changes in the exercising skeletal muscles, so-called peripheral fatigue. An opposing model [1] holds that exercise performance is regulated by the central nervous system (CNS) to ensure that homeostasis is maintained. Recently we [2, 3] and others [4] have shown that the rating of perceived exertion (RPE), a marker of "fatigue", rises as a linear function of the duration of exercise that remains. The model also predicts that agents which interfere with these central regulatory controls in the central nervous system (CNS) could enhance exercise performance by allowing the body to approach more nearly its metabolic and cardio-respiratory limits. Accordingly, the purpose of this study was to measure the effects of an amphetamine (methylphenidate) on exercise performance at a fixed rating of perceived exertion of 16.

Methods: Eight elite cyclists ingested 10mg Methylphenidate in a randomized, placebo controlled cross-over trial.

Results: Compared to placebo, subjects receiving methylphenidate cycled for ~ 32% longer before power output fell to 70% of the starting value. At the equivalent time at which the placebo trial terminated, subjects receiving methylphenidate had significantly higher power outputs (19%), oxygen consumptions (13%), heart rates (12%), ventilatory volumes (11%) and blood lactate concentrations (43%) although EMG activity remained unchanged.

Discussion: Thus the ingestion of a centrally-acting stimulant allowed subjects to exercise for longer at higher cardiorespiratory and metabolic stress indicating the presence of a muscular reserve in the natural state. This suggests that endurance performance is not only "limited" by mechanical failure of the exercising muscles ("peripheral fatigue"). Rather performance during prolonged endurance exercise under normal conditions is highly regulated by the CNS to insure that whole body homeostasis is protected and an emergency reserve is always present.

CARDIOVASCULAR ADJUSTMENTS TO AND FROM PROLONGED DRY AND IMMERSED APNOEA IN RESTING BREATH-HOLD DIVERS

PERINI, R., GHEZA, A., MOIA, C., FERRETTI, G.,2
1. UNIVERSITY OF BRESCIA, 2. CENTRE MEDICAL UNIVERSITAIRE GENEVE

Introduction: Diving response is characterised by peripheral vasoconstriction, with increased blood pressure (BP), decreased heart rate (HR) and decreased cardiac output (Q'). Breath-holding "per se" has been shown to elicit similar responses, although of lesser intensity. Scarce descriptions of the time courses of cardiovascular adjustments to prolonged apnoea can be found. Data on HR and BP dynamics after apnoea are even less. Our aim was to describe the cardiovascular changes in the recovery of maximal static apnoea.

Methods: Static apnoea to volitional exhaustion was performed by 8 breath-hold divers (age: 32.5±4.5 yrs) in air (DRY) and by 6 divers (30.5±2.4 yrs) while immersed below the surface of 27 °C water (IMM). BP profile was continuously recorded (Portapres) and beat to beat values of systolic and diastolic pressures (Ps and Pd), HR and stroke volume (SV; Beatscope®) were obtained. Ps, Pd, HR and SV, and hence Q', were calculated before (ctrl), every 30 s and in the last 10 s (end) during apnoea, and 5 s, 10 s, 20 s, 30 s, 60 s, 120 s and 180 s after the resumption of breathing.

Results: Apnoea lasted 134.2±35.05 s in DRY and 179.3±34.4 s in IMM ($p>0.05$). After 30 s of breath-holding, HR was about 20 b/min below ctrl in both groups and did not further change, being at end 60.7±13.7 b/min in DRY and 56.1±16.2 b/min in IMM ($p>0.05$). At 30 s of apnoea, both Ps and Pd were significantly above ctrl by 15-20 mmHg and 18-20 mmHg, respectively, with no difference between groups. Then, a continuous slight increase occurred in DRY, being Ps and Pd at end 146.3±39.2 mmHg and 93.3±13.6 mmHg, respectively. In IMM, Ps and Pd remained stable for 90 s, then increased and reached 206.0±23.9 mmHg and 111.8±11.4 mmHg at end, respectively ($p<0.05$ vs DRY). In both groups, SV was unchanged and Q' was 25% below ctrl during the entire apnoea. With the resumption of breathing, both in DRY and IMM, HR immediately increased, attaining ctrl values after 5 s, while Ps and Pd decrease showed a 5 s delay. Ctrl values of both Ps and Pd were resumed after 30 s. No subsequent changes were found. No change in SV occurred, so that Q' was restored in the first 5-10 s of recovery.

Discussion: The observed time-courses of cardiovascular parameters suggest a main role of breath-holding "per se" in eliciting the initial bradycardia and hypertension of apnoea. The successive adjustments, at least in static apnoea, seem to be limited to a further vasoconstriction, being the vascular response greatly enhanced by water immersion. Recovery of both HR and BP is extremely rapid in any case, being complete within 1 min. We conclude that: a) cardiac and vascular adjustments during and immediately after prolonged apnoea are distinct; b) chemorereceptor stimulation may induce the vascular response as breath-holding goes on; c) water immersion plays a prominent role in eliciting hypertension; d) the rapidity of HR recovery is compatible with the notion of withdrawal of increased vagal tone.

ANALYSIS OF SOMATOTYPE CHARACTERISTICS OF ELITE MALE AND FEMALE ATHLETES IN CYPRUS

ANIL, E., TINAZCI, C.

NEAR EAST UNIVERSITY

Introduction: Somatotype has been used to demonstrate similarities and differences between several groups of individuals including athletes of different sports. Since 1967, the Heath-Carter somatotype method has been utilised successfully by several investigators (Carter, 1970). Mostly, studies on somatotyping have been carried out on athletes of European and North American countries Data are lacking, however, on somatotype studies of Turkish Cypriot athletes.

Also, Somatotype has a great role in reaching the sportive success. In athletes selection, it is important to select athletes which have the right somatotype for the target field of sport. At this selection it is also necessary to know the pecularities of the somatotype needed for the mentioned sport. For these reasons, the aim of this research is to find differences between somatotype pecularities of elit female and male athletes.

Methods: In this research, 56 male and 40 female 20-32 years of age were examined to determine physique fitness. Physique was determined by using the Heath-Carter anthropometric somatotype.

The athletes taken into examination are training at least 4 days a week with their teams and the trainings are continuing avarage 90 minutes. Measures are taken from 10 different areas of the body. Skinfold thicknesses (triceps, suprailiac, subscapula and calf), diameter (humerus and femur) and circumference (biceps, calf), weight and height of the athletes were measured. This research was completed within three months (February-April 2008). All statistical data (mean and Standart deviation) were evaluated on SPSS software programme.

Results: In this research, the lowest endomorph value is measured as 1.8 in football team, the lowest mesomorph value is measured as 3.6 in female basketball players and the lowest ectomorph value is measured as 1.2 in handball men team. In this research, the highest endomorph value is measured as 5.2 in tennis men team, the highest mesomorph value is measured as 6.9 in handball men team and the highest ectomorph value as 2,7 is measured in tennis women team.

Discussion: When the somatotype values of Turkish Cypriot elit athletes are examined, it is seen that there are differences in these values between Turkish Cypriot athletes and other country athletes.

RELIABILITY OF A NON-TRADITIONAL POSITION FOR IN VIVO ULTRASOUND MEASUREMENT OF HUMAN MUSCLE FIBRE PENNATION ANGLE.

SHEARD, P.W., HARTFREE, C.L.

UNIVERSITY OF BEDFORDSHIRE

Twelve physically active individuals had consecutive images taken of their Vastus lateralis using B-mode ultrasound at 10MHz with a linear array probe. Measurements were taken in the traditional, closed kinetic chain position with the hip, knee and ankle flexed at 90 degrees, with the foot supported and all muscles in a relaxed state (10 images) and in the novel, open kinetic chain position with the hip and ankle flexed at 90 degrees and the knee flexed at 85 degrees via the minimal extensor muscle contraction necessary to maintain the open kinetic chain position (10 images).

In an effort to 'reset' the muscle architecture between measurements and to reduce the chance of creep deformation (Lederman 2005) from repeated contractions, series of 10 box steps, dominant limb leading, were completed between measurements as a correlate to the activity of daily living (ADL) of stair climbing. Box height was 19.2 cm, and a tempo of 100 steps per minute (1 beat being 1 leg movement, the equivalent of 25 complete box steps per minute) was regulated by metronome (SQ44, Seiko (UK) Ltd, Berkshire, UK). Two of the subjects volunteered for further testing and measurements were re-taken on five days, over a period of eight, to determine intra-subject variability.

Inter-subject reliability showed an improvement of ~30%. Intra-subject reliability showed an improvement of ~28%. The variability in the measures at 90 degrees (SD = 1.52 degrees) were more than twice that recorded at the 85 degrees (SD = 0.74 degrees) position. These results indicate that measurements taken at the novel position are ~30% more reliable and this improved reliability will allow for a ~76% reduction of sample size, while maintaining similar statistical power, in future studies.

THE EFFECT OF MOTIVATIONAL AND RELAXATION MUSIC ON AEROBIC PERFORMANCE, RATING PERCEIVED EXERTION AND SALIVARY CORTISOL IN ATHLETE MEALS

GHADERI, M., AZARBAYJANI, M.A., RAHIMI, R., AGHA ALINEJAD, H.

AZAD UNIVERSITY OF MAHABAD., AZAD UNIVERSITY BRANCH OF CENTRAL TEHRAN., AZAD UNIVERSITY OF MAHABAD., TARBIAT MODARES UNIVERSITY, TEHRAN.,

Introduction: Music is a source of motivation and inspiration that is much valued within the realms of sport and exercise. Relationship between music and physiological and mental change of human body traditionally was in considering of scientists. Likewise, listening of music during submaximal exercise resulted lower increase of salivary cortisol.

Methods: Thirty male physical education college students (ages: 25.66±3.89 yr, height: 176.65±7.66 cm, weight: 78.45±16.20 kg, body fat percent: 12.86±5.74 and Vo2max: 38.36±9.19 ml/kg/min) voluntarily participated in this study and divided to three groups: motivational music, relaxation music, and no music. All subjects run to exhaustion with 80-85 percent of maximal heart rate on the treadmill. For measuring of cortisol, not stimulated samples of saliva collected, 15 minutes before and 5 and 30 minutes after the exercise. RPE was obtained every 5 minutes during exercise.

Results: Based on the findings, aerobic performance during the motivational music treatment was significantly higher than the relaxation and no music treatment. Furthermore, RPE and cortisol concentration significantly were lowered 5 minutes after exercise for relaxation music treatment than motivational music and no music treatment. But there were no significant differences in salivary cortisol concentrations at 30 minutes after exercise between three groups.

Discussion: The first finding of present study showed that listening of music during exercise, regardless of its type; determine higher running time for measure of aerobic performance. This findings corresponding with results of (2,3) but is contrast to finding of (1). Based on present study findings, although during listening of music increased running time and decreased rating of perceived exertion, no significant differences was found between this variable after listening of motivational and relaxation music. Furthermore, although in both groups of motivational and relaxation music, aerobic performance was better, it is noted that operation of every type of music has special characteristic. Mark et al (4) found that muscles stress change with music kinds so they stimulant music increase and relaxation music decrease muscles stress. This study provided some support for the hypothesis that listening motivational and relaxation music reduce physiological and psychological arousal during submaximal exercise and increase aerobic performance.

CHANGES IN THE CROSS SECTIONAL AREA OF INFERIOR VENA CAVA AND STROKE VOLUME DURING SITTING CROSS-LEGGED

SHO, O., AKIRA, Y., KAZUKI, N., KAZUTOSHI, S., TERUMASA, T., NOZOMI, M., YUKA, N., TOSHIHIKO, M.

KAWASAKI UNIVERSITY OF MEDICAL WELFARE

Purpose: Zen meditation in water is the exercise program of a pregnant woman. Zen meditation in water is the program that the pregnant women sit cross-legged down under the water with breath-hold. It is known that heart rate decreased during Zen meditation in water. It was considered increase of venous return by physical characteristics of water caused the decrease of heart rate. We hypothesized that decreases in heart rate were caused by not only physical characteristics of water but also the posture of sitting cross-legged. The purpose in this study was to investigate the venous return during Zen meditation on land. In addition, we evaluated the stroke volume during Zen meditation on land. Methods: Eleven healthy young male volunteered to participate in this study. All subjects signed the informed consent forms prior to participation in this study. The age, body weight and body height of subjects were 21 (SD: 1) years old, 65.6 (SD: 7.0) kg and 171.8 (SD: 6.1) cm, respectively. This study was consisted in two conditions. One was sitting cross-legged condition (Cl-condition), the other was sitting the chair condition (SC-condition). Each subjects performed sitting cross-legged and sitting the chair for three minute, respectively. We measured the cross sectional area of inferior vena cava using ultrasound during sitting cross-legged. We determined the cross section of inferior vena cava at the level of processus xiphoideus. After recording the images of the cross section of inferior vena cava to the computer, we calculated the cross sectional area of inferior vena cava in computer. Furthermore, we measured heart rate throughout experiment. In addition, we measured stroke volume of six of all subjects, using ultrasound Doppler. The age, body weight and body height of six subjects were 21 (SD: 1) years old, 63.4 (SD: 7.4) kg, 14.8 (SD: 3.3) %, respectively. Results and Discussion: The cross sectional area of inferior vena cava of Cl-condition was 5.05 (SD: 1.10) cm2. The cross sectional area of inferior vena cava of SC-condition was 4.03 (SD: 1.14)cm2. A numerical value of Cl-condition was higher than that of SC-condition ($p<0.05$). Heart rate in Cl-condition was 63.5 (SD: 6.4) bpm. Heart rate in SC-condition was 67.5 (SD: 10.2) bpm. Furthermore, stroke volume in CL-condition was 76.3 (SD: 11.2) ml, and that was 72.3 (SD: 11.6) ml in SC-condition. Heart rate and stroke volume were no difference between SC- and CL-condition. These date suggest that increases of the cross sectional area of inferior vena cava of Cl-condition was caused by defuse of development at both way of a vein. Because, it was considered that it was not possible to recruit the milking action during sitting cross-legged. Furthermore, we imply that the decrease of heart rate during Zen meditation in water is caused by not the posture but the increase of venous return that breath-hold and water pressure induce.

GENDER INFLUENCE ON POST-RESISTANCE EXERCISE HYPOTENSION AND HEMODYNAMICS

QUEIROZ, A.C.C., REZK, C., TEIXEIRA, L., TINUCCI, T., FORJAZ, C.L.M.

UNIVERSITY OF SÃO PAULO – UNIVERSITY CENTER FIEO – SANTO AMARO UNIVERSITY

Introduction: Post-resistance exercise hypotension has been extensively described in men and women. However, gender influence on this response was not studied yet. Thus, the aim of this study was to compare post-resistance exercise hypotension and its hemodynamic mechanisms in men and women.

Methods: Twenty-two normotensive subjects (9 male and 13 female) underwent two sessions: control (C - 40 min of rest) and resistance exercises (E - 40-50% of 1 RM, 6 exercises, 3 sets, 20 repetitions). Before and after interventions, blood pressure (BP- auscultatory), heart rate (HR-ECG), and cardiac output (CO – CO2 rebreathing) were measured. Changes observed in each session were compared between genders by a three-way analysis of variance ANOVA for repeated measures. Data are presented as mean±SE.

Results: BP responses were similarly in both genders, systolic BP reduced in the E (-6.4 ± 1.0 mmHg, $p<0.05$), and did not change in the C. Diastolic and mean BP decreased in E (-1.8 ± 0.5 and -3.1 ± 0.6 mmHg, $p<0.05$, respectively), and increased in C (3.4 ± 0.5 and 1.8 ± 0.4 mmHg, $p<0.05$, respectively). Hemodynamic mechanisms differed between genders. In women, CO decreased similarly in both sessions, while SVR increased less after E than C session (4.1 ± 1.8 and 6.6 ± 1.7 units. $p < 0.05$). On the other hand, in males, CO decreased more in the E than C session (-0.9 ± 0.3 and -0.4 ± 0.1 L/min, $p < 0.05$), while SVR increased similarly in both sessions. Stroke volume decreased in the E session in both genders, but this decrease was more pronounced in the males, while heart rate increased similarly after exercise in both genders.

Conclusion: In conclusion, post resistance exercise hypotension was similarly in both men and women. However, its mechanisms differ between genders, depending more upon a decrease in CO in men, and in a deficiency to increase SVR in women.

JUMP TRAINING INDIRECTLY PROMOTES MARROW FAT VOLUME REDUCTION BY PROMOTING OSTEOBLAST DIFFERENTIATION OF MARROW STROMAL CELLS

YUKI, A., YOTANI, K., AKIMOTO, R., TAMAKI, H., TAKEKURA, H.

NATIONAL INSTITUTE OF FITNESS AND SPORTS

Introduction: Marrow stromal cells can differentiate into osteoblasts and adipocytes. While jump training is known to increase bone formation in rats and human, its effect on adipogenesis is unclear. In the present study, we assess the effects of jump training on bone marrow adipocyte lineage differentiation in comparison to osteoblast lineage differentiation.

Methods: 4-week-old Fischer 344-strain rats were divided into a control group (Control n = 6) and jump training group (Jump, n = 5). The rats were trained for 4 weeks at a jumping rate of 20 repetitions per day for 5 days/week. The training began with an initial jump height of 20 cm, after which the height was progressively increased up to 35 cm by the fourth week. After the training period, the animals were sacrificed and the tibiae were excised. The tibiae were rapidly frozen in isopentane and cooled using liquid nitrogen for carboxymethyl cellulose (CMC) gel block preparation. The frozen tibiae were re-embedded in 5% CMC gel and frozen. Each CMC block was covered with a polyvinylidene chloride film coated with synthetic rubber cement. Serial longitudinal sections (4 - 20 μm) were cut using a cryostat with a disposable tungsten carbide blade at -25°C. The fat volume and bone volume were assessed by Oil Red O staining and Alizarin red S staining, respectively. Immunohistochemical analysis was performed to assess the cellular localization of the proteins runt-related transcription factor 2 (Runx 2) and peroxisome proliferator-activated receptor γ2 (PPARγ2), which play an important role in the regulation of osteoblast and adipocyte differentiation. Quantitative microscopic analysis was performed using a digital microscope equipped with a video monitor and a personal computer with image analysis software (Image J ver. 1.38). The mRNA extracted from the marrow was analyzed using a real-time polymerase chain reaction.

Results: Jump training increased the bone volume and decreased the lipid droplet number ($p<0.05$). The number of cells expressing Runx2 and the Runx2 mRNA levels were significantly increased in the Jump group compared to the controls ($p<0.05$). Conversely, there were no significant differences in the number of cells expressing PPARγ2 and the PPARγ2 mRNA levels between the Control and Jump groups.

Conclusion: These findings suggest that jump training does not directly inhibit adipocyte lineage differentiation but decreases marrow fat volume indirectly by promoting osteoblast lineage differentiation.

RELATIONSHIP BETWEEN MUSCLE FIBER DISTRIBUTION, NEUROMUSCULAR AND METABOLIC RESPONSES DURING LEG PRESS EXERCISE

NAVARRO-AMEZQUETA, I., IZQUIERDO, M., GONZÁLEZ-IZAL, M., GRANADOS, C., MALANDA, A., IBÁÑEZ, J., VICENTE-RODRÍGUEZ, G., CALBET, J.A.L., GOROSTIAGA, E.M.

STUDIES, RESEARCH AND SPORT MEDICINE CENTER, GOVERNMENT OF NAVARRE. ELECTRIC AND ELECTRONIC ENGINEERING, PUBLIC UNIVERSITY OF NAVARRE. UNIVERSITY OF LAS PALMAS DE GRAN CANARIA, SPAIN

Aim of the study: To examine the relationships between muscle fiber distribution, neuromuscular [muscle power and surface electromyography activity (sEMG)] and metabolic (blood lactate and ammonia concentration) responses during a high-intensity leg press exercise [5 sets of 10 repetition maximum (10RM), with 2-min rest].

Methods: Twelve physically active males were biopsied from the vastus lateralis muscle to determine their percent distribution of type I, type IIa and type IIx muscle fibers as identified through myofibrillar adenosine triphosphatase activity. Two groups were selected on the basis of high (73.5±8.5 % type I fibers; HST group) or low (50.3±7.7 % type I fibers; LST group) percentage of type I fibers. A bilateral leg extension exercise machine was instrumented to measure one repetition maximum (1RM) and power output during the concentric phase of the leg extension. sEMG of the vastus medialis and lateralis muscles (FInsm5 spectral index)(1) was measured. In addition, the subjects performed a graded cycle ergometer exercise to estimate their maximal oxygen uptake (VO2max)(3).

Results: No significant differences were found between groups in estimated VO2max (58.2±3.9 and 57.5±6.3 ml·kg-1·min-1), 1RM (178.7±37.2 and 200.5±14.7 Kg) and 10RM (148.2±34 and 166,7±14.1 Kg) for HST and LST, respectively. At the end of the exercise, peak power output in LST decreased by 33.7±21.1 % (from 862.6±182.5 to 558.7±180.5 W, $P<0.05$), whereas no significant changes were observed in HST (from 708.2±264 to 690.3±228.6 W). The average peak blood ammonia and lactate concentrations were significantly higher ($P<0.05$) in LST (120.3±30.3 µM and 11.4±2.5 mM) compared with HST (58.8±25.9 µM and 8.7±1.9 mM), respectively. The individual percentage of IIx type fibers correlated positively with peak power output decrease ($p<0.05$; $R2=0.58$), blood ammonia ($p<0.01$; $R2=0.47$) and blood lactate ($p<0.05$; $R2=0.37$) peaks, as well as with the individual increases in FInsm5 spectral index ($p<0.01$; $R2=0.62$).

Discussion: The results of this study show that the subjects with higher % of IIx fibers present higher peak blood ammonia and lactate values, higher peak power output decrease, as well as higher changes in FInsm5 spectral index. The higher increase in peak blood ammonia observed in subjects with a higher % of type IIx fibers suggests that the decline in the energy state of the muscle is more pronounced in subject with higher percentage of type IIx fibers (2). The correlation observed between % of type IIx fibers and FInsm5 spectral index, could reflect a changes in the motor unit recruitment pattern. These results suggest that differential exercise-induced neuromuscular and metabolic responses may be related to muscle fiber type composition.

EFFECT OF SHORT-TERM SUPPORTLESSNESS UPON PERFORMANCE OF LOCOMOTION TEST WITH VOLUNTARY ION OF SPEEDS AT A STABLE AND UNSTABLE TREADMILL

VINOGRADOVA, O., VORONOV, A., POPOV, D., FOKIN, K., TRUSHEVA, T., KOZLOVSKAYA, I.

INSITUTE FOR BIOMEDICAL PROBLEMS

INTRODUCTION: Step-wise locomotion test with voluntary selection of speeds is used for evaluation of physical fitness in a Russian system of counter measures for preserving health and efficiency of cosmonauts under unfavorable conditions of microgravity. Test consists of 4 steps with rising intensity at a passive treadmill. Speed at each step is selected by the subject individually according to following wording: walking, jogging, moderate running, fast running. The duration of each step and friction of a treadmill are fixed. According to the technical requirements for International Space Station equipment the treadmill is to be vibro isolated from the body of the Station, that is the treadmill is unstable.

The aim of the study was to evaluate the efficacy of locomotion exercise at the unstable treadmill under control conditions and after 6 hours of "dry immersion" (head-out water immersion with waterproof fabric separating subject from water) mimicking the conditions of supportlessness.

METHODS: 8 healthy young male subjects gave their informed consent to participate in a study. They performed test at the stable and unstable treadmill both under control conditions and after 6-hours dry immersion.

RESULTS AND DISCUSSION: Total way covered by a subject during test was significantly lower at unstable treadmill than at stable. After dry immersion the total way covered at a stable treadmill did not change and at an unstable treadmill – decreased. Under control conditions maximal running speed at the unstable treadmill in comparison with stable was unchanged and after immersion was decreased. Sensation of the perceived exertion during test did not change in all cases except one. It is understandable as the test is organized in such a way that the subject is choosing the speeds according to his perceived exertion. The impact loads significantly decreased at an unstable platform apparently because of damping. After dry immersion impact loads at the stable treadmill did not affect, but significantly enforced at an unstable treadmill.

Energy cost of exercise was evaluated as an increase of energy consumption in response to an increase of locomotion speed during jogging-running part of the test. Energy cost of locomotion had a tendency for an increase during exercise at an unstable treadmill. After immersion the energy cost of exercise at unstable treadmill increased both in comparison with the cost at stable and unstable treadmill. EMG-activity of m. soleus and m. rectus femoris increased during exercise at unstable treadmill. That means maintenance of vertical posture became more difficult. After immersion activity was redistributed between different muscles.

CONCLUSION: Thus changes in energy cost of exercise at unstable treadmill and after immersion may be connected with redistribution and increase of activity for different muscle groups under conditions of unstability and as a result of short-term period of supportlessness.

PP-PH14 Physiology 14

THE EFFECT OF NAHCO3 INGESTION ON POWER OUTPUT DURING EXERCISE AT A CONSTANT LEVEL OF PERCEIVED EXERTION.

RENFREE, A.

UNIVERSITY OF WORCESTER

Manipulation of acid-base status has been demonstrated to influence RPE during exercise (Kostka & Cafarelli 1982), suggesting that shifts in blood [H+] are linked to sensory processes. Ingestion of NaHCO3 has been demonstrated to reduce RPE during supra lactate threshold (>LT) intensity exercise (Robertson et al 1986) indicating that ingestion could also result in increased muscular power output during exercise at similar RPE's. The purpose of this study is therefore to investigate the effect of NaHCO3 ingestion on power output during cycling at an RPE associated with >LT exercise.

Ten recreationally active male participants (26+2.4 years) performed an incremental exercise test on an electronically braked cycle ergometer for identification of LT and RPE at a range of submaximal workloads using the Category Ratio Scale (Borg 1982). Participants performed four further experimental trials, two at an RPE associated with >LT exercise, and two at an RPE associated with <LT exercise following ingestion of either 0.3 g.kg-1 NaHCO3 or a CaCO3 placebo. Participants cycled at a constant cadence (60-70 rpm) and controlled resistance to pedalling themselves using large buttons on the ergometer console. On commencing exercise, three minutes were given to adjust power output to equate with the required RPE which was then maintained for a further 4 minutes. Power output, heart rate, and breath by breath respiratory gas exchange measures were collected throughout the 4 minutes, and capillary blood samples were taken for blood lactate and blood gas analysis immediately pre- and post- exercise. Differences in power output and respiratory gas exchange measures were identified using a two-way ANOVA for repeated measures, and paired sample t-tests were used to identify differences in pre- and post-exercise blood parameters.

Power output was higher ($P<0.05$) following NaHCO3 than following CaCO3 at all times during >LT, but not <LT exercise. No significant differences in respiratory gas exchange measures or HR were observed at any time during >LT or <LT trials.

These results suggest that manipulation of acid-base status influences muscular power output at a fixed RPE during >LT but not <LT exercise. Further work is required to ascertain the effects of acid-base manipulation on performance and pacing strategy during self paced maximal exercise trials as it seems as though the strategy used during such activity results from both peripheral physiological feedback and knowledge of the endpoint of exercise (St. Clair Gibson et al 2006). Although the present study indicates that alteration of a peripheral physiological variable can influence power output at a given RPE, the requirement to maintain a submaximal level of exertion means that the activity performed is not representative of athletic competition.

THE ACUTE EFFECT OF TAURINE INGESTION ON 3KM RUNNING PERFORMANCE AND FORCE IN TRAINED MIDDLE DISTANCE RUNNERS

BALSHAW, T.G., BAMPOURAS, T.M., BARRY, T., SPARKS, S.A.

UNIVERSITY OF CUMBRIA, LANCASTER

Introduction: Taurine (TA) can increase force production of isolated mammalian skeletal muscle tissue while depletion of it decreases muscular function (Bakker and Berg, 2002; Hamilton et al., 2006). Although prolonged TA administration appears to benefit endurance performance in trained endurance athletes (Lee et al, 2003), little research exists examining the acute effects of TA on performance (Rutherford et al, 2006).The current study investigated the acute effect of 1000mg of TA on maximal 3km time trial (3KTT) performance and lower limb muscular force production (MFP) in well-trained, competitive middle distance runners (MDR).

Methods: Six male MDR (age: mean 20.10, s = 1.11 years; 800m personal best times: mean 123.03, s = 5.18 seconds) participated in a double blind, randomised, crossover designed study. Following a standardized warm-up, participants completed a laboratory-based self-paced, maximal 3KTT on a treadmill ingesting either TA or placebo (PL), two hours prior to testing. Capillary blood lactate (LAC), glucose (GLU) and MFP during three countermovement jumps (without arm swing) were measured pre- and post-3KTT. Respiratory exchange ratio (RER), heart rate (HR), rating of perceived exertion (RPE), and split times were recorded at 500m intervals. Wilcoxon's test was used to analyse overall 3KTT performance. All other variables were analysed using Friedman's test, followed by Wilcoxon's test with Bonferroni adjustment, if differences were found.

Results: No significant differences ($P > 0.05$) were found for any of the variables between conditions. However, the TA condition demonstrated better performances in 3KTT but not MFP (TA: mean 650.00, s = 56.68 seconds; PL: mean 655.50, s = 68.22 seconds and TA: mean 1196.37, s = 133.08 N; PL: mean 1289.53, s = 243.08 N, respectively).

Discussion: The failure to detect significant differences in performance between conditions indicates acute ingestion of TA may have no effect on 3KTT performance or peak lower limb MFP of well trained endurance runners in middle distance events. The findings of this study provide an insight into the acute effects of TA on both endurance and MFP performance, as previous studies indicated TA benefiting performance in longer duration exercise trials and after prolonged administration (Lee et al., 2003). The results also raise questions over the potential influence of TA on MFP in vivo (Bakker and Berg, 2002). More research is required to establish potential effects of different TA dosages on endurance performance of different duration.

EFFECTS OF A 24-H FASTING AND A SUBSEQUENT MODERATE AEROBIC CYCLING ON BLOOD ADIPONECTIN CONCENTRATIONS AND NEUTROPHIL RESPONSES

LI, T.L., LIN, C.L., CHEN, Y.C.

NATIONAL DONG HWA UNIVERSITY

The combination of exercise and fasting is a popular way in weight reduction. Adiponectin is produced by adipose tissue and has been shown to associate with body mass index (BMI), insulin resistance, and inflammation. The purpose of this study was to investigate the influence of a 24-h fasting and a subsequent moderate aerobic cycling on blood adiponectin levels and neutrophil responses.

With local ethics committee approval, ten male volunteers (age 22.0±0.6 years, height 1.69±0.02 m, body mass 72.7±2.5 kg, BMI 25.2±0.6, VO2max 35.15±2.91 mL•kg-1•min-1; means ± SEM) participated in this study. After a preliminary trial of VO2max measurement, subjects completed two main trials (fasting and control) in a counterbalanced order. Subjects dined a standardized dinner (1082±38 kcal•kg-1: CHO 137±5 g, protein 53±2 g, fat 36±1 g) between 18:00-18:30 in both trials. Subjects kept fasted status henceforward in fasting trial, whereas subjects ate standardized breakfast at 09:00 (216 kcal•kg-1: CHO 54 g, protein 25 g, fat 16 g) and lunch at 12:00 (identical meal to dinner) in control trial, before completing a 1-h cycling at 50% VO2max between 18:30-19:30 the following day. Blood samples were taken at pre-dinner (Pre-DN), pre-exercise (Pre-EX), and post-exercise (Post-EX). Haematological analysis was performed using an automated cell counter. Plasma adiponectin levels were determined using ELISA kits. fMLP induced neutrophil oxidative burst (OB) activity was measured using a chemiluminescence assay. Results were analysed using a two-way repeated measures ANOVA with post hoc Tukey test. Statistical significance was accepted at $P<0.05$.

The main findings of this study were: (1) the blood counts of leukocytes were not affected by fasting but exercise ($P<0.01$); (2) neutrophil OB activities were not affected by either the 24-h fasting or the 1-h moderate cycling; (3) adiponectin levels were lower in fasting trial than that in control trial at post-EX ($P<0.05$). In conclusion, the findings suggest that a 24-h fasting prior to moderate aerobic cycling does not appear to affect neutrophil responses but plasma adiponectin concentrations.

EFFECT OF TRAINING STATUS ON ADIPONECTIN CONCENTRATIONS

BOUASSIDA, A., LAKHDAR, N., BEN SAAD, H., ZAOUALI, M., ZBIDI, A., TABKA, Z.

FACULTY OF MEDICINE IBN EL JAZZAR, SOUSSE

Introduction: Several studies exploring the effects of acute exercise on adiponectin concentration have resulted in conflicting results (Simpson and Singh, 2008). Jurimae et al., (2005) and Jurimae et al., (2006) showed delayed increases (after 30 min) in adiponectin concentrations, respectively following maximal exercise and following a constant intensity exercise performed by trained rowers. The purpose of this investigation was to analyse the effect of sub-maximal acute exercise at different intensities on plasma adiponectin and insulin concentrations in trained and untrained subjects.

Methods: Seven trained (elite handball players) and eight untrained subjects participated in this study. Subjects performed two submaximal cycling exercises of 20 minutes each: moderate and heavy. The intensity of exercises was respectively at 60% and 80% of maximal oxygen consumption (VO2max). Blood samples were obtained before, at the end, after 30, 60 and 90 min of recovery.

Results: Adiponectin concentrations were unchanged after both exercises and during recovery in trained and untrained subjects. Insulin concentrations were significantly lowered ($P<0.05$ and $P<0.01$) at the end and during recovery in both protocols and groups. The comparison between groups indicated that trained subjects presented lowered control adiponectin and insulin concentrations than untrained

counterparts during the moderate and the heavy exercise: -51.2%, P<0.05 and -44.4% P<0.05, respectively for adiponectin and -35.2%, P<0.05 and -35.2% P<0.05, respectively for insulin.

Discussion: In accordance with our results, Kraemer et al., (2003) and Ferguson et al., (2004) reported no significant changes in adiponectin concentrations after respectively, a strenuous intermittent running exercise in well-trained runners and a 60 min sub-maximal aerobic exercise in healthy normal weight males and females. In our study, we supposed that the handball elite players undergo a heavy training that can induce significant changes in adiponectin receptors and explain the lowered control adiponectin levels. Our results suggested that 1) 20 minutes acute aerobic exercises not stimulate the production and the release of adiponectin during 90 minutes recovery in trained and untrained subjects, 2) it appears that adiponectin is not associated with insulin modifications and 3) handball athletes showed significantly lower resting adiponectin and insulin response with respect to untrained subjects. This result is probably the consequence of increased level of receptor expression induced by training.

QUANTIFICATION аND NORMALIZATION OF TRAINING LOADS BY USING THE CRITERIONS OF EXERCISE PULSE COST

VOLKOV, N., POPOV, O., VOITENKO, Y.

RUSSIAN STATE UNIVERSITY OF PHYSICAL EDUCATION AND SPORT

Introduction: Adaptation to influence of physical loads in sports training may be quantitatively described by relationship "dose-effect" . The value of trained function increase for the period of observation is assumed as a parameter of achievable effect. A dose of influence of physical load is defined as the product of intensity of exercise energy expenditure on the period of the physical load action.

The energy cost in exercise can be estimated on the basis of direct recording of metabolic shifts at physical work, and also by an exercise pulse cost derived from the analysis of heart rate change dynamics during work and recovery (Volkov et all 2005).

Methods: 26 well-trained male swimmers, middle-distance runners and skaters (age 18-24 years, height 162-186 cm, body mass 62-83 kg), ranging from club to international level, volunteered to take part in the study. All subjects performed 5 all-out tests - 10 s, 30 s, 60 s, 120 s and 360 s duration without preliminary warm-up. The gas volume, the O2 and CO2 fractions in the expired air were measured using a monitor system (Meta-Laizer 3B-R2, Cortex, Germany). O2-intake, O2-debt, O2-requirment, aerobic and anaerobic energy output were calculated with a special computer program. The blood lactate concentration is determined using an enzymatic method Dc Lange. Acid-alkaline balance parameters were determined using a pH and blood gases microanalyzer (AVL-800, Radiometer, Denmark).

Results: Changes of parameters total pulse cost in dependence with values of exercise limiting time close reproduce appropriate relationships for parameters oxygen requirement and energy cost of exercise. Thus, pulse cost indices may be used as objective criteria for quantification physical loads as well at the development of programs of optimization of training in various kinds of sports. In exercises 10-s duration power was 850 (108) W, pulse cost of exercise 222 (59) beats, oxygen requirement rate 32.4 (5.2) l min(-1), maximum lactate accumulation 8.63 (1.93) mmol l (-1). In exercises 60-s duration the corresponding data were 380 (37) W, 450 (136) beats, 11.01 (1.28) l min(-1), 15.11 (0.96) mmol l (-1). In exercises 3-min duration the corresponding data were 170 (14) W, 870 (182) beats, 4.4 (0.34) l min(-1), 15.67 (1.49) mmol l (-1). As a criteria of achived training effect is used a increase of physical performance and as a criteria of physical load dose is used a product of relative power and total pulse cost of exercise.

Conclusions: Calculations of exercise pulse costs allow precise and specific selection of training loads for each athlete. The standards for training and competition loads based on parameters of exercise pulse cost should be defined differentially for athletes specializing in different sports with different training regiments.

OXYGEN UPTAKE DURING SIMULATED FIREFIGHTER-WORK: THE TRONDHEIM FIREFIGHTER-TEST

VON HEIMBURG, E., MEDBO, J.I.

NORTH TRONDELAG UNIVERSITY COLLEGE

Introduction: Firefighting and rescue work may be physically very demanding [1]. Therefore, testing of firefighters' physical ability is needed. Trondheim fire brigade has developed a standardized test (Trh-test) for examining whether their firefighters are suited to serve as smoke divers. The Trh-test test consists of three main parts: First, emergency where the firefighter complete seven tasks to arrive at the scene of fire (solving a small puzzle, balance, hose pulling, connecting and disconnecting hoses, carry heavy cans, crawling thru a tunnel, walk to the scene of fire). Second, physical work in a heat chamber (120-140 °C; carry 20 blocks of concrete, each weighing 18 kg). Third retreat, repeating all tasks in part 1 in opposite order. The whole set of tasks should be carried out as fast as possible and within 21 min. This study's aim was first to measure the oxygen uptake directly throughout the Trh-test. A second aim was to compare the performance with the subjects' maximal oxygen uptake and lactate threshold attained when dressed up like a firefighter.

Methods: 21 professional firefighters (20 men, one woman) in Trondheim fire brigade served as subjects. Each firefighter was dressed up for smoke diving, wearing 28 kg as the basic equipment plus 4 kg of instruments for the present experiments. Oxygen uptake was measured by the portable Metamax II analyzer. Because of a hot and polluted environment, the subjects inspired from bottles with pressurized air and expired thru the Metamax II analyzer that was modified to work for the present experiments [2].

Results: The subjects completed the whole test in 11–22 min, and the fastest subjects where those with the highest maximal O2 uptake and the highest O2 uptake during the Trh-test. The O2 uptake during the Trh-test test averaged 67% of the maximal, and the peak O2 uptake, seen near the end of work in the heat chamber, was 80% of the maximal. For faster and well fit subjects the O2 uptake exceeded that corresponding to the lactate threshold during physically demanding parts of the test, but not so for less fit subjects. The heart rate reserved averaged 15 bpm with little difference between fitness level, and the heart rate was above that corresponding to lactate threshold during most of the test. Consequently, the post-test blood lactate concentration averaged 9 mmol/L.

Conclusion

The Trh-test is physically demanding and discriminates between physically fit and less fit subjects. The O2 uptake during the test is higher for physically fit subjects and varies between different tasks.

THE EFFECTS OF HIGH FREQUENCY LOCAL VIBRATION TRAINING ON HORMONAL REPONSE AND MUSCLE CONTRACTILE PROPERTIES IN MEN.

IODICE, P., GIALLUCA, G., BELLOMO, R.G., GALATI, V., SAGGINI, R.

UNIVERSITY OF CHIETI

Objective. The aim of this study was to evaluate the acute and cumulate reponse of the muscular performance and blood hormone concentrations following local high intensity vibrational (HLV) treatment in men.

Materials and Methods. To test the acute effects of HLV on muscular performing and hormonal profile, 9 subjects, moderately trained, were studied in two different occasion with (vibration) and without (control) HLV treatment (VISS Circle, San Pietro in Casale, Bologna, Italy), the protocol was the same on the same days. In second occasion, after 3 day, the subjects performed HLV treatment for 30min at 300Hz (f =300Hz; A=4mm). The protocol consisted of performing jumping (CMJ) on force platform, maximal isometric voluntary contraction (MVC) of leg extensor muscle, as well as blood collection for analysis, before, immediately after and again 1 hour later HLV treatment.

To test the cumulate effects of HLV, 36 subjects were randomly assigned to two training programs: a vibration group (cV group) which performed HLV, 12 session 3days/wk, and a resistance training group (cR group) which performed leg extention exercice, 12 session 3days/wk. Before, after and again 2 month later the end of training program the subjets performing a MVC test and isokinetic (100°/sec) testing of knee flexing-extension movement on leg extention exercice.

Results. The acute effects: results showed a significant increase in the growth hormone (GH) and CPK ($p<0.05$,$p>0.05$), whereas cortisol (C) and LDH levels decreased ($p<0.05$). No change in testosterone (T) plasma concentration was observed. GH, CPK, C, T and LDH levels didn't change in control group (1). Muscular strength improved, as indicated by increase in MVC performance ($p<0,05$), it could have been induced by an increase in the syncronisation activity of the motor units. CMJ performance doesn't show significant change.

The cumulate effects showed a significant improved in muscular strength performances, both MVC and Isokinetic test increase ($p<0.01$;$p<0.05$) at end of treatment, our results showed an long term effect in HLV treatment, increase persist after 2 month the end of treatment.

Conclusion. Acute effects of HLV training causes a modification in hormonal plasma concentration, increase GH and decrease C, but increases in neuromuscular system were independent response. MVC increase of 7.0% seems to be related with high frequency vibration stimulus able to improve MUs synchronization. 4weeks HLV training causes an increment of muscle contractile force, as much as in the case of a resistance training. The improvement obtained persist 2 months after training. In conclusion, The methodical of high vibratory stimuli are a valid tool to be used in a sport training and rehabilitative therapies context in order to maintain and improve muscular strength.

RELIABILITY OF ELECTRICAL TRAIN STIMULATION TO INDUCE MUSCLE CRAMP IN THE CALF MUSCLES

PEGORARO, R., JUBEAU, M. , WATSON, G., NOSAKA, K., LAURSEN, P.

1. EDITH COWAN UNIVERSITY, 2. UNIVERSITY OF BURGUNDY

Introduction: Muscle cramp is a forceful, involuntary skeletal muscle contraction, but its underlying mechanisms are not well understood. The lack of understanding of muscle cramp may in part arise from its unreliable occurrence with traditional protocols. It has been reported that electrical train stimulation (ETS) can be used to induce cramp in the small flexor muscles of the foot, and a relationship exists between the threshold frequency (TF) of ETS to induce cramp and the susceptibility to muscle cramp from muscular exertion (1). However, no previous studies have used ETS to induce muscle cramp in lower leg muscles. In an attempt to establish a quantitative measure of muscle cramp, the present study examined the test-retest reliability of the TF of ETS to induce calf muscle cramp.

Methods: Using a Compex 2 stimulator, ETS was applied to the calf muscles of both (dominant and non-dominant) legs in 10 men (19-44y) who reportedly experienced prior cramp during training or competition. Each leg was treated separately, and the order was counterbalanced amongst subjects. Subjects were supine with their legs supported by a specially designed bench while the ankle was at maximal plantarflexion. ETS consisted of 2 s (with 500 ms ramp time) of 300 µs square pulsed waves followed by 30 s rest; current was set to maximum tolerable intensity (35-60 mA). Stimulation commenced at 10 Hz and increased by 3 Hz until cramp occurred, as confirmed by a spontaneous EMG signal. The protocol was repeated 30 min after the first test and seven days later. Reliability of TF at cramp occurrence was analysed using the intraclass correlation coefficient (ICC), limits of agreement (LOA) and coefficient of variation (CV).

Results: Muscle cramp was induced in all subjects, but the TF varied amongst subjects (13-55 Hz). Mean TF value to induce muscle camp for the dominant leg was 25.0 ± 7.6 Hz for the first test and 23.7 ± 5.0 Hz for the second test. The non-dominant leg also showed similar values. Test-retest reliability, as indicated by ICC, LOA and CV, were 0.94, 5.4 % and 9.2 %, respectively for the dominant leg, and 0.72, 9.8 % and 15.4 %, respectively for the non-dominant leg.

Discussion: This study showed that ETS can induce muscle cramp to the calf muscles, and that the TF of ETS was a reliable measure to assess the risk of calf muscle cramp susceptibility. Most subjects cramped within a 3 Hz difference between tests, but some had up to a 15 Hz difference. Interestingly, those who reported a lower susceptibility to cramp had a greater difference in TF between tests, suggesting that the test is more reliable in those who are more susceptible to cramp. Factors thought to influence muscle cramp, such as electrolyte disturbance, dehydration, environmental conditions and fatigue should be examined using ETS.

LOCALLY CONFINED CALCIUM DEPENDENT MORPHOLOGICAL CHANGES TO MITOCHONDRIA OF THE MOTOR END-PLATE DUE TO CARBACHOL STIMULATION.

VOIGT, T.

UNIVERSITY OF BERN

Disturbance of the motor end-plate calcium homeostasis for hours leads to vacuolisation of the mitochondria in the vicinity of the motor end-plate (MEP) and necrosis of muscle fibres. Little is known, however, about the onset of these morphological changes due to this disturbance. To improve our understanding of the MEP calcium homeostasis, it would be beneficial to temporally and topographically pin-point the first visible signs of morphological changes to mitochondria. In order to disturbe the MEP calcium homeostasis, omohyoid muscles of mice were stimulated for 1 to 30 minutes with the acetylcholine agonist carbachol which leads to an inward current of free calcium in the MEP. The fibre-type-specific morphological changes to the MEPs and mitochondria were evaluated using light- and electron-microscopy and compared with laser-scanning live-recordings of Rhod2-AM labeled mitochondria of MEPs during carbachol stimulation. Localised calcium dependent contractures of different severity underneath the motor end-plate were observed within some but not all muscle fibres depending on the duration of carbachol incubation. But the most prominent contractures were confined to slow muscle fibres. The mitochondria in the MEP as well as in the contracture zone underneath the MEP of those muscle fibres with strong contractures i.e. mostly of type I fibres manifested electro-translucent spots in the matrix whereas the mitochondria outside the contracture zone looked normal. The live-recordings during the carbachol stimulation showed sequestering of calcium into the mitochondria of the MEP area wherease the calcium content of the mitochondria outside the MEP did not change. We interpret this as a first sign of calcium overload of the mitochondria and as a hint towards differences in the handling of the calcium homeostasis in different muscle fibre types.

ACTIVATION OF THE HUMAN PRIMARY AND SECONDARY SOMATOSENSORY CORTEX FOLLOWING TACTILE STIMULATION

ONISHI, H., SOMA, T., OYAMA, M., KIRIMOTO, H., FURUSAWA, A.A., OISHI, M., KAMEYAMA, S.

NIIGATA UNIVERSITY OF HEALTH AND WELFARE

Introduction: Our goal is to examine the sensory feedback from periphery to generation of the movement evoked cortical magnetic fields. We reported that the first component of the movement evoked magnetic fields (MEF 1) was due not to the onset of joint movement but to that of muscular contraction. However, the generators of the second and third components of MEF (MEF 2 and 3) that observed with long latency after electromyographic onset are not fully understood. In this study, MEG recordings were performed to investigate the neural mechanisms following the tactile stimulation of the index finger.

Subjects and Methods: Ten healthy male subjects (mean age 29.2±10.3 years) participated in this study. All subjects had given their written informed consent, and the study was approved by the ethics committee at our university. For MEG measurement, we used a 306ch whole-head MEG system (Neuromag, Elekta, Finland) and tactile stimulator that was made of non-magnetic materials (KGS, Japan). MEG signals were sampled at 1000Hz with band-pass filtering from 0.03 to 330 Hz. The averages of above 300 epochs for SEFs were obtained. Tactile stimuli were applied to the tip of right index finger. Tactile stimulation was used the four teeny pins with 1.3mm diameter and 0.7mm high. The distance of each top of pins was set at 2.4mm. Inter stimulus interval was set at 2 second and the pressurization was continued during 1 second. For analysis of SEF, the bandpass filter was set from 0.5 Hz to 50 Hz. The sources of the components of interest in the SEFs were estimated as the equivalent current dipoles (ECD). The ECD locations and moments were calculated using a spherical conductor model of 3D axes determined with the fiducial points, i.e. the nations and bilateral preauricular points. We accepted ECDs with a goodness-of-fit > 90% for analysis.

Results: Clear SEF signals were recorded from contralateral hemisphere for all subjects at around 57ms and 140ms after pressurization (57.4±12.7 ms and 140.0±14.6 ms) or depressurization (56.9±13.3 ms and 144.0±17.0 ms), and these ECD locations were in area 3b. Moreover, long latency responses (169.4±33.0 ms after pressurization, and 172.2±36.7 ms after depressurization) were identified in ipsilateral hemisphere, corresponding to secondary somatosensory cortex (S2).

Discussion: In this study slight intensity of tactile stimuli was used, and a clear SEF signal was recorded from bilateral hemisphere after pressurization and depressurization. The long latency activation was detected clearly at ipsilateral S2. S2 was speculates to serve a higher level of cognitive function in somatosensory information processing, such as attention, objective recognition and integration of nociceptive and non-nociceptive inputs. In this study, we could record S2 activation without attention or recognition. These methods and results may clarify the S2 function and the generator of MEF2 and 3 during voluntary movement.

A METABOLOMIC APPROACH TO INVESTIGATE THE METABOLIC CHANGES INDUCED BY ACUTE AND CHRONIC PHYSICAL EXERCISE IN YOUNG WOMEN

DUGUE, B., ENEA, C., PETITPAS-MULLIEZ, J., BOILDIEU, N., EUGENE, M., SEGUIN, F.

UNIVERSITY OF POITIERS, FRANCE

Metabolomic is a comprehensive method for metabolite assessment, measuring the overall metabolic signature of biological samples. We used this approach to investigate biochemical changes due to acute and chronic physical exercise.

Twenty-two women using the same oral contraceptives were allocated to an untrained group (n=10) or a trained group (n=12), depending on their physical training background. The subjects performed a short-term intensive exercise test (Wingate anaerobic test). Urine specimens were collected before and 30 min after the test. The samples were analysed by 1H NMR spectroscopy and multivariate statistical techniques were utilized to process the data.

Clear separations of the urine profiles from the specimens collected before vs. 30 min after the test and from the untrained vs. trained subjects were observed. The main metabolites in response for the changes in the urinary profiles were creatinine, lactate, pyruvate, alanine, β-hydroxybutyrate, acetate and hypoxanthine. For each of those metabolites the excretion rate was calculated and statistical analysis was performed (two-way analysis of variance followed by Tukey post-hoc analysis when appropriate). Higher creatinine excretion was observed in trained compared with untrained women. In both groups, the excretion of lactate, pyruvate, alanine, β-hydroxybutyrate and hypoxanthine increased similarly after the completion of the Wingate-test ($p<0.03$). However, a significant interaction (group by time) was observed for acetate, suggesting that the excretion of this metabolite increased in a lower extent in trained than in untrained subjects. These metabolic changes may be concerned with the redox status and the oxidative stress of muscular cells.

In conclusion, metabolomic studies in the field of clinical studies, pharmacology, toxicology, etc, …, should consider intense physical activity as an important biological factor influencing the outcome of the test. Moreover, metabolomic is a promising tool to profile urine of athletes, to make a deep insight into physiologic states and clarify the changes induced by short-term intense physical exercise.

ON MUSCLES, TENDONS AND HIGH HEELS

CSAPO, R., MAGANARIS, C.N., SEYNNES, O.R., NARICI, M.V.

1. INSTITUTE FOR BIOMEDICAL RESEARCH INTO HUMAN MOVEMENT AND HEALTH, MANCHESTER METROPOLITAN UNIVERSITY, FACULTY OF SCIENCE AND ENGINEERING, 1,2. UNIVERSITY OF VIENNA, CENTER OF SPORT SCIENCE.

Introduction: Animal experiments have shown a remarkable remodeling of skeletal muscle when placed at short length for long periods of time (1). One common condition that places human plantarflexor (PF) muscles in a shortened position is high-heel wearing. In the present study we tested the hypothesis that regular use of high heels leads to changes in the architecture of the leg muscles by decreasing the fascicle length of the PF while increasing that of the dorsiflexor (DF) muscles. Furthermore, since placing tendon in chronic slack position, as in prolonged bed rest, has been shown to cause a decrease in tendon stiffness (2), long-term high-heel wearing was expected to alter also tendon mechanical properties. Eventually, we wished to demonstrate the effects of chronic use of high-heels on skeletal muscle functioning.

Methods: To test these hypotheses, we examined a) the torque-angle relationship of the PF and DF muscles by Cybex dynamometry, b) fascicle length and pennation angles in the gastrocnemius medialis (GM) and tibialis anterior (TA) muscle by ultrasound, c) tendon length by ultrasound, d) triceps surae muscle volume and joint moment arms (MA) by magnetic resonance imaging (MRI) and d) Achilles tendon mechanical properties evaluated by ultrasound and dynamometry, in habitual high-heeled (HH) shoe wearers and in aged-matched controls (CTRL) habitually wearing flat shoes.

Results: The results of this pilot study show similar GM:TA fascicle length ratios, as measured in a standing position. However, greater fascicle lengthening in the GM could be observed in HH during passive rotation of the foot. As MA were found to be equal in both groups, these findings suggest that the total compliance of the GM muscle-tendon unit may be altered in HH. Although previous investigations have shown that during passive changes in joint angle, tendons contribute to the total length change of the muscle-tendon unit by up to 73% (3), in the present study resting tendon length and passive tension, as measured in different ankle positions, were found to be similar in both groups. One potential mechanism that may account for the higher rate of length change of GM fascicles in HH is an increased stiffness of the series elastic component between the heel and the GM muscle fascicles (tendon plus aponeurosis) or part of it. Furthermore, our data suggest differences in torque-angle relationships, indicating that muscle function may be influenced by high-heel wear.

BEHAVIOR OF BLOOD LACTATE IN PUBERTAL AND POST-PUBERTAL SPORTSMEN AFTER AN INTERMITTENT MAXIMAL EFFORT

DA SILVA GRIGOLETTO, M., DE SÁ, C.A., GÓMEZ-PUERTO, J.R., RIVILLA, M.L., VIANA-MONTANER, B.H., VAAMONDE, D., NARANJO, J.

JUNTA DE ANDALUCIA - CENTRO ANDALUZ DE MEDICINA DEL DEPORTE

INTRODUCTION: The ability of undergoing anaerobic work throughout infancy and adolescence has been the aim of several studies. Nevertheless, the results of such studies on the relationship between maturational status and anaerobic metabolism have been rather controversial (Praagh and Doré, 2002). The aim of the present study was to analyze the anaerobic response in male sportsmen (children and adolescents) to an intermittent maximum progressive test (Yo-Yo IR1), with regards to blood lactate behavior.

METHOD: Fifty-nine sportsmen with ages ranging from 9 to 17 voluntarily participated from the study. The subjects were federated basketball players, with a weekly training frequency of three to four sessions, and regularly participating in competitions. They were categorized according to Tanner criteria (Marshall and Tanner, 1970), into pubertal (age = 10.97 ± 2.05 yr; body mass = 49.16 ± 12.46 kg; height = 156.56 ± 14.86 cm), and post-pubertal (age = 14.73 ± 1.71 yr; body mass = 70.94 ± 13.15 kg; height = 179.75 ± 8.67 cm). A sexual maturation self-assessment was performed in two different occasions (intraclass correlation coefficient = 0.90); the reproducibility and concordance with the medical assessment of this method has been previously proven (Matsudo and Matsudo, 1994). In addition, the sportsmen underwent a Yo-Yo IR1 test to voluntary exhaustion and blood lactate concentrations were measured at different timepoints (1 minute, 3 minutes, and 5 minutes during recovery).

RESULTS: The absolute values for peak lactate were not statistically significant ($p > 0.05$) among pubertal and post-pubertal sportsmen (8.81 ± 2.25 and 8.86 ± 2.03 mmol/l, respectively). On the other hand, relative values of lactate, as expressed with regards to body mass, and to achieved work (0.18 ± 0.07 and 0.13 ± 0.03 mmol/kg; 0.00035 ± 0.00023 and 0.00010 ± 0.00005 mmol/kgm/min, respectively) were significantly greater ($p < 0.05$) in pubertal subjects than in post-pubertal subjects.

CONCLUSION

Despite the fact that absolute values of blood lactate were not different among pubertal and post-pubertal subjects, relative values evidenced a greater role of anaerobic metabolism in pubertal subjects.

PLASTICITY OF MOTOR UNIT CONTRACTILE PROPERTIES EVOKED BY ONE MONTH TREADMILL AND WHOLE BODY VIBRATION TRAINING IN THE RAT MEDIAL GASTROCNEMIUS MUSCLE

LOCHYNSKI, D., CELICHOWSKI, J., KACZMAREK, D., KRUTKI, P.
UNIVERSITY SCHOOL OF PHYSICAL EDUCATION

Increased physical activity considerably affects the neuromuscular system and changes in morphological, biochemical and metabolic parameters of skeletal muscle depend from the frequency, intensity and duration of employed training programme. The aim of the study was to compare the effect of endurance and whole body training on motor unit contractile properties in rat medial gastrocnemius muscle. Two kinds of 4-week trainings - treadmill and whole body vibration trainings were applied. 23 Wistar rats were divided into three groups: trained on a treadmill (n=7, locomotion speed 27 cm/s, 1 km daily, 5 days weekly, for 4 weeks), trained on vibratory platform (n=5, Power Plate®, 50 Hz vibration of 2 mm amplitude, 30 s daily, 5 days weekly, for 4 weeks) and control (n=11). The contractile properties of isolated motor units were studied. Functional isolation of units was achieved by electrical stimulation of filaments of the ventral roots. A total of 400 motor units were studied (157 in the treadmill and 101 in the vibration group, and 142 in the control group). They were divided into: fast fatigable (FF), fast resistant to fatigue (FR) and slow (S) types. Following treadmill training, percentage number of FF units decreased whereas FR units increased. The distribution of the fatigue index changed within these two types of fast units. The population of FF units exhibiting outmost fatigue indices was reduced whereas proportion of FR with high fatigue resistance increased. The twitch and tetanus forces increased considerably in fast motor units, mainly in those of the FF type what was probably due to short running periods following moments when animals stopped on a moving belt. During short running periods FF type motor units were recruited into activity. The contraction and relaxation times shortened in the FR and S motor units. The vibration excited mainly muscle spindles and increased activity of motor units through the stretch reflex loop. Results of the whole body vibration study reveal that changes in motor unit properties were different from obtained after treadmill training. The distribution of motor units did not change. Force increased substantially only in FF motor units. The contraction and relaxation times shortened in fast motor units. No changes in contractile parameters of slow units were noted. In conclusion, contractile parameters changed differently in response to two applied forms of training. This can be related to differences in recruitment strategy of motor units used during locomotion and vibratory training and differences in the duration of activity (one hour locomotion versus 30 second vibration evoked activity). It is shown that moderately increased daily physical activity, i.e., locomotion with low speed and short lasting whole body vibration, can considerably change motor unit properties. Of three unit types, FF motor units seem to exhibit the greatest plasticity in response to "extra physical activity" induced by training.

THE EFFECT OF SKIMMED MILK ON THE HYDRATION STATUS OF MALE COLLEGIATE ATHLETES DURING AND AFTER SUB-MAXIMAL CYCLING

DOBSON, A., GOODMAN, M.
UNIVERSITY OF THE WEST OF ENGLAND (HARTPURY COLLEGE)

Milk could be seen as an effective hydration solution due to its naturally high electrolyte content and the presence of carbohydrate in a concentration similar to that of commercial sports drinks (Sherreffs et al. 2007). Whilst the macronutrients (carbohydrate and protein) found in milk have been used as a recovery aid following exercise (Karp et al. 2006), little evidence currently exists regarding the potential role milk could have on the hydration of athletes during and after exercise (Sherreffs et al., 2007). Therefore the purpose of the present study was to investigate the effect of skimmed milk on the hydration status of male collegiate athletes during and after sub-maximal cycling. Twelve healthy male collegiate athletes (age 22 ± 2 years; body mass 97.8 ± 15.2 kg; height 178 ± 18 cm) who were lactose tolerant volunteered to take part in the present study. Subjects completed one familarisation trial followed by two experimental trials. Using a randomised cross-over experimental design subjects performed two separate steady-state cycling trials at 60% VO2max for 40 minutes. Subjects ingested either skimmed milk (0.2% fat) or water. Subjects ingested 100ml of fluid every 10 minutes during exercise and then 200ml of fluid every 15 minutes for an hour following exercise. Blood haematocrit, urine volume and urine osmolality were measured at the start of exercise, at the end of exercise and one hour following exercise. The blood haematocrit level of subjects ingesting water rose significantly ($p<0.001$) from the start to the end of exercise when compared to the consumption of milk. The urine output of subjects ingesting water was significantly higher ($p<0.001$) than that of subjects when they consumed milk. The greatest difference was found at one hour post exercise where urine output was 461 ± 195ml and 298 ±185 ml, respectively. Pre-exercise urine osmolality was not different between trials ($p>0.05$). One hour following the end of exercise there was a significant decrease ($p<0.05$) in urine osmolality following water ingestion, however this did not occur following the ingestion of milk ($p>0.05$). Skimmed milk could be suggested as an effective hydration drink during exercise and as a post-exercise re-hydration drink for individuals that are lactose tolerant.

BASKETBALL COACHES KNOWLEDGE ABOUT HYDRATION

MATKOVIĆ, B., RUPČIĆ, T., MATKOVIĆ, BR.
FACULTY OF KINESIOLOGY UNIVERSITY OF ZAGREB

Introduction: Water is the nutrient a basketball player needs the most, about 2-3 L/day. As the most largely represented substance in the human body water is a medium where metabolic reactions occur, but it also participates in some.

There has been evidence that even dehydration which reduces the body mass by only 2% causes problems during physical activity and a 5% loss of body mass through dehydration decreases the physical working capacity by 30 % (Armstrong and cow; 1985; Saltin & Costill, 1988). Dehydration has proved to have a negative impact on aerobic activities and sprint, to speed up fatigue and, what is particularly significant, affects the ability to play (Burke, Hawley, 1997; Casa and cow; 2000).

The aim of this study was to test the basketball coaches' knowledge of hydration.

Methods: The sample consisted of 52 Croatian basketball coaches at the age 26 to 53. For this investigation a questionnaire was composed with ten questions regarding the basic principles of hydration. The questionnaire was completed anonymously. The obtained data were analyzed by standard statistical procedures, with statistical software package SPSS 13.0.

Results and Discussion: According to the results it is obvious that knowledge about hydration of the coaches is not on adequate level. In general coaches are aware that establishing the balance of body fluids upon activity is a very important part of recovery, and that this is even more important in hot and humid conditions. Fast and full rehydration is extremely important when it comes to tournaments. Rehydration during recovery implies not only the compensation for the lost volume, but also for the lost electrolytes, primarily sodium, that are lost through perspiration during the game. On the other hand most of the coaches have no idea of the amounts or the content of sport drink and they think that thirst is a good parameter of the fluid needs. Very few of the investigated coaches make connection about the rehydration and refilling energy sources. They never heard about the possibility of excessive liquid intake and the possibility of related hyponatremia.

EFFECTS OF HYDRATION ON ELITE SURFING PERFORMANCE

ALI, A., FOSKETT, A., CARRASCO, A.
MASSEY UNIVERSITY

Sports performed in hot ambient conditions with minimal reliance on fluid ingestion are likely to be affected by the physical, cognitive and skill performance decrements attributed to exercise-induced dehydration. PURPOSE: To determine whether surfing performance is affected by dehydration and whether fluid ingestion can attenuate any performance decrements. METHODS: Twelve male national (Australia) and international level surfers completed two 100-min surfing sessions, in wetsuits, separated by seven days. Following a randomised cross-over design, one trial required the consumption of 3 ml•kg-1 body mass (BM) of water at 20 min intervals (FL) whilst in the other trial no fluid was consumed (NF). A battery of cognitive tests, upper and lower-body muscular endurance tests and hydration status were assessed prior to and immediately following the surfing session. Performance was assessed, in accordance with the Association of Surfing Professionals (ASP) World Tour guidelines, for two 20 min periods during each trial. Ambient conditions and wave quality were consistent with those expected at Sydney's northern beaches and were similar between trials.

RESULTS: BM loss was greater in NF than in FL (3.9 ± 0.7% vs. 1.6 ± 0.7%; $P<0.05$). Surfing performance was significantly impaired in NF with lower scores (20.3 ± 7.1%) in this trial. Cognitive function, upper- and lower body muscular endurance were impaired in NF ($P<0.05$) whereas only upper-body muscular endurance decreased following FL ($P<0.05$). CONCLUSIONS: Body mass losses during surfing are severe enough to significantly impair surfing performance, cognitive function and muscular endurance. Consumption of 3 ml•kg-1 BM water every 20 min may attenuate these decreases in performance.

RELATIONSHIPS AMONG WEEKLY AMOUNT OF PHYSICAL EXERCISE PRACTICE, DIETARY HABITS AND BODY COMPOSITION IN WOMEN.

D'ANGELO, E., DI BLASIO, A., DI DONATO, F., DI GREGORIO, S., DI RENZO, D., PANTALONE, P.P., RIPARI, P.,3.
G. D'ANNUNZIO UNIVERSITY, CHIETI

Introduction: Literature indicates that the amount of physical exercise is inversely related with percentage body fat (%BF) in men while the same relationship was not well observed in women (Westerterp et al., 1997). Hypothesis is linked both to energy intake and macronutrient composition of daily meals in relation with physical activity energy expenditure and gender (Paul et al., 2004). The aim of the study was to investigate the relationships among the amount of physical exercise practice, dietary habits and body composition in women.

Methods

We recruited 52 female (24.49±3.63 yrs) university students. Nobody had gone on a diet during the last 2 years. Qualitative and quantitative characteristics of daily meals were assessed by a dietician using 3-day dietary records, by WinFood-due software (Medimatica, I). Physical activity was investigated by International Physical Activity Questionnaire (IPAQ), while physical exercise practice by a structured questionnaire requiring information about weekly min of training, frequency and consecutive years. Body composition was estimated by single-frequency electrical bioimpedance (Akern, I). We created 3 sub-samples according to the terziles of total weekly min of training. No physical exercise (1st), 0-180 weekly total min (2nd), and > 180 weekly total min (3rd) of exercise were the 3 groups. MANCOVA and post-hoc analysis were performed twice. The first, to assess differences in dietary habits among groups using variables of IPAQ as covariate; the second, to assess differences in body composition among groups using daily macronutrient distribution as covariates.

Results: The first post-hoc analysis showed high lipid (p=0.019) and low carbohydrate (p=0.003) intake in the 3rd respect to 1st and 2nd group. The second post-hoc analysis showed that 3rd had a best muscle mass (p=0.027) and body cellular mass (p=0.05) than the other groups, while no differences were found in %BF. Both 3rd and 2nd had the same consecutive years of exercise practice.

Discussion: Our results suggest that, in women, if high weekly min of training elicit body anabolic response, on the other hand, only physical exercise practice is not enough to decrease fat mass due to the high lipidic diet associated with high weekly min of training. Further studies are needed to know the main causes of data observed.

ANTHROPOMETRIC PROFILE AND HABITUAL FOOD INTAKE OF BRAZILIAN CHILDREN AND ADOLESCENTS WITH LOW SOCIOECONOMIC LEVEL

RAMOS, L.F.A.O., SANTOS, M.P., SILVA, A.F., BELLUZZO, I.G., CORRÊA, S.E.C., CARDOSO, J.P., SILVA, P.S., MEDEIROS, L.S., PIACEZZI, A.C.X.

FOUNDATION OF SUPERIOR EDUCATION OF PASSOS, UNIVERSITY OF THE STATE OF MINAS GERAIS, PASSOS

Background: The nutritional transition is marked by a change in food intake habits and reduced leisure time and physical activity leads to a rapid increase in overweight and obesity.

Methods: This study included 289 children and adolescents (51.9% boys), aged 7-14 years (10.8 ± 2.0) of one public school from Passos, Minas Gerais. The nutritional status was assessed by anthropometric data (body mass index for age (BMI-for-age) (WHO, 2006) body fat percentage for age (BFP-for-age) (Guedes & Guedes, 1998)) and the habitual food intake was analyzed by a food frequency questionnaire consisting of a food intake table worked out in detail according to alimentary standard of this aged group. Differences between genders with anthropometric data were performed by Mann-Whitney test.

Results: As assessed by BMI-for-age 2.4% of children and adolescents were classified as underweight, 72.0% as healthy weight, 13.5% as overweight and 12.1% as obese. According to BFP-for-age, 22.5% were classified as low body fat, 32.2% as healthy body fat and 45.3% as high body fat. With regard to habitual food intake it was verified inappropriate habits, since there is a high daily food intake of products with high energy density and nutritional poor value such candies (43.1%), soda (33.0%), cookies (26.0%), fried foods (20.6%), chips (17.4%) including the addition of sugar to milk, juices and other beverages practiced by 63.9% of children. On the other hand, it was verified a lower daily intake of nutritive and healthy foods like fruits (41.7%) and vegetables (33.3%) important for child growth and development. There was no statistical difference in the nutritional status of boys and girls.

Discussion: This nutritional profile is typical of the nutritional transition that occurs in developing countries with an epidemiological overlap which overweight and obesity coexist with malnutrition, with a trend towards decreased rates of protein-energy malnutrition and increased incidence of obesity and chronic-degenerative diseases.

Conclusion: Childhood is a great development period which child learns quickly to organize cultural, cognitive, social and physically. The lifestyle acquisition occurs in this period as eating habits and physical exercise practice. Monitoring health during childhood has a great importance for the health control in adulthood. In this context, assess the prevalence and incidence of nutritional disorders in childhood becomes an important strategy to propose effective measures and action plans aiming to promoting health and integrated control of major risk factors.

CHILDHOOD PREVALENCE OF OVERWEIGHT, OBESITY AND THINNESS IN RIO MAIOR, PORTUGAL.

SEABRA, P., FRAGOSO, I., VARELA-SILVA, M.I.

SPORT SCIENCE SCHOOL OF RIO MAIOR, PORTUGAL, FACULTY OF HUMAN KINETICS, LISBOA, PORTUGAL, LOUGHBOROUGH UNIVERSITY, UK

Introduction: Childhood obesity as well as thinness are two major public health concerns (Cole et al., 2007). The World Health Organisation (WHO) recommends the use of the Body Mass Index (BMI) for the assessment and establishes the cut-off points to the definition of both conditions. In Portugal, the study conducted by Padez et al. (2004) in 7 to 9 years old children, of both sexes, revealed a prevalence of overweight/obesity of 31.5% (20.3% overweight, 11.2% obesity). Compared with boys, girls generally presented higher percentages in overweight and in obesity. Another study in Portugal, with children 6 to 10 years, from Sintra, showed 35.6% of overweight/obesity, but no differences were found between sexes (Ferreira & Marques-Vidal, 2008). Concerning thinness, we have no knowledge of studies in Portugal. Therefore, the aim of this study is to assess the prevalence of overweight, obesity and thinness in children from Rio Maior, Portugal, using the WHO standards from 2007.

Methods: We assessed 643 children (332 boys), 5 to 9 years old, from the Rio Maior county's public and semi-public school network. Informed consent and assent were obtained. Height and weight were measured according to the International Society for the Advancement of Kinanthropometry (Marfell-Jones et al., 2006). BMI z-scores and percentages of overweight, obesity and thinness (for age and sex) were calculated.

Results: In the total sample, we found 20.1% of overweight, 12.9% obese and 1.5% thin children. Boys and girls revealed similar percentages of overweight plus obesity (33.8% and 32.1%, respectively). Thinness is almost inexistent in girls (only 2 girls at age 8) and residual in boys (2.4%, n=8). Boys show higher percentages of overweight than girls, except at 7 and 8 years and also in obesity, except at age 5.

Discussion: Children from Rio Maior show identical percentages of overweight and obesity that those found in Padez et al. (2004) and Ferreira and Marques-Vidal (2008) studies. Our sample reveals the same tendency find in the developed countries. Life styles should be studied to better understand the results. Thinness is virtually inexistent in this sample and therefore does not seem to constitute a major health concern.

NUTRITIONAL STATUS AND SEDENTARY LIFESTYLE OF BRAZILIAN CHILDREN FROM A PUBLIC AND PRIVATE SCHOOL SYSTEM

RAMOS, L.F.A.O., MOTA, T.F., NEIVA, C.M.,2

1. FOUNDATION OF SUPERIOR EDUCATION OF PASSOS, UNIVERSITY OF THE STATE OF MINAS GERAIS, PASSOS. 2. UNIVERSITY OF FRANCA, FRANCA

Background: Socioeconomic status is linked to health condition. It is therefore important to investigate the extent of socioeconomic differences in nutritional status and the possible behavioral predictors of these changes.
Methods: This study included 99 children (51.2% girls), aged 8-10 years (9.0 ± 0.8), randomly selected from one public (n=49) and one private school (n=50) from Franca, São Paulo. The nutritional status was assessed by anthropometric data (body mass index for age (BMI-for-age) (WHO, 2006) body fat percentage for age (BF%-for-age) (Guedes & Guedes, 1998)) and the habitual food intake was analyzed by a food frequency questionnaire. The sedentary lifestyle was assessed by asking the children directly the time daily of computer use and watching TV. Differences between genders and school system with anthropometric data and sedentary lifestyle were performed by Mann-Whitney test.
Results: According to BMI-for-age 61.2% and 56.0% of children from public and private school were classified as normal range, respectively, 14.3% and 22.0% as overweight, 24.5% and 20.0% as obese. Only one (2.0%) child from a private school was classified as underweight. As assessed by BF%-for-age, 6.1% and 12.0% of children from public and private school (respectively) were classified as low body fat, 28.6% and 22.0% healthy body fat, 65.3% and 66.0% as high body fat. Regarding to habitual food intake It was observed the presence of inappropriate habits, since there is a high food intake of products with high energy density and low nutritional value such candies (34.7% and 46.0%), soda (18.4% and 32.0%), cookies (14.3% and 18.0%); fried foods (8.2% and 2.0%), fast food/chips (2.0% and 24.0%) including the addition of sugar in beverages practiced by 32.7% and 20.0% of children from private and public school, respectively. On the other hand, it was verified a lower intake of nutritive and healthy foods like fruits (26.5% and 36.0%) and vegetables (34.7% and 46.0%). Children of the public school spent more time watching TV ($p<0.000$). No statistically significant associations were found in any others comparisons performed with nutritional status (BMI-for-age and BF%-for-age) and sedentary habits in relation to gender or school system.
Conclusion: The school environment has been considered optimum space for the nutritional assessment and interventions, moreover, it is a great agent to promote the nutritional education, since infancy is the period of habits acquisition that perpetuate until the adulthood, as well as propagating the concept of healthy lifestyle, therefore it makes of the child a multiplier of its knowledge.

EXAMINING THE TRAVELLING RULE IN EUROPEAN BASKETBALL: A DISCUSSION OF THE PEDAGOGICAL AND FAIRPLAY IMPLICATIONS OF YOUTH BASKETBALL INSTRUCTION

MILLER, B.W., FOSNÆS, O.

HEDMARK UNIVERSITY COLLEGE

Introduction: As a primary rule in basketball, the teaching and understanding of the travelling rule serves as a centerpiece for the pedagogical instruction of children and youth. The rule's interpretation is fairly straight forward as presented in the FIBA rules and regulations manual (2005, 2008), yet one could argue that not an organized basketball game is played which does not contain som element of controversy regarding the travelling rule. To this end, travelling, or the "lack" of travelling in top level European basketball has clearly warranted the attention of several researchers and basketball instructors alike (Fosnæs, 2009). The purpose of the present paper is to focus on the study by Fosnæs and colleagues (2009) by discussing the potential pedagogical conflict and fair play issues by teaching the travelling rule as regulated by FIBA.
Method: Dvds of 4 games of the European championship in Basketball in Serbia 2005 were analyzed. Regarding the travelling rule (FIBA, 2005, 2008) we examined situations when offensive players gained possession of the basketball, started to dribble, and/or stopped to attempt a jump-shot. The movements were examined utilizing frame by frame analysis.
Results: As presented by Fosnæs and colleagues (2009), on the average100 touches of the ball occurred in every period, meaning roughly 400 actions in every game. In our analysis 30 % - 40 % of the actions or movements with the ball were in fact in violation of the travelling rule. The interesting thing that we found was that considerably often the violation was not called a travelling violation, but rather overseen or simply 'missed' by the official in position to make the call.

Discussion: Clearly, an argument can be made for officials simply not making the proper violation call, officials are in fact human. However, it may very well be that officials are simply not as likely to make the travelling violation call. This issue will be discussed from a pedagogical perspective where teaching the travelling rule and its understanding among youth may in fact be a deviation from the understood act of travelling in organized basketball. Furthermore, the travelling theme will be discussed from a fair play perspective (Reddiford, 1998) in that if the assumption is that travelling is a more subjective violation among officials, the outfall may in fact create a sense of self-deception among players in order to gain an unfair advantage in games where officiating of the act of travelling is subjectively liberal.

THE TECHNICAL DEMANDS OF ATTACKING AND DEFENDING IN COACHED AND UNCOACHED RUGBY LEAGUE SMALL-SIDED GAMES

FOSTER, C., TWIST, C., LAMB, K., NICHOLAS, C.

UNIVERSITY OF CHESTER

Introduction: In recent years, small sided-games (SSGs) have emerged as a multi-component training method which can achieve aerobic conditioning and skill development simultaneously. However, whilst the physiological demands elicited within SSGs have been studied (Hoff et al., 2002; Hill-Haas et al., 2008) the technical demands of skills performed within SSGs have not been analysed. Furthermore, the effects of coaching on the skills within SSGs have not been previously examined, despite studies stating that coached SSGs increase player motivation (Impellizzeri et al., 2006). Accordingly, the purpose of this study was to examine the technical demands of attacking and defending in coached and uncoached SSGs in junior rugby league players.

Methods: Following ethical approval, 17 junior players from a professional club (age 13.4 ± 1.1 years, stature 1.68 ± 0.11 m, body mass 61.5 ± 14.9 kg) volunteered to participate in eight, four-minute conditioned SSGs. Players engaged in both attacking and defensive roles (non-contact) and in coached and uncoached conditions. An analysis of attacking and defending skills was carried out using a hand notation system. Analysis included: game statistics (frequency of tries scored, errors made and set completion percentages), attacking variables (frequency of attacking involvements derived from the frequency of passes and attacking runs, i.e. dummy runs, hit ups and pass plays; Eaves and Broad, 2007), defending variables (frequency count of the number of touches). The success rate of passes and touches was also conducted, taken as the skill outcome and if the skill met pre-set coaching criteria.

Results: Statistical analysis revealed similarities in the mean percentages of successful passes and touches between the coached (84.3 ± 8.4 and 83.8 ± 7.0) and uncoached (79.5 ± 13.2 and 84.4 ± 6.5) conditions, respectively. Moreover, independent t-tests revealed no significant ($P>0.05$) differences between the coached and uncoached SSGs for any of the game statistics or attacking or defending variables.

Discussion: Whilst the presence of a coach might be expected to increase the frequency and success rate of both attacking and defending skills, this study has demonstrated no difference in the skill frequency or success rate between coached and uncoached SSGs. This finding may reflect the players' habituation to SSG training and that players possess high skill levels and require no additional motivation. Furthermore, the findings of this study indicate that skills used in matches and practised traditionally in a closed environment can be carried out successfully in SSGs in a pressurised game environment.

THE RELATIVE AGE OF ELITE JUNIOR SOCCER AND ICE HOCKEY PLAYERS IN SWITZERLAND

ROMANN, M., FUCHSLOCHER, J.

SWISS FEDERAL INSTITUE OF SPORT MAGGLINGEN

Purpose: Identifying talented athletes at an early age has become one of the major issues in many competitive sports (Abbott & Collins, 2004). The relative age, which refers to the difference in age between children in the same selection year, has a significant influence in the talent identification process for many sports (Musch & Grondin, 2001). The primary purpose of this study was to determine, if the relative age effect (RAE) exists in elite junior soccer and ice hockey players in Switzerland.

Methods: 344 Swiss male elite junior ice hockey (age 15.3±1 yr.) and 183 soccer players (age 15.2±1.4 yr.), members of the national teams U15-U20, were evaluated. The year was divided into four quarters (Q1: January, February, March; Q2: April, May, June; Q3: July, August, September and Q4 October, November, December). The percentage of players born in the respective quartiles was compared to the distribution of male births in Switzerland (expected frequencies), which were obtained from the Swiss Federal Institute of Statistics. Statistical comparisons were calculated using the chi-square test.

Results: The RAE was found with a distribution of Q1=53.0%, Q2=18.0%, Q3=19.7%, Q4=9.3% for soccer and Q1=42.4%, Q2=27.6%, Q3=19.5%, Q4=10.5% for ice hockey. The month of birth distribution differed statistically significantly from that of the general Swiss male population for the respective years in both groups ($p<0.001$). The data concerning Q1 highlighted an over-representation of players, whereas a decreasing number of players were born in the subsequent months.

Discussion: The RAE that exists in many competitive sports worldwide is clearly evident in the selection process of elite junior soccer and ice hockey players in Switzerland. In particular, the chance of being selected to a national team is 5-fold higher for Q1 compared to Q4. Our results suggest, that a significant part of what coaches see as early talent may be explained by the relative age advantage. To avoid this effect in the future, we propose a more equitable slotting system into age divisions with three rotating calendar cut-off dates.

DIFFERENCE BETWEEN THE ROTATIONAL THROW AND THE GLIDE THROW TECHNIQUES ON SHOT PUT EVENT

AOYAMA, S., FUKUDA, S., AOYAMA, T., TSUNODA, N.

UNIVIRSITY OF KOKUSHIKAN

Introduction: In recently, many shot put throwers performing the rotational throw technique is increasing in shot put event. What are some of the advantage and disadvantage of the rotational throw and the glide throw techniques. The purpose of this study was to clarify the difference of technical factors between the rotational throw and the glide throw techniques for design of skill training program.

Methods: Subjects were seven male Japanese right-handed elite shot put throwers who can use the rotational throw and the glide throw techniques (age:22.7±2.3yrs, height:176.6±6.8cm, body weight:107.6±15.1kg, rotational throw:14.1±1.3m, glide throw:13.4±1.5m). All the subjects performed total six throws that three rotational throw technique and three glide throw technique same as a competition rules. Rotational throw technique and glide throw technique were measured by 3-D analysis (APAS) that was analyzed for release speed, release angle, release high, shot acceleration (horizontal, vertical and total acceleration) and shot movement speed. Throwing movement was divided by turn-phase and push-phase during shot put movement.

Results: Shot put performance was significantly related to the release speed in both throw techniques (rotational throw: r=0.501, glide throw: r=0.579). Shot acceleration of vertically and total acceleration in rotational throw technique were significantly higher than glide throw technique during the push-phase. Similarly, shot moved speed in the rotational throw technique was significantly higher than the glide throw technique during the on turn-phase.

Discussion: From these results, it was cleared that developing of the release speed is most important factor in shot put for both throwing techniques. The rotational throw technique to the pushing vertical direction may important factor during the push-phase. And also, the rotational throw technique may energy stored on lower limb and trunk during the turn-phase in the rotational throw skill training.

KINEMATIC ANALYSIS OF THREE DIFFERENT SPRINT START POSITION IN NOVICE ATHLETES

MILANESE, C.

FACULTY OF MOTOR SCIENCES

KINEMATIC ANALYSIS OF THREE DIFFERENT SPRINT START POSITIONS IN NOVICE ATHLETES

Milanese Chiara*,**, Bertucco Matteo*,***, Ferrari Giorgia*, Zancanaro Carlo*,**

*Faculty of Motor Sciences, **Department of Morphological and Biomedical Sciences, ***Department of Neurological and Visual Sciences, University of Verona, Italy

Introduction: The kinematic patterns of elite athletes performing the sprint start in the track received considerable attention (1-5) in attempt to provide coaches and athletes an invariant biomechanical model for training; however, little information regarding novice athletes is available. Novice athletes tend to stand up too soon when leaving the blocks, thereby gaining little benefit, if any, from the original block position. This study was aimed at examining whether changing the angle at the knee joint in the rear leg in the set position, influence step length and velocity of the centre of mass (COM) in the first two steps. Results would help defining the best start position of novice sprinters.

Methods: Eleven novice sprinters (6 males and 5 females, age 23,5 ± 2,12 yrs, height 1,72 ± 0,05 m, weight 60,9 ± 5,52 kg) took part in this study. Participants were asked to perform the sprint start at three different knee angles of the rear leg (90°, 115°, 135°). The block was placed at a medium block spacing according to Schot & Knutzen (1992). Each subject performed 10 trials at each knee angle. Kinematic analyses were performed with a VICON (8 cameras, 250Hz) system and software to yield the traveled distance and the COM velocity in the two first steps in the horizontal direction.

Results: The results indicate that horizontal velocity of COM at the first step is greater at 90° (p=0,019 and p=0,05 vs 115° and 135°, respectively); at the second step, the COM velocity was greater at 90° than 115° or 135°; however, a significant difference was only present at 115° vs 135° (p=0,020). No significant difference was found in the length of the first two steps, although the greatest value was at 90°.

Discussion: These preliminary results indicated that novice sprinters produce greater velocity and step length with a rear leg knee angle between 90° and 115°. It can be hypothesized that, in novice athletes and in the given block setting, lower angles allow to develop larger force in the muscle groups involved in sprint start. Analysis of EMG data is presently being undertaken to validate such hypothesis. Further, analysis of the thrust angle will show whether lower angles at the knee make the novices' performance closer to that of experienced sprinters. This would help coaches in choosing the more effective angle at the knee of the rear leg, which is currently suggested in the 134° -145° range.

THE RELATIONSHIP BETWEEN VISUAL ACUITY AND GAME PERFORMANCE IN WATER POLO

KOMORI, Y., MOCHIZUKI, K., ENOMOTO, I., MAEDA, A., KONO, I.

DOSHISHA UNIVERSITY

Introduction: Recently the number of people who are shortsighted have increased in Japan. Likewise the number of reports on the importance of correcting visual acuity from the standpoint of game performance and safety in sports have also increased. Players of water polo are unable to correct their visual acuity since players are prohibited from using glasses or swimming goggles during play. Thus low visual acuity players use contact lenses in the water. Disposable type lenses are becoming popular with those players who use contact lenses. However, players without corrected visual acuity are also playing the game even though their uncorrected visual acuity is below 0.1 (Komori, 1998.) It is known that a decline of vision affects game performance in baseball and table tennis. However, the relationship

between visual acuity and game performance in water polo is undocumented. Thus the present study focuses on the effect of corrected visual acuity in game performance during water polo play.

Methods: Five male water polo players (age: 18.0±3.4 yrs) participated in the study. The participants played games in two conditions; in the first game the players were using contact lenses and in the second game they were not. Their corrected visual acuity with contact lenses was between 0.8 and 1.0. The uncorrected visual acuity of players was 0.01 and 0.1. The indicators of game performance were (1) the rate of errors; (2) the rate of contributed play; and (3) the rate of ball contacts. The indicators of errors and contributed plays followed the results reported by Enomoto et al. (2001). The participants completed self-evaluations regarding their play.

Results: The results showed the significant difference in the rate of errors committed by players with corrected visual acuity using contact lenses and those with uncorrected visual acuity. According to their responses of questionnaire, there was a significant difference in aspects of the game related to vision between players with corrected visual acuity and those with uncorrected visual acuity. For example, players felt that they could more clearly see their opponents, the goal, and the ball movements in corrected visual acuity conditions as compared with those playing in uncorrected visual acuity condition.

Conclusion: These findings showed that corrected visual acuity using contact lenses led to a decrease in errors committed; clear vision during games led to significant improvements in game performance. In conclusion, the study suggested the corrected visual acuity is an important factor in scoring and winning.

DEVELOPMENT OF BIA EQUATIONS FOR ESTIMATING BODY COMPOSITION OF ELITE MALE WRESTLERS

KARLI, U., ACIKADA, C., ALPAR, R., HAZIR, T., DOGU, G.

1. ABANT IZZET BAYSAL UNIVERSITY, SCHOOL OF PHYSICAL EDUCATION AND SPORT, BOLU, TURKEY, 2. HACETTEPE UNIVERSITY, SCHOOL OF SPORT SCIENCES AND TECHNOLOGY, AND FACULTY OF MEDICINE, ANKARA, TURKEY.

Introduction: Body composition is associated with successful participating in elite wrestling. Although, BIA is relatively simple, quick, portable and noninvasive method for estimating body composition (Wagner and Heyward, 1999), use of inappropriate equations in BIA measurements can lead systematic prediction errors (Heyward and Stolarczyk, 1996). Therefore, the purpose of this study was to develop bioelectrical impedance equations for estimating body composition (fat free mass) of elite male wrestlers.

Methods: Hundred and eleven highly active elite male senior wrestlers (mean ± SD, age: 21.054±2.993yr, height (H): 171.852±7.518cm, body weight (BW): 78.362±15.931kg) were participated in this study as volunteers. H, BW, bioelectrical impedance analysis (BIA) and hydrostatic weighing (HW) measurements with residual volume were performed at least four hours after breakfast between 11:00 and 13:00 o'clock. Each subjects resistance (R), reactance (Xc) and impedance (Z) values were recorded by BIA and fat free mass (FFM) was calculated by using the hydrostatic weighing (HW) measurements as the reference variable. Pearson Correlation Coefficient was used to measure the interrelationship between reference variable (FFM) and independent variables. Then, Multiple Linear Regression Analysis was performed using the FFM as the reference variable and other measured items as the explanatory variables in order to form prediction regression equations (EQ) for BIA. Finally, validity of the equations was examined with Cross Validation Method.

Results: Five equations were derived for FFM to use in BIA measurements. The explanatory variables of the equations were BW, R, height squared (Hsqr), Xc, Z, resistance index (Hsqr/R) and impedance index (Hsqr/Z). The multiple coefficient of determination (R square= Rsqr) and standard error of estimate (SEE) of the equations are given as followed: Rsqr =0.98384, SEE =1.45821kg (EQ1); Rsqr =0.98375, SEE =1.46214kg (EQ2); Rsqr =0.98543, SEE =1.37370kg (EQ3); Rsqr =0.98533, SEE =1.37825kg (EQ4) and Rsqr =0.98613, SEE =1.36336kg (EQ5). By the use of Stepwise Linear Regression Analysis, the results of this study indicated that BW, R, Hsqr, and Xc as ideal explanatory variables to estimate FFM of elite male wrestlers in BIA measurements. Final prediction equation and its Rsqr and SEE are given as followed: FFM= 19.69292 + 0.5233 (BW) – 0.05256(R) + 0.00085(Hsqr) + 0.11211(Xc); Rsqr = 0.98613, SEE= 1.36336.

Conclusion: Finally, cross validated prediction equations with high Rsqr and low SEE were derived for FFM of elite male wrestlers to use in BIA measurements. Population specific equations should be developed for accurate estimation of body composition in specific homogeneous groups.

GAME PERFORMANCE AND ACTIVITY PROFILE OF WHEELCHAIR BASKETBALL PLAYERS

YODA, T., YASUMATSU, M., KAWANISHI, M., ISHIWATA, T., TANAKA, H.

1. DOKKYO UNIVERSITY (JAPAN), 2. RIKKYO UNIVERSITY (JAPAN), 3. YOKOHAMA NATIONAL UNIVERSITY (JAPAN)

Introduction: The specific rule in wheelchair basketball is the Player Classification System in which players are classified into classes (Class I, II, III, and IV) based upon the players' functional capacity to play (Class I is the most disabled). The players are required to have good skills for controlling wheelchair as well as for playing basketball. However, there is little study that analyzed both game performances and activities. The aim of this study was to compare these two abilities between a Japanese top team and a team in the medium level.

Methods: We recorded video images of players of the team C (the men's top team in Japan) and the team K (medium level) in the preliminary game of the Japan wheelchair basketball championship in 2007. From the video images we measured the wheelchair basketball performances and compared each data of team C and team K. The wheelchair basketball performances were classified the game performance and the activity profile which was divided into high, middle, low intensities of pushing the wheel (high being fast rotation of the wheel and low being slow rotation).

Results: The number of screen plays per one offence period was also higher in the team C than in the team K. In the team C, field players almost equally played for passing, dribbling and screening, however the number of attempted shots and rebounds were higher in Class III and IV players. In the team K, players of Class III and IV held possession for the majority of the offence. As for the control of wheelchair, the rate of high intensity in total playing time was higher in the team C than in the team K. The average time of high intensity in team C was longer than in team K.

Discussion: It was reported that the players' moving distance of high intensity in one game became longer as the league was proceeded to higher level in soccer (Bangsbo, 1994). Our result also showed similarly that the rate and time of high intensity in the top team in Japan was longer. These results indicate that players in the top team can keep high physical strength through the game. On the other hand, it has shown that the game performances in basketball are highly position-dependent, especially in wheelchair basketball (Wang et al., 2005). We observed that players of team C played almost equally, but Class III and IV players played in the lane under the basket predominately. In addition, all players of the top team in Japan handled the ball out side of the lane and screened for their team player regardless of the functional class. These suggest that the players of the top team in Japan have high basketball skills in order to make chances for other player and can maneuver the wheelchair as an individual, also team.

ANTHROPOMETRICAL PARAMETERS AND BODY COMPOSITION INFLUENCE SWIMMING PERFORMANCE IN YOUNG SWIMMERS.

LÄTT, E., JÜRIMÄE, J., HALJASTE, K., CICCHELLA, A., PURGE, P., JÜRIMÄE, T.

UNIVERSITY OF TARTU

Introduction: Participating in a competitive sport at a young age has been associated with specific body proportions (Damsgaard et al., 2001). The present study analysed the development of the anthropometrical parameters and body composition in young swimmers and assessed the effect of these parameters on swimming performance during biological maturation.

Methods: Main anthropometrical parameters and biological age were measured in 55 young swimmers (29 males and 26 females). Maximal 400-m front-crawl swimming test was performed in a 25-m swimming pool, where the energy cost of swimming (Cs) was assessed. Peak oxygen consumption (VO2peak) was assessed by means of the backward-extrapolation technique recording VO2 during the first 20 sec of the recovery period after a maximal trial of 400-m distance. Body composition parameters were measured using dual-energy X-ray absorptiometry (DXA).

Results: During the 2-year follow-up study period, the age, height, body mass, fat free mass (FFM), bone mineral mass (BM), arm span, and biological maturation values for all swimmers, body mass index (BMI) and spine BMD for boys and body fat% and total BMD for girls significantly increased during each year ($p<0.05$). Partial correlation analysis revealed that 400-m swimming performance time was elated ($p<0.05$) to body height ($r>-0.468$) and arm span ($r>-0.397$) values, VO2 was related to body height ($r>0.395$) and arm span ($r>0.394$) at all three measurements after controlling for age and pubertal status in boys. In addition, the Cs of the 400-metre swimming performance was related ($p<0.05$) to the body mass ($r>0.411$), BMI ($r>0.412$), and spine BMD ($r>0.500$) values at all three measurement points in girls. Tracking of the measured physical characteristics over the two year study period was very high for boys ($r>0.880$) and relatively high for girls ($r>0.694$).

Discussion: Swimmers usually start serious training at a very early age, and anthropometrical parameters affect swimming performance in young swimmers (Jürimäe et al., 2007).The result of present study also found that swimmers with good anthropometrical characteristics also have a better swimming time. . The tracking coefficients of the physical parameters were high; hence it is important to pay attention to the selection process of young female swimmers. Anthropometric parameters track highly during puberty (Leppik et al., 2006) and the early biological maturation of swimmers has been attributed to sport-specific selection (Baxter-Jones et al., 1995).

MATURITY-ASSOCIATED VARIATION IN THE GROWTH AND FUNCTIONAL PROFILE OF SOCCER PLAYERS 13-14 YEARS OF AGE

FIGUEIREDO, A.J., COELHO E SILVA, M.J., MALINA, R.M.

UNIVERSITY OF COIMBRA

The literature suggests that youth soccer players advanced in biological maturity tend to be more successful as the transition from early (10-12 years) to mid-adolescence (13-15 years) occurs. The present study considers variation in body size and proportions, functional characteristics and soccer-specific skills associated with maturity status in youth soccer players 13-14 years of age.

The sample consisted of 72 male players with chronological ages (CA) 13.1-14.9 years (14.1±0.6). Somatic characteristics included weight, height, sitting height and four skinfolds. Leg length was estimated as height minus sitting height and the ratio of sitting height to height was calculated. Hand-wrist radiographs were taken and skeletal age (SA) was assessed with the Fels method (Roche et al., 1988). Players were classified as late, on time (average) or early by the difference between SA and CA. Functional status was assessed with the 10x5-meter agility test, vertical jump (squat, counter-movement), 7x30-meter sprint (anaerobic test, Bangsbo, 1994), YO-YO intermittent endurance test – level 1 (Bangsbo, 1994). Four ball manipulation soccer skills were measured.

Distribution of players by maturity status was: late 4 (6%), on time 45 (62%) and early 23 (32%). Given the small number of late maturers, comparisons were limited to on time and early maturing players. Weight ($p<.01$), height ($p<.01$), sitting height ($p<.01$), estimated leg length ($p<.01$), sitting height ratio ($p<.01$), squat jump ($p<.01$) and counter-movement jump ($p<.01$) differed significantly between the two maturity groups. Other functional tests and soccer-specific skills did not differ by maturity status.

In conclusion, results suggest that boys advanced in biological maturation are larger in size with a distinct advantage in muscular power of the lower limbs compared to players on time in maturation. Performances in aerobic, anaerobic and soccer-specific skill tests did not differ among youth players of contrasting maturity status. The results suggest that soccer-specific training may function to reduce maturity-related variation among adolescent players.

Results of the study are relevant to talent development, and highlight the need to perhaps selective guide the small, later maturing skilled player.

INFLUENCE THAT WALKING SPEED EXERTS ON YOUNG PERSON'S WALKING EFFICIENCY

YAMAMOTO, M., MIYAKAWA, T.

KAWASAKI UNIVERSITY OF MEDICAL WELFARE

BACK GROUND:As for walking, various human movements and their relation are deep. So walking is an important basic movement for humans. Especially, walking is one integral part of human movement in senior citizens, it is an index for revealing the actions of everyday life. Recently we can see a lot of studies about walking movement for senior citizens. According to a precedent study, Fuchimoto et al.(2003) issued a report on the oxygen uptake per unit distance increase when walking at speeds less than 3.7km/h or more than 4.6km/h. Furthermore, Tanaka et al.(2003) issued a report to the time of speed of around 4.0km/h, a vertical direction and the conversion rate of the kinetic energy of the flat direction became the largest. PURPOSE:In this study, we assumed the work efficiency of walking. And we aimed to clarify the influence that a difference in walking speed gave to walking efficiency. METHOD:The subjects were five healthy adults. We affixed reflection markers to 18 physical characteristic points on the body. We analyzed image and gas analysis while walking. Walking conditions were 3.0km/h condition(S-condition), 4.2km/h condition(N-condition) and 5.4km/h condition (F-condition). Potential energy, kinetic energy and mechanical energy were measured for 10 cycles while walking. The energy consumed was measured using gas analysis. RESULTS:The external work is the difference of the maximum and the minimum of mechanical energy during 1 cycle. The external work shows the amount of energy that a source spent while walking. The external work showed that the S-condition was 28.7±15.1J, the N-condition 25.1±6.3J, and the F-condition 37.5±24.9J. Significant differences were not recognized between each condition. We thought that the external work grew larger with increases in the speed. But between 3.0km/h and 5.4km/h, the external work at this speed did not have any influence. Energy consumed per 1 cycle showed that the S-condition was 149.7±52.9J, the N-condition 163.1±69.4J, and the F-condition 225.7±79.0J. This shows the significant difference between S-condition and F-condition, N-condition and F-condition. Like a precedent study, the energy consumed had a tendency to become larger with the increase in speed. Walking efficiency in that S-condition was 15.4±5.9%, the N-condition 12.1±2.1%, and the F-condition 13.1±8.3%. Significant differences were not recognized between each condition. Elsewhere, walking is the same repetition of left and right movement. So we thought that the change of the mechanical energy would stay constant. But the laterality was large and small for persons split up into two groups. This reason was because of habit when walking and an anamnesis of the subjects. CONCLUSION:In this study, the influence that walking speed gives to walking efficiency from 3.0km/h to 5.4km/h used as a setting range, was not recognized. And laterality of mechanical energy was large and small for persons split up into two groups.

APPLICABILITY OF FUNCTIONAL METHODS FOR DETERMINATION OF HIP JOINT CENTRE - A PILOT STUDY

WISSEMANN, I., KORNETKA, D., BRUEGGEMANN, G.P.

GERMAN SPORT UNIVERSITIY COLOGNE

Introduction: In order to estimate joint moments of the hip, precise determination of hip joint centre (HJC) is necessary. In the literature two approaches of determination of HJC are discussed: functional and predictive methods (Ehrig 2006). Functional methods consist of individual computation of HJC based on a recorded calibration movement and mathematical models (Ehrig 2006, Gamage 2002). Predictive methods estimate HJC with a fixed mathematical term and individual anthropometrical data (Bell 1990, Seidel 1995). Predictive methods are commonly practiced in movement analysis, although they demonstrate errors of 2-3cm (Kirkwood 1999, Leardini 1999, Seidel 1995). Computer simulation and mechanical modelling demonstrate lower errors in functional methods (Ehrig 2006, Gamage 2002, Halvorsen 1999). From the literature it remains unclear if functional methods are more precise than predictive methods in authentic testing conditions.

Methods: 8 subjects were recruited for the study. HJC was determined by MRI for each subject. Functional calibration movements were recorded by 12 infrared highspeed cameras (VICON, 120Hz). From these recordings HJC was computed using two different functional approaches: algebraic sphere-fit method (S4) and a transformation technique (symmetrical centre of rotation estimation, SCoRE, Ehrig 2006). Errors of the two implemented functional methods were determined by comparing computed HJCs to MRI results.

Results: Mean errors of S4 were 16.1mm (SD 6.3mm), mean errors of SCoRE were 12.4mm (SD 8.6mm).

Discussion: Errors found in this study were higher than errors of functional methods reported in literature from tests based on computer simulation and mechanical linkages (1-5mm error, Camomilla 2006, Ehrig 2006). Testing conditions, especially movement of skin and resulting artefacts may explain this result. Data indicate that HJC can be determined more precisely by functional methods than by predictive methods even in authentic testing conditions: errors found in this study are lower than reported errors of predictive methods (20-30 mm, Kirkwood 1999, Leardini 1999, Seidel 1995). Further studies with increased number of subjects are needed to systematically evaluate the implemented algorithms in authentic testing conditions in order to establish a precise method of HJC determination for accurate gait analyses.

THE INFLUENCE OF EXHAUSTING SSC EXERCISE ON THE LOWER LIMB NEUROMECHANICAL BEHAVIOUR <PRELIMINARY STUDY>

JOÃO, F., VELOSO, A., MONIZ-PEREIRA, V., AGOSTINHO, R.

HUMAN KINETICS FACULTY

Introduction: This pilot study is the first part of an investigation about changes and re-organization of the musculoskeletal system when subjected to cyclic load exercise, and the aim was to assess and analyze changes in temporal, kinematic, kinetic and electromyographic data during an exhaustive jumping exercise.

Methods: One healthy adult performed a sequence of 10 unilateral hops, followed by 25 drop jumps. The sequence was repeated ten times (until task failure). Motion capture was collected with 8 cameras (Ocqus-300) at 200Hz. Synchronously, ground reaction force (GRF) was collected, EMG data (tibialis anterior (TA), gastrocnemius medialis (GAS), biceps femoris (BF), vastus lateralis (VL)), transmitted by telemetry and collected at 1kHz and A/D converted. 3D Joint moments were calculated by inverse multibody dynamics. Kinematic and kinetic data were calculated with Visual 3D software for biomechanics modeling. 5 jumps of each sequence were averaged after time normalization and the results for the variables under study were plot for qualitative comparison.

Results: During the last hop sequence, the maximal plantar flexion increased 20.3%, the maximal knee angle 19.2% and the hip angle also increased 44.4% in comparison with the first sequence. While ankle and knee moments of forces increased 10%, and 25.3% respectively, the hip moment of force decreased 34.5%. The EMG for the pre-activation phase is not conclusive because there isn't a visible tendency being least marked on the case of VL. During the contact phase similar patterns of muscle activation were observed between first and last sequence for GAS and BF. TA burst appear latter on the last sequence changing from 10% of support time to 30%. VL presented a clear increase on the activation level from the first to the last sequence showing a 30 % difference.

Discussion: The different joint moment results may be a good indicator that the muscle-tendon structures that cross these joint are affected by fatigue (Kuitunen,2007). Those changes occur mainly by alterations in the hop pattern, with an increased participation of the knee extensor muscles to produce the required mechanical power. It is clear the influence of exhaustion in the re-organization of the mechanical production by the musculoskeletal system (Winter,1991). These effects are also noticed in the kinetic results, especially in the vertical GRF, when it starts to appear some impact force peaks and with the "trade" of knee and hip moments of force results. Our results could suggest that the changes in the musculoskeletal system are related to the levels of fatigue, and these changes should be taken in to account when modeling the musculoskeletal system.

DOES THE EXAMINER AND THE MARKER PLACEMENT TECHNIQUE AFFECT THE GAIT KINEMATIC DATA?

MONIZ-PEREIRA, V., JOÃO, F., AGOSTINHO, R., CARNIDE, F., VELOSO, A.

FACULTY OF HUMAN KINETICS

Introduction: Motion capture using a video-based optoelectronic stereophotogrammetric system (OSS) allows the assessment of the instantaneous positions of markers located on the surface of the skin and, thus, a kinematics analysis of movement. Cereatti et al (2006) states 3 sources of error affecting motion analysis techniques: instrumental errors, soft tissue artifacts (STA) and anatomical landmark (AL) misplacement. The purpose of this study was to analyze the influence of the examiner (exm) and of two anatomical landmark (AL) placement techniques (real AL (RAL), fixed on the skin, vs vitual AL (VAL), created with a pointer) on lower limb length and maximal ROM on the sagital plan.

Methods: Six students of the University (age: 20.12±0.78), without any gait pathology, participated on the study. The later procedures were followed: (1) antopometric data assessment, (2) palpation and fixation of the real ALs, (3) data collection I - static and dynamic (gait) trial. A 10 camera (Oqus 300) OSS, from Qualisys Motion Capture System at a sample frequency of 200Hz was used, (4) palpation and creation of the virtual ALs using Visual 3D from C-motion inc, (5) data collection II - static and dynamic (gait) trial (6) Repetition of steps 1 to 5 for 3 examiners. In Visual 3D right lower limb lengths, segment lengths residuals and angular displacement in the sagital plan were collected. Statistical analysis was done with with SPSS 16.0.

Results: Differences between methods were only significant for thigh length assessed by exm 1 (~7.8mm which corresponds to ~2% of thigh length) and hip maximal ROM in sagital plan for exm 3 (~0.3º which corresponds to ~0.75% of maximal ROM). Differences between examiners were only significant between exm1 and 3 with RAL for foot length (~5.9mm which corresponds to ~4.6% of foot length) and between exm1 and 3 with RAL for hip ROM (~0.5º which corresponds to ~1.35% of maximal ROM). Segment lengths residuals were: 5mm for the foot (~4.3% of foot length), 2mm for the shank (~0.6% of shank length) and 3mm for the thigh (~0.8% of thigh length).

Discussion: Neither the method nor the examiner seemed to have a great influence in the tested gait kinematic variables. The value of the error obtained through the segments residuals for both methods is superior for the foot (~4%) and does not reach 1% for the shank and the thigh. This was probably because of the camera set up, since none of the cameras was at the foot level. In order to obtain more accurate kinematic data, previous studies about the best data collection procedures should be made and, even with the best possible conditions achieved, error assessment and compensation should be performed for each evaluated task.

UNIVERSITY OF JYVÄSKYLÄ

MODELING THE FORCE – VELOCITY RELATIONSHIP IN ARM MOVEMENT
Ahti Rahikainen, Janne Avela, Mikko Virmavirta

Department of Biology of Physical Activity
University of Jyväskylä, Finland

Introduction: Modeling the force-velocity dependence of a muscle-tendon unit has been one of the most interesting objectives in the field of muscle mechanics. The so-called Hill's equation (Hill 1938 and 1970) is widely used to describe the force-velocity relationship of muscle fibers. Hill's equation was based on the laboratory measurements of muscle fibers and its application to the practical measurements in muscle mechanics has been problematic. Therefore, the purpose of this study was to develop a new explicit calculation method to determine the force – velocity relationship, and test its function in experimental measurements. This study continues the development of earlier study (Rahikainen 2004).

Methods: Herein the force-velocity relationship has been given as an equation of motion. The model was based on the motion analysis of arm movements. Experiments on forearm rotations and whole arm rotations were performed downwards and upwards at maximum velocity. According to the present theory the movement proceeds as follows: start of motion, movement proceeds at constant maximum force, movement proceeds at constant maximum power, stopping of motion. The measurements of arm movements were performed by a special motion camera system which represents the movement as a series of object images. Between these images the paths of the mark light attached to the moving object can be seen as a broken light-line.

Results: Theoretically derived equation, in which the motion proceeds at a constant maximum power (hypothesis), fitted well the experimentally measured results. The values of friction coefficient C and power and friction coefficient ratio P/C were obtained within the curve fitting, whole arm rotation downwards C = 2.83 kg m / s^2, P/C =360 1/s^2, whole arm rotation upwards C = 2.83 kg m / s^2, P/C =250 1/s^2 and forearm rotation downwards C = 2.38 kg m / s^2 and P/C =285 1/s^2. The constant maximum force hypothesis did not seem to fit the measured results.

Conclusions: A further development of Hill's force–velocity relationship was derived, in which Hill's model was transformed into a certain kind of a constant maximum power model. The results of the present study were compared with the mechanics of Hill's model. For the constant maximum force hypothesis a different kind of equation was suggested which would better fit the measured results.

DEVELOPMENT OF BIOMECHANICAL MODELS WITH ADAMS LIFEMODELER SOFTWARE

AGUIAR, L., VELOSO, A., SANTOS-ROCHA, R., BRANCO, M., JOÃO, F., MONIZ-PEREIRA, V.

FACULTY OF HUMAN KINETICS, TECHNICAL UNIVERSITY OF LISBON, AND THE SPORT SCIENCES SCHOOL OF RIO MAIOR, POLYTECHNIC INSTITUTE OF SANTARÉM

Mechanical loading is related with the magnitude of the external and internal forces; with the frequency of forces applied on the body; with the repetition of load application; and with the way musculoskeletal structures deal with the internal forces. Computer models using ADAMS Lifemodeler software (Mechanical Dynamics, In.) are being developed in order to study the complex movements of the joints and the mechanical loads in specific anatomical structures. These models simulate the dynamic behaviour of a rigid multibody system and allow recreate various conditions of movement performance, allowing the analysis of daily physical activities, several sports and individual motor performance. This software derivates a series of movement equations for the model, applying the methods of Lagrangian dynamics. The resulting motion equations are integrated, resulting in a model simulation. Mathematically, the inverse dynamics solves the movement equations that define the model to obtain the joints reaction forces and joints moments. The main goal of this study is the development of biomechanical models that simulate physical locomotion activities of high and low intensity with a moderate speed which allow characterize the biomechanical effect, caused by applied external loads. For the construction of models, the transfer of data between software is a key to facilitate the process of modelling. This is the main focus of the present study. Three-dimensional multibodies mechanical dynamic models will be created, allowing simulating the motor tasks in real conditions. The internal forces can be calculated after the ground reaction forces and kinematics data are obtained, using an inverse dynamics solution and anthropometric information. Muscle forces can be determined using electromyography and anthropometric information. Inverse dynamics is the specialised branch of mechanics that bridges the areas of kinematics and kinetics. It is the process by which forces and moments are indirectly determined from the kinematics and inertial properties of moving bodies. In this work, the main tool in the modeling process and dynamic simulation is the inverse dynamics. Two areas of research are of major interest: the quantification of mechanical load acting on the biological structures of the young and the elder woman; and the simulation of conditions of practice.

3D ANALYSIS OF SWITCH LEAP TO RING POSITION ACCORDING TO THE INTERNATIONAL CODE OF POINTS

GRANDE RODRIGUEZ, I.

PHYSICAL EDUCATION AND SPORT SCIENCES FACULTY, POLITECNICA UNIVERSITY

Introduction: Gymnastics disciplines are characterized by its high technical demands. To check the results of technical training it's necessary to measure if the skill achieve the requirements exposed in the International Code of Points (FIG, 2009). For this purpose it´s useful to applied biomechanics tools to carry out a completed 3D video analysis of each skill. But kinematics variables must be translated to these requirements to make these results more interesting to coaches. The aim of our study was to define a comprehensible card including kinematics results that can help coaches to know if the skill achieves the requirements exposed in the International Code of Points.

Methods: A 3D video analysis of switch leap to ring position was performed. 10 gymnasts from Junior and Senior Spanish national team were filmed. Two synchronized DV video cameras at 50 Hz and 1/1000 exposure time were used. The area was calibrated with a prism (4x2x2 m) that defined 12 control points. A 17 segment body model was used to calculate temporal, angular and spatial variables. 20 body points were manual digitized in all frames. The raw position data were smoothed by the fifth order splines (Woltring, 1986).

Results: The mean results of this leap were: The impulsion phase duration was 0.13±0.01 s. The take off velocity was 3.21±0.13 m•s-1 and the angle of release was 59.31±4.15º.The amplitude of the swing leg was 61.2±12.4º. During this phase gymnasts perform a 34.44±11.56º knee extension.

The mean flight phase duration was 0.53±0.02 s flight. During the flight gymnasts reached a maximum split angle of 179.3±18.90º. The foot tip achieved a height of 8.7±12.6 cm above shoulder. The angle between the front leg and the horizontal was 12.4±8.9º.

Discussion: According to the Code of points the switch leap to ring position have five specific requirements: free leg swing minimum of 45°, reach an amplitude of 180° split, front leg has to reach the horizontal, back foot above shoulder height and arch position of the back (FIG, 2009). This variables except the arch position could be calculated with the 3D analysis kinematics results. As the results of this analysis we detected that 4 gymnasts didn't reach the requirements of the leap. The principal handicaps to perform all the requirements were: front leg has to reach the horizontal (4 cases) and amplitude of 180° split (2 cases). The designed card exposed these aspects so it can help coaches to focus attention to these specific aspects to achieve a correct leap.

KINEMATIC AND FORCE COMPARISON BETWEEN WALKING AND NORDIC WALKING. A PILOT STUDY

SCHENA, F., PELLEGRINI, B., BORTOLAN, L.

UNIVERSITÀ DEGLI STUDI DI VERONA

Introduction: Nordic walking has become a popular fitness sport in the recent years. This exercise is often recommended to orthopaedic patient and obese people as it is believed that the use of walking poles could reduce lower limb loading. Controversial results have been found in the literature that investigate these aspect and the absence of coherence were often related to insufficient skill of the subjects. The aim of this study was to develop and test an experimental protocol for the comparison of kinematic and force parameters between walking and Nordic Walking.

Methods: Two highly expert Nordic Walking trainers (S1 and S2) participated to the study. They were asked to perform walking (W) and Nordic Walking (NW) on a large treadmill at two different speeds (4 km/h and 7 km/h) and 4 different slopes (-20%, -10%, 0%, +10%). Mean ground reaction force (MF) and peak force at contact phase (PF) and center of pressure (CoP) were measured at 100 Hz by means of Novel Pedar insoles. For NW condition, the forces applied trough the poles were recorded by load cells inserted under the handgrip. Trunk inclination, knee angle, and pole inclination were measured at 100 Hz by a 6 cameras Qualysis Motion Capture system and were considered during the first part of the stance phase. The vertical component for pole force was calculated by total force and poles inclination. Mean data over at least 20 cycles were obtained for each condition.

Results: No significant differences were found in MF between W and NW condition for both athletes. Mean values for vertical component of pole force assumed values always lower than 3% of the plantar forces. Greater PF values were found in NW condition respect to W for S1 at the slopes of -10% and 0% at both speed and for S2 at every speed and slope. On flat slope, PF for S1 were 804 ± 34 N for W and 909±23 N for NW and for S2 PF were 650 ± 27 N for W and 713±20 N for NW. Lower knee angle were found for NW condition respect to W particularly at high speed and downhill condition. The trunk inclination values were higher for NW at every speed and slope for both subjects. At 0% slope the trunk flexion for S1 was 88.5 ± 0.8° for W and 84.75 ± 0.4° for NW and for S2 was 88.7 ± 1.2° for W and 81.5 ± 0.6° for NW.

Discussion: The results of this study demonstrate that the use of the walking poles do not lead to a decrease of vertical ground reaction force. The amount of the force exerted vertically trough the poles confirm moreover that their use can not contribute significantly to support body weight. Changes in the knee joint and trunk kinematic suggest that a positive effect of Nordic Walking on the knee loading could arise from a different transfer of the plantar force through the joints. This hypothesis can be further investigated applying inverse dynamic analysis to compare the two forms of locomotion.

DEVELOPMENT OF BIOMECHANICAL MODELS USING ADAMS LIFEMODELER SOFTWARE <CORRECT MODEL>

AGUIAR, L., VELOSO, A., SANTOS-ROCHA, R., BRANCO, M., JOÃO, F., MONIZ-PEREIRA, V.

FACULTY OF HUMAN KINETICS, TECHNICAL UNIVERSITY OF LISBON

INTRODUCTION: Computer models are being developed in order to study the complex movements of the joints and the mechanical loads in specific anatomical structures. These models simulate the dynamic behaviour of a rigid multibody system and allow recreate various conditions of movement performance, allowing the analysis of daily physical activities, several sports and individual motor performance. The main goal of this study is the development of biomechanical models that simulate physical locomotion activities of high and low intensity with a moderate speed which allow characterize the biomechanical effect, caused by applied external loads.

METHODS: To obtain the kinematic data it was used a high resolution optoelectronic system, working in the infrared spectrum (Qualysis Q-Trac, Motion Capture System). Through the Visual 3D C-Motion software, Inc., by inverse dynamics, it is possible to do a kinematic and kinetic analysis of the movement. The next proceeding was to exporting the kinematic data of each marker that define the segments of the lower limbs. The internal forces can be calculated after the ground reaction forces and kinematics data are obtained, using an inverse dynamics solution and anthropometric information. Muscle forces can be determined using electromyography and anthropometric information. To construct the model, this ADAMS Lifemodeler software (Mechanical Dynamics, In.) derivates a series of movement equations for the model, applying the methods of Lagrangian dynamics. The resulting motion equations are integrated, resulting in a model simulation. Mathematically, the inverse dynamics solves the movement equations that define the model to obtain the joints reaction forces and joints moments.

RESULTS: With a kinematic data file, it was possible to simulate the swing movement using generic anthropometric proprieties. The model under development aims to simulate the activity of Step exercise with a 135 beats per minute of speed, on a 15 cm heighted platform.

DISCUSSION: In the modeling process, joints stiffness and damping proprieties influence rigidity the model. Also for the contact surfaces should be considered these two properties, as well as the motion influencers of the movement model. In this work, the main tool in the modeling process and dynamic simulation is the inverse dynamics. For the construction of models, the transfer of data between software is a key to facilitate the process of modeling. In this work, the main tool in the modeling process and dynamic simulation is the inverse dynamics. It is the process by which forces and moments are indirectly determined from the kinematics and inertial properties of moving bodies. Two areas of research are of major interest: the quantification of mechanical load acting on the biological structures of the young and the elder woman; and the simulation of conditions of practice.

OPTIMISATION OF A BICYCLE CHAINRING FOR LOWEST MAXIMUM MUSCLE ACTIVITY USING THE COMMERCIAL SOFTWARE ANYBODY

PURDUE, A.I., FORRESTER, A.I.J., RASMUSSEN, J.

UNIVERSITY OF SOUTHAMPTON

Introduction: A cyclist's bike is set up in the configuration which they find the most comfortable, with it being generally assumed that this yields the most efficient position. This study investigates the effect of configuration on efficiency and numerically optimises the set up using an AnyBody musculoskeletal model. Multivariable optimisation of cycling biomechanics has been done before (Hull M L & Gonzalez H, 1989) with similar variables being explored, however this study utilises the more advanced mechanism of specific muscle force resolution available in AnyBody. With an optimum position for the rider obtained we then consider the chain ring. A bicycle drive train is extremely efficient (~ 98%) although the rider interface is subject to noticeable losses , partly due to the "one size fits all" nature of the circular chainring. As such the computational model will be used to assess the effects of varying the local radius to improve the total efficiency for a specific athlete.

Methods: Experimental torque data for varying power and cadence is collected, for a competitive cyclist, using a stationary bicycle fitted with instrumented cranks mounted on a trainer, which enables power output to be controlled at varying cadences. Fourier analysis of the experimental data is used to create a surrogate model for torque to be utilised in the computer model. A parameter study followed by numerical optimisation is carried out using a 2D model and initial variables of seat height, seat longitudinal position, cadence and crank arm length. The chain ring shape is then manipulated so as to affect better muscle efficiency in powering the bike.

Results: Experimental data from the instrumented cranks shows the torque profiles to be asymmetric in nature. This indicates that calibration of the model using experimental data must be carried out. The data also shows a large dependency on the cadence for the "purity" of the torque profile with smoother profiles being produced closer to the optimum cadence.

Visual inspection of the parameter study results and screening plot produced shows a large variation in maximum muscle activity depending on configuration. A high dependency on cadence, crank arm length and seat height is also shown, with seat longitudinal position revealed to be less important. Values of 170mm for the crank arm length and 90rpm for the cadence are found to be optimal. These coincide with values which are generally accepted in cycling.

Discussion: The results clearly show that variable interaction occurs (particularly with cadence) and that configuring the bicycle correctly and pedalling at the right cadence can lead to a large decrease in the maximum muscle activity. This should increase the efficiency and delay the onset of fatigue. The results show that a personalised set up based on rider specific data will prove more successful in competition.

INDUCTION OF LYMPHOCYTE DEATH BY SHORT AND LONG DURATION TRIATHLON COMPETITIONS

LEVADA-PIRES, A.C., CURY-BOAVENTURA, M.F., GORJÃO, R., HIRABARA, S.M., PUGGINA, E.F., PELLEGRINOTTI, I.L., CURI, R., PITHON-CURI, T.C.

1. UNIVERSITY OF SÃO PAULO, SÃO PAULO, SÃO PAULO, BRAZIL, 2. METHODIST UNIVERSITY, PIRACICABA, SÃO PAULO, BRAZIL 3. CRUZEIRO DO SUL UNIVERSITY, SÃO PAULO, SÃO PAULO, BRAZIL

Purpose: The effect of triathlon competitions on death of lymphocytes from elite athletes was investigated. Methods: Blood was collected from sedentary volunteers and triathletes at rest and after a short duration triathlon (SDT) and after a long duration triathlon (LDT-half ironman) competitions. Results: The training to both triathlon competitions reduced lymphocyte proliferative capacity by 59% as compared to sedentary volunteers. Long and short duration triathlon competitions decreased ConA-stimulated lymphocyte proliferation by 41% and 61%, respectively, when compared with the sedentary group. Both triathlon competitions did not change lymphocyte proliferation as compared to rest condition. There was no difference in the parameters associated with lymphocyte death when sedentary volunteers were compared with triathletes at rest. Lymphocytes from triathletes after SDT competition showed an increase in DNA fragmentation (2.2-fold), phosphatydilserine externalization (2.9-fold) and mitochondrial transmembrane depolarization (2.4-fold) and did not alter membrane integrity when compared to cells from athletes at rest. In contrast, the LDT competition raised the proportion of lymphocytes with loss of membrane integrity by 22% when compared to cells from athletes at rest and did not change the apoptotic parameters. The LDT competition induced an increase of ROS production lymphocytes by 1.6 fold as compared to triathletes at rest. However, short duration competition did not alter ROS production by lymphocytes when compared to cells from triathletes at rest. ROS production by lymphocytes after LDT competition was 60% higher than in SDT. The fatty acids concentration was increased by 3.3 and 1.5 fold by LDT and SDT, respectively. The plasma levels of oleic, linoleic and stearic acids were increased by 1.6, 1.6 and 2.4-fold, respectively, in triathletes when compared with sedentary volunteers. The plasma concentration of these three fatty acids found after a triathlon competitions stimulated ROS production in lymphocytes and was toxic for 24 h cultured lymphocytes obtained from healthy volunteers as previously demonstrated by our group. Conclusion: Evidence is presented herein that a LDT competition caused lymphocyte death by necrosis. On the other hand, SDT induced lymphocyte apoptosis. The mechanism for lymphocyte death induced by the triathlon competitions may involve an increase of ROS production at different extents and increase in plasma levels of oleic, linoleic and stearic acids. EFFECTS OF BLOOD FLOW AND VOLUME ON EDEMA INDUCED BY EXERCISE AND VENOUS-STASIS

YAMAUCHI, J., KIDA, K.

THE UNIVERSITY OF TOKYO/FRIEDRICH-SCHILLER UNIVERSITY JENA, ST. MARIANNA UNIVERSITY SCHOOL OF MEDICINE

Exercise and venous-stasis affect to the local blood circulation and volume in the limb. However, it is unknown how limb volume changes induced by exercise and venous-stasis are related to peripheral skin and muscle blood flow. Therefore, the purpose of the study was to investigate how dynamic exercise (DEx) and venous-stasis (VS) affected to the local volume and peripheral skin and muscle blood flow of hand and forearm. We hypothesized that the increase in hand and wrist volume (HWV) after both dynamic exercise and venous-stasis would be differently responded to microvascular system. Six men (age, 34.7±7.0 yr; height, 172.5±6.4 cm; body mass, 68.2±6.9 kg, mean±S.D.) volunteered for this study. Before and after DEx and VS, HWV was measured with a hand volumeter, and on the separate day, peripheral blood flow (PBF) was measured with photoplethysmography at the surface of flexor carpi radialis muscle (FCR) and index fingertip. PBF at FCR were further detected to the blood flow of skin (SBF) and muscle (MBF) and blood volume of skin (SBV) and muscle (MBV). Initially during rest, HWV and PBF were measured after the hand was passively hung for 5 minutes. Venous-stasis was created by a 14.5-cm-wide pneumatic arm tourniquet, which was inflated to 60 mmHg, around upper arm for 5 minutes. Dynamic handgrip exercises were performed at 20% of the maximum voluntary contraction (MVC) with an ergonomic hand exerciser by repetitive contraction and relaxation of the hand at a maximum frequency, consisted of 6 sets of 30-second exercise with 10-second rest interval between exercises. In order to determine intensity of handgrip exercises, maximum isometric handgrip strength was measured with a handgrip dynamometer. Data are presented as means±S.D. Both after DEx and VS, HWV increased significantly from 445.2±40.6ml to 455.8±44.0ml ($p<.01$) and from 451.8±39.1ml to 464.8±40.2ml ($p<.01$), respectively. These increases represent 2.3±0.8% ($p<.001$) and 2.9±1.5% ($p<.01$) of resting HWV after DEx and VS, respectively, and no significant difference was seen between these ($p>.05$). PBF at index finger was decreased after DEx, but not significantly changed after VS. SBF and MBF both after VS and DEx were not significantly changed but tended to increase after DEx. SBV and MBV were increased after VS, but not significantly changed after DEx. These results suggest that the higher HWV after dynamic exercise is likely to be caused by increase in blood inflow, while the higher HWV after venous-stasis is caused by decrease in blood outflow, thereby increased venous volume.

EFFECT OF PRIOR ECCENTRIC EXERCISE ON THE VO2 KINETICS DURING HEAVY CYCLING EXERCISE IN MALE BASKET-BALL PLAYERS

STASIULIS, A., DUBININKAITE, L.

LITHUANIAN ACADEMY OF PHYSICAL EDUCATION

Introduction: The oxygen uptake (VO2) kinetics may vary with work rate or under different conditions of exercise e.g. prior exercise. The aim of this study was to examine the influence of prior drops without jumps on VO2 kinetics during heavy cycling exercise in male basketball players.

Methods: Eight male basketball players of national level (age 19,5 ± 0,53 yr, height 191,0 ± 5,8 cm, and weight 86,5 ± 9,78 kg) volunteered to participate in this study. Subjects completed four protocols on separate days. During the first day they performed continuous increasing cycling exercise (ICE). In the second examination the subjects performed constant cycling exercise (CCE) with which consisted of 3 min unloaded cycling, 9 min cycling with intensity in the middle between maximal oxygen uptake (VO2peak) and first ventilatory threshold (79.5 ± 2.5 % of VO2max) and 3 min of unloaded cycling. In the third examination the subjects performed one hundred drops from 0.47 m height with eccentric contractions of thigh muscles at the end every 20 s (D), rested passively for one hour and then performed CCE. Following 24 hours the fourth examination was performed using the same protocol as in the second one. Testing was performed on mechanically braked cycle ergometer (Monark 834E) while cycling at 70 rpm. At the end of each 9 min CCE, a blood sample was collected from the finger tip for immediate analysis of blood lactate concentration ([lactate]). Rating of perceived exertion was evaluated by the subject at the end of each CCE, and muscle pain was assessed on the next day after eccentric exercise. Pulmonary gas exchange was measured breath-by-breath throughout all tests. VO2peak was determined as the highest value in 15 s period before the subjects' volitional termination of the ICE. The VO2 response during exercise and recovery periods of CCE was fitted the bi-exponential function. The first 20 s were always removed from the analysis. In addition the slow component was calculated as the difference between the end exercise VO2 and the 3rd min VO2.

Results: Prior eccentric exercise had no effect on time constants of VO2 response during on- and off-transitions during CCE. The VO2 values at the 3rd, 6th and 9th min of CCE did not change significantly during all examinations. The rating of perceived exertion was slightly but not significantly elevated at the end of CCE one hour and 24 hours after eccentric exercise. The subjects felt moderate muscle pain (4,0 ± 2,9) 24 hours after eccentric exercise.

Discussion/Conclusion

The prior eccentric exercise did not cause any change of VO2 kinetics during heavy CCE in male basketball players despite augmented efforts and muscle pain. This may be associated with adaptation of basketball players to such kind of activities which are often involved in their training process.

RELIABILITY AND CONCURRENT VALIDITY OF MAXIMAL SPRINT RUNNING PERFORMANCE MEASUREMENTS ATTAINED ON A NON-MOTORISED TREADMILL

HIGHTON, J., LAMB, K., TWIST, C., NICHOLAS, C.

UNIVERSITY OF CHESTER

Introduction: The use of non-motorised treadmill (NMT) ergometry to assess sprint running performance allows the measurement of variables which are potentially useful to researchers and coaches (e.g. power, peak running speed). However, the use of NMT ergometry is only appropriate if its results are both repeatable and indicative of performance in the field. Accordingly, the aims of this study were to assess the inter- and intra-day reliability of sprint performance variables attained on a NMT over distances associated with multiple-sprint sports and to statistically assess the concurrent validity of sprint times attained on a NMT against those attained during maximal over-ground sprint running.

Methods: Following habituation, 12 male team-sport players (age 22.3 ± 3.6 y, stature 1.79 ± 0.57 m, body mass 80.3 ± 8.44 kg) performed 3 maximal sprints over 30 m on the NMT (Woodway, Force 3.0) on two occasions and a further assessment of over-ground running performance over 30 m in a random order, each separated by 24 h. Performance variables measured during each trial included time to 10, 20 and 30 m (s), peak and mean power (W), peak and mean speed (m•s-1), time to peak speed (s) and force (N).

Results: No significant differences (P > 0.05) were observed for performance variables attained on the NMT on the same day or between days, demonstrating that no systematic bias was present. For intra-day measurements, ratio limits of agreement indicated that split times over 10 (0.99 */÷ 1.14), 20 (0.99 */÷ 1.07), and 30 m (0.99 */÷ 1.06), peak running speed (1 */÷ 1.05) and force (1 */÷ 1.04) demonstrated the least variance. The highest levels of agreement between days were observed in 10 (1.04 */÷ 1.16), 20 (1.02 */÷ 1.09) and 30 m (1.02 */÷ 1.07) split times, mean (0.99 */÷ 1.07) and peak (1 */÷ 1.06) running speed. The coefficient of variation was < 9% for all variables for intra- and inter-day measurements except time to peak running speed (11.9 and 13.5% respectively). Significant differences (P < 0.05) were observed between split times over 10, 20 and 30 m on the NMT and over-ground running, with times consistently lower by approximately 30% during over-ground running over all distances. However, a significant correlation (r = 0.8, P < 0.05) between over-ground and NMT sprint times indicated that faster sprinters over-ground were predominantly faster on the NMT.

Conclusions: This study demonstrates that measurements of sprint time and peak running speed provide the most reliable measures of sprint performance on a NMT. Measurements of both power and force demonstrate acceptable levels of agreement and may also provide useful information for sprint-related research studies and the assessment and monitoring of multiple-sprint sport athletes. Whilst agreement between sprint performance over-ground and on the NMT was poor, NMT ergometry may provide a viable indication of over-ground sprint performance by identifying slower and faster athletes.

NANDROLONE EXCRETION IN SEDENTARY VERSUS PHYSICALLY TRAINED YOUNG WOMEN

ENEA, C., BOISSEAU, N., PETITPAS-MULLIEZ, J., DIAZ, V., DUGUÉ, B.

UNIVERSITY OF POITIERS, FRANCE

We investigated the effects of the menstrual cycle, oral contraception and physical training on exhaustive exercise-induced changes in the excretion of nandrolone metabolites (19-norandrosterone (19-NA), and 19-noretiocholanolone (19-NE)) in young women.

Twenty-eight women were allocated to an untrained group (n=16) or a trained group (n=12), depending on their physical training background. The untrained group was composed of nine oral contraceptive users (OC+) and seven eumenorrheic women (OC-), while the trained group was entirely composed of OC+ subjects. Three laboratory sessions were conducted in a randomised order: a prolonged exercise test, a short-term exercise test and a control session. Urine specimens were collected before and 30, 60 and 90 minutes after the exercise test and at the same times of the day during the control session. Urinary concentrations of nandrolone metabolites were determined by gas chromatography coupled to mass spectrometry.

Urinary concentrations of 19-NA and 19-NE ranged from undetectable levels to 1.14 ng/mL and 0.47 ng/mL, respectively. Nandrolone excretion was not affected by the menstrual cycle phase (early follicular vs. mid-luteal), prior physical training, oral contraception or acute physical exercise. Therefore, a urinary concentration of 2 ng/mL of 19-NA appears to be fair as the upper acceptable limit in doping control tests for female athletes.

EXAMINATION OF BLOOD HEMOGLOBIN CONCENTRATION MEASURED BY THE OSM2 INSTRUMENT

MEDBØ, J.

NATIONALE INSTITUTE OF OCCUPATIONAL HEALTH

Introduction: Blood hemoglobin concentration is regularly measured by automatic instruments that report the value in around 1 min. This may be convenient, for example when testing athletes for possibly too high concentrations. The OSM2 from Radio-meter is an example of such instruments. Results from that instrument have been compared with those of a time-con-suming but very accurate reference method using the hemi-globin-cyanide principle. It was of particular interest to see to what extent OSM2 reports the hemoglobin concentration accurately and precisely. Moreover, possible sources of bias were examined. It was also examined whether arterial and femoral-venous blood were affected similarly.

Methods: Four healthy, moderately trained young men (nonsmokers) cycled for 2 min to exhaustion. Blood samples were drawn from indwelling catheters in the femoral artery and vein before exercise, during exercise, and in the 1 h recovery. Blood hemoglobin concentration was analyzed using both the OSM2 and the hemiglobin-cyanide method of Baxter Dade. In addition blood acid-base parameters were measured [1].

Results: Blood hemoglobin concentrations reported by the OSM2 were linearly related to those of the control method with a random variation of 0.14 mmol/L (1.5%). For arterial blood OSM2 showed a constant bias of –0.36 mmol/L (–4%). For femoral-venous blood the bias varied by the hemoglobin concentra-tion, being negative at low concentrations and positive at high concentrations (–3 to +2%). Consequently, the arterio-venous (a-v) difference differed systematically between the two methods. The varying bias in the results of OSM2 for femoral-venous samples correlated with blood pH, pCO2, O2-saturation of hemoglobin (sO2), and with the hemoglobin concentration itself (cHb). Partial correlation analyses sug-gest that only the latter two correlations were independent, while correlations of the bias with pH and pCO2 were removed when correcting for the effect of sO2 and cHb.

Conclusions: OSM2 measures blood hemoglobin concentration quite precisely, but there is a variable bias of up to 4% in absolute value. At high hemoglobin concentration the instruments reports too high values for femoral-venous blood. The instru-ment does not report a-v differences reliably. A review of the literature suggests that problems identified here may be present in other instruments using similar principles too.

EFFICIENCY AT HIGH WORK RATES IN WORLD CLASS SKIERS

ETTEMA, G., SANDBAKK, Ø., LEIRDAL, S., HOLMBERG, H.C.

1.HUMAN MOVEMENT SCIENCE PROGRAMME, NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY, TRONDHEIM, NORWAY, 2 OLYMPIATOPPEN MIDT-NORGE, TRONDHEIM, NORWAY, 3 SWEDISH WINTER SPORTS RESEARCH CENTRE, DEPARTMEN

Introduction: Energy delivery and mechanical efficiency, a measure related to technique, are key factors in endurance performance. Efficiency is normally measured at low intensities to obtain steady state aerobic conditions. However, in competitive skiing, efficiency is important at higher intensities with a combination of aerobic and anaerobic energy delivery. Therefore, the present study aimed to study efficiency at relatively high, and up to maximal, work rates. Furthermore, we aimed to investigate the effects of performance level by

comparing World Class and National level athletes. Methods: Eight world class (26.1±3.5 yr, 184.8±5.6 cm, 83.3±6.4 kg, fat percent 8.8±2.6%, FIS-points 20.5±13.1) and eight national class (24.5±2.3 yr, 186.4±6.6cm, 82.8±6.6 kg, fat percent 9.9±1.5%, FIS-points 87.4±27.7) Norwegian male cross country skiers participated in the study. After a preliminary warm up, all athletes performed three 5-min stages at 14, 16 and 18 km h-1 on a 5% inclination using the skating V-2 technique while roller skiing on a treadmill. Furthermore, the athletes performed an incremental treadmill velocity test at a 5% incline, leading to a maximal obtainable speed after 5-7min. Gross efficiency was calculated by external power output divided by internal power. External power was calculated taking into account both work rate against gravity and frictional rolling forces. Internal power was calculated using gas exchange and blood lactate values. The effect of velocity on efficiency and group differences with regard to this was tested using a one-way ANOVA for repeated measures. Furthermore, the groups were compared for efficiency at their own maximal speed during the incremental test. Results: Compared at absolute work rates (i.e., the 3 velocities) the world class skiers showed higher efficiencies than the national class (15.17±0.37%; 15.15±0.43%; 15.21±0.63% vs 13.95±0.71%; 14.43±0.58%; 14.54±0.57%, at 14, 16 and 18 km h-1, respectively). The group differences were highly significant (P=0.002). The statistical analysis showed that the velocity effect was not significant (P=0.073). The apparent small trend was caused by the difference between 14 and 16 km h-1 in the national class group. Compared at relative work rates (maximal speed during the incremental test) the 2 groups seemed to have a similar difference in efficiency, as at absolute work rates, but it did not reach statistical significance (15.58±1.04% vs. 14.78±0.62%; P=0.083). Discussion: The current results indicate that, in addition to the higher energy delivery capacity, world class athletes also utilise a more effective technique at an absolute work rate (i.e., velocity) than national level athletes. However, at the same relative work rate, these differences, at least statistically, are less clear.

NUTRITION STRATEGIES FOR A 3-WEEK SOLO DESERT CROSSING: A CASE STUDY

KOEHLER, K., HUELSEMANN, F., DEMAREES, M., BRAUN, H., MESTER, J., SCHAENZER, W.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: Under extreme conditions such as during expeditions, nutrition may become a limiting factor for the extremist's health and performance. The diet should provide sufficient energy in order to minimize the use of endogenous stores such as adipose tissue and muscle protein.

In the present case, a dietary regimen was prepared for an unsupported solo crossing of the Atacama desert (Chile/Peru). During the designated route of approximately 700 km altitude varied from 600 to 4300 m. Due to restricted transport capacity, it was necessary to closely calculate the energetic requirements of marching under varying conditions (load, inclination, altitude).

METHODS: All measurements were performed on the same subject (35 y, 197 cm, basal weight: 80 kg). Treadmill walking tests were conducted with speed increasing from 2 to 7 km/h. A total of 8 tests were performed a) with and without an inclination of 7.5 %, b) with and without additional weight of 30 kg and c) at sea level and in a hypobaric chamber at simulated altitude of 3500 m.

During each walking test, indirect calorimetry was performed to calculate energy expenditure (EE). Furthermore heart rate was recorded, capillary lactic acid was determined and steps were counted using the SenseWear Pro3 Armband. In simulated altitude, oxygen saturation was also measured.

During the desert crossing, the SenseWear Pro 3 Armband was worn during all wake periods and used to calculate walking speed. EE was extrapolated using an algorithm previously determined with treadmill data. Additionally, the subject recorded his diet and used global positioning system (GPS) to confirm his position occasionally.

RESULTS & DISCUSSION: EE during the simulation increased exponentially with walking speed, at sea level without inclination and without additional weight from 1.9 +- 0.1 (2 km/h) to 3.9 +- 0.2 kcal/min (7 km/h). In average, EE was increased by the additional weight (30 kg) by 3.5 +- 0.2 kcal/min, by simulated altitude by 1.7 +- 0.2 kcal/min and by an inclination of 7.5 % by 2.6 +- 0.2 kcal/min.

Maximal EE of 11.1 +- 0.7 kcal/min was reached at simulated altitude with additional weight and inclination at a speed of 5 km/h, when the subject aborted due to exhaustion. Under these conditions, peak values of heart rate (165 /min) and lactic acid (3.8 mmol/L) were reached and oxygen saturation was reduced to 76 %.

The most efficient walking speed was 5 km/h. At this speed EE lay in the range of 32 +- 2 kcal/km (sea level, no additional weight, no inclination) and 133 +- 8 kcal/km (3500 m altitude, additional weight, 7.5 % inclination).

During the crossing the subject walked a total 597 km (26 +- 7 km/d) during 158 h (6.9 +- 1.8 h/d) in an average speed of 3.8 +- 0.4 km/h, which was later verified by GPS data. Daily EE (4646 +- 963 kcal/d) was substantially higher than energy intake (1873 +- 761 kcal/d). The difference of 2772 +- 1390 kcal/d was in good agreement with the actual weight loss of 10.5 kg.

FIFTEEN-YEAR EXPERIENCE OF USE OF PHYSICAL CULTURE DEVICES DURING SCOLIOTIC DISEASE TREATMENT

ULYANOV, D., KOVALENKO, T., SHKLYARENKO, A.

VOLGOGRAD STATE UNIVERSITY

Present research actual continuity. At the present moment developmental physiology focuses its particular interest on a very important part of vital activity: infantile motor activity. Children and teenagers physiological activity has multiple forms and motor actions. Two forms of hypodynamia (enforces and spontaneous) are observed in its functional structure. From the point of view of physical culture, the enforced form of hypodynamia is more common for sclerotic disease.

Study methods and management. The research presents analysis of fifteen-year experience of children and teenagers locomotor apparatus multifunctional changes during the scoliotic disease treatment with the use of physical culture devices.

Research results and their discussion. The reasonability of abandonment of traditional orthopedics prohibition system to use all range of physical culture devices providing natural development of central motor programs with accurate exercise selection excluding asymmetry according to the principle of individual load dosage was proved. We made new methodological approaches towards physical exercise

application ensuring body structure visual deviation smoothing, posture correcting, satisfying the need of scoliotic patients in motor activity, reducing psychological stress caused by cosmetic body deformity. The differentiated analysis of functional correction of infantile scotiotic disease (different severity levels) was made. The necessity of use of a new method applying different physical culture devices was justified. It is based not on prohibiting but on accurately dosing of physical load according to structure analysis of spine motor functions, posture pathologic stereotypes (sitting, stretching and walking manners), physical development and exercise performance assessments at different ontogenesis stages. The method is used to prevent evident body deformations disabling young women, limiting their genetic capacities as for reproductive performance and causing psychological stress.

Conclusions.

1. Sanative physical exercise valuation assumption was baed on initial importance of motor-viscerogenic reflex. Bilateral communication of motor and vegetative activities were not equal in the study analysis: the motor function was considered to be the fundamental.

2. The force of movement, its adequate rate and direction were used to solve the set problems. Whereby, we applied the most conformable, biologically justified methods of stimulating of adaptive, protective and compensatory organism properties to prevent and treat scoliotic processes.

3. The application of the present study results in the children`s sanitary and pedagogical institutions (secondary and high schools, colleges, heal-improving summer camps, etc) as well as domiciliary helped to obtain efficient vertebral deformity (kyphoscoliosis) prevention and correction at the stage of intense bone growth, as well as rehabilitation of children and teenagers with progressing scoliotic disease in different ontogenesis periods.

THE PARAMETERS OF MULTISEGMENTAL MONOSYNAPTIC RESPONSES OF LEG MUSCLES IN SUBJECTS WITH LUMBAR NERVE COMPRESSION

ANDRIYANOVA, E.

VELIKIYE LUKI STATE ACADEMY OF PHYSICAL EDUCATION AND SPORTS

Introduction: The subject of the present study is condition of patients with signs of lumbar nerve compression. The disorder is widespread among athletes who perform exercises loading the lumbar area.

Methods: The reflex motor responses of 16 symmetrical leg muscles (m. biceps femoris, m. vastus lateralis, m. rectus femoris, m. medial head of the gastrocnemius, m. soleus, m. tibialis anterior, m. extensor digitorum brevis, m. flexor digitorum brevis) were evoked percutaneously by electric stimulation of the spinal cord at the L2- L3-L4 level in condition of rest (G.Courtine, S.J. Harkema, Ch.J Dy et al., 2007).

Results: The research revealed a significant decrease of multisegmental monosynaptic responses' (MMRs) maximal amplitude of the left and right m. soleus in comparison with that of healthy subjects. It testifies that in the background of the studied disorder it is reflex excitability of alpha-motor neurons of the muscles with the greatest amount of the slow motor units that is low. And m. soleus is the slowest of all and it is distal to the compression area.

It is evident that there is an electric impulse speed decrease in monosynaptic nerve circuits of the studied shin and foot muscles which are more distal in comparison with thigh muscles. It should be noted that all the muscles with statistically significant increase of the latent period of MMRs, compared with the control group parameters, have a similar function, they are all flexors either of shin, feet or toes, and besides they have a great number of slow motor units.

The significant increase of the MMRs' threshold for most of the studied muscles allows to assume that lumbar nerve compression mostly affects low threshold afferents of the corresponding peripheral nerves, innerving both proximal and distal leg muscles. The large muscles, regardless of their composition and function, have a higher degree of impairment.

Discussion: The results of the research allow to suppose the presence of a number of inter- and intra - muscle coordination peculiarities in the background of lumbar nerve compression. Consequently, they lead to a change of voluntary motor pattern.

THE EFFECT OF RESTRICTING THE PERCEPTUAL TASK IN TEMPORAL ORGANIZATION OF THE SWIMMING CRAWL: SURFACE CHARACTERISTICS

BRITO, C.A.F., BELVIS, W.C., OLIVEIRA, M.

UNIVERSIDADE MUNICIPAL DE SÃO CAETANO DO SUL (USCS)

Introduction: Research into motor coordination has sought to discuss the occurrence of temporal organization in motor skills, in order to understand the nature of their representations (variances and constants). However, there have not been studies that manipulate perception maintaining surface characteristics constant. This study's hypothesis was to see if there are significant differences between the flexible parameters of the crawl, maintaining the stroke's rhythm and distance after restricting the task in the field of perception. The objective of this study was to observe how restricting the ability to swim can influence the superficial parameters of the crawl.

Method: Descriptive and experimental methods were used. There was mixed random-systematic sampling among 5% of high-ability swimmers (n=6) from São Caetano do Sul enrolled with DETUR in 2008 (n=106). A Seiko chronometer watch with a 100 (25 meter) lap memory was used. The process was also filmed. Perturbation was carried out by light shone onto the retina, forming a configuration according to the degree of complexity (paper was used in swimming goggles), at a natural rhythm. The option of the parametric test statistic was allowed by verifying normality of distribution through the Kolmogorov-Smirnov test. Data were analyzed using Mauchly's Test of Sphericity and ANOVA was used for repeated measures (Contrast). Probability was 5% ($p<0.05$). Data were analyzed using SPSS.vs.13.0.

Results and Discussion: We observed significant differences ($p<0.05$) in the flexible parameters (time, speed, extent and swimming strategy) of the crawl after perception was manipulated, even when maintaining both the distance to be executed and what was considered a normal swimming rhythm. It thus confirmed our experimental hypothesis. No significant differences were observed (p≥0.05) in the frequency of movement due to restrictions, thus remaining a constant. This behavior has been observed in high-ability swimmers, but without perceptual restriction (Freudenheim et al., 2005). One possible explanation for this behavior is that these swimmers maintain the same rhythm in their structure due to their conscious perception of the environment (Capacity to determine parameters – Brito, 2008).

THE INFLUENCE OF RESTRICTING THE PERCEPTUAL TASK IN TEMPORAL ORGANIZATION OF THE SWIMMING CRAWL: SIGNIC REPRESENTATION

BRITO, C.A.F., BELVIS, W.C., OLIVEIRA, M.

UNIVERSIDADE DE SANTO AMARO (UNISA)

Introduction: Research into motor coordination has sought to discuss the occurrence of temporal organization in motor skills. Thus there has been an effort to understand this structure and discover the nature of its representations, in its variances and constants. The central task of this research was to describe how the behavior of swimming can be controlled (synchronization), but with its representation described after its action. The objective of this study was to observe signic representation in regard to its auto-organization after restricting visual perception.

Method: Descriptive and experimental methods were used. There was mixed random-systematic sampling among 5% of high-ability swimmers (n=6) from São Caetano do Sul enrolled with DETUR in 2008 (n=106). Perturbation was carried out by light shone onto the retina, forming a configuration according to the degree of complexity. The rhythm was called natural – six attempts for each swimmer. The symbolic representation was related through open questions (a structured questionnaire). All subjective reports were described in an individualized and separate form a week after the experiment. Subjective answers were grouped according to categories. The non-parametric correlation of Spearman's rho was used. Probability was 5% ($p<0.05$). Data were analyzed using SPSS.vs.13.0.

Results and Discussion: The results of this study corroborate the idea that temporal organization of the swimming crawl, in its varying aspects, is dependent on a perceptive structure in terms of its synchronization. This structure consciously and unconsciously exercises a function in its perceptual representation, as pointed out in motor behavior studies (Freudenheim, et al., 2005). We found a negative correlation (-0.812; p≤0.05) between the level of experience and its density in responses. While the correlation appears contradictory this field of perception was perceived differently, in its signic quality, to descriptions of forces and restrictions. A more experienced swimmer commented on difficulty in swimming in the second and third phases of the experiment and that in the fifth and sixth "there was almost no vision in the pool (…)", but only at the deep end, as pointed out in other studies (Brito, 2008).

A PHENOMENOLOGICAL STUDY ABOUT OCCURRENCE OF FACTORS FOR SENSUOUS CONSCIOUSNESS

SATO, M.

NUMAZU COLLEGE OF TECHNOLOGY

Introduction: An outward change of a movement is the central theme on that acquisition. For example, if a movement has three segmental structures such as A-part, B-Part, C-Part on that acquisition, then A-part will be learned at first, next B-part, and last of all C-part, and then each three parts will be combined together. And in the movement correction, a necessary part for a correction is taken out, then it is corrected and it is incorporated with other parts. However, a learner shapes his movement by sensuous consciousness. This sensuous consciousness is understood as Kineasthese in the meaning of phenolmenologist Husserl, E. (Husserl, 1973). Kineasthese is a coinage of Husserl, E.. Kaneko defines ability to generate such Kineasthese as ability for emergence or occurrence, and systematized the factor of this ability(Kaneko, 2005). Therefore, the aim of this study was investigated the development of some factors constituting a sensuous consciousness in a learning-process of the movement vertically.

Method: To clarify the development of these factors, Flick-flack by two beginners in artistic gymnastic was selected as object. And it was from 28th April 2004 till 10th September 2005 for the investigation period. I was used the questionnaire and VTR photography of learning situation as materials of an investigation. Four factors (image how about own body, image for execution result, image about the possibility to success of Flick-flack and the possibility of a movement correction) were investigated as questionnaire items.

Result: Two learners got possible to do stable execution finally. Until learner 1 and 2 reach stable execution, they showed three characteristic changes in this investigation. In these changes, they lost much ability in these factors by some causes.

Conclusion: Factors of a sensuous consciousness disappear and occur by various causes on acquisition of a movement. This shows at the same time that an acquisition of a movement can not be made up of mosaic from external viewpoint of the movement. Coaches, trainers and sport teachers should consider an internal point of view, especially a sensuous consciousness of athletes.

VIRTUAL GOLF PUTTING: CORTICAL ACTIVATION DURING REAL GOLF PUTTING COMPARED TO NINTENDO WII PUTTING PERFORMANCE

REINECKE, K., CORDES, M., LERCH, C., SCHUBERT, M., WEISS, M., BAUMEISTER, J.

UNIVERSITY OF PADERBORN

Purpose: Motor Learning in a virtual reality environment is often used in today`s surgical education as well as in rehabilitation settings. In this context video games like the Nintendo Wii system may also play a role in motor learning related to sports and exercise. While energy expenditure has been compared in virtual and real situations less is known about differences in cortical activity. EEG is able to observe the load of working memory related to focused attention (Theta frontal) and sensory information processing (Alpha 2 parietal). The aim of this pilot study was to examine differences of working memory functions between real and Wii based virtual sports situations using the golf putt as a model. Therefore EEG was measured during real and virtual putting in reference to resting situations in order to find an alternative training method for goal-directed sports performance like golf.

Methods: Ten male golfers (26.0±0.7 years; 81.8±5.6 kg; 184.5±6.0 cm; handicap 30.0±10.0; 2.9±1.0 years of golf experience) were asked to putt twice for 2min each in both the real and the virtual Wii situation. A rest in sitting position (2min) followed each performance.

Cortical activity was recorded continuously at 6 electrode positions using international EEG standards (10:20 System). Fast Fourier transformation determined power at two frequencies: Theta (4.75-6.75 Hz) at Fz, F3, F4 and Alpha-2 (9.75-12.5 Hz) at Pz, P3, P4. ANOVA with repeated measures was computed in a 2 (real/virtual) x 2 (performance/rest) x 2 (trials) design.

Results: Compared to virtual putting Theta spectral power was significantly higher during real performance at F3 (F1,9=9.618; p<.02; part. η²=.517) and F4 (F1,9=5.856; p<.04; part. η²=.394). In reference to rest Theta power demonstrated significantly increased values during performance at Fz (F1,9=18.191; p<.01; part. η²=.669), F3 (F1,9=19.012; p<.01; part. η²=.679) and F4 (F1,9=15.319; p<.01; part. η²=.630).

Increased Alpha-2 power during real and virtual performances compared to rest reached significant level at Pz (F1,9=6.063; p<.04; part. η²=.403), P3 (F1,9=6.260; p<.04; part. η²=.410) and P4 (F1,9=6.122; p<.04; part. η²=.413).

Conclusion: In the concept of working memory increased frontal Theta power generated in the anterior cingulated cortex (ACC) indicates higher focused attention. That may lead to the idea that the attention level during real putting seems to be higher. In contrast the quantity of sensory information processing inversely related to parietal Alpha-2 power showed no differences between real and virtual putting. Furthermore activational patterns during real and virtual performance were different compared to resting conditions. In summary there are some similarities in cortical activation patterns between putting on a green and with the Nintendo Wii system which may support the idea to use virtual performance as an alternative training method. Further studies are needed to confirm these first results.

STATIC AND DYNAMIC BALANCE BETWEEN GENDERS FROM 4 TO 18 YEARS OF AGE

CABEDO, J., UNNITHAN, V., GUERRA, M., ROCA, J.

UNIVERSITY RAMON LLULL

Introduction: To end of years 70, has been an increasing interest inside of psychology to observe the evolution of the different human capacities so as Baltes (1981) mentioned. The aim of this study was to look at the differences with respect to age and gender for static and dynamic balance in children and adolescents aged 4 to 18 years.

Method: A sample of 2420 subjects (1289 male and 1131 female) aged from 4 to 18 years old volunteered for the study. A one-leg static balance test and a Gesell dynamic balance test were performed to obtain balance data in both, males and females. Both gender groups were stratified by 1 year increments, starting from age 4 until 18 years old. Descriptive statistics and a one-way ANOVA for all stratified groups were run.

Results: The results demonstrated significant ($p<0.05$) gender differences for static balance at 11 y (male: 135.38 ± 6.07s vs female: 154.04 ± 5.52s). Meanwhile for dynamic balance gender significant differences ($p<0.05$) were found at: 12 y (male: 3.66 ± 1.68s vs female: 4.30 ± 2.25s), 13 y (male: 2.85 ± 1.46s vs female: 3.56 ± 1.75s), 14 y (male: 2.56 ± 1.34s vs female: 3.26 ± 1.74s), 15 y (male: 2.39 ± 1.05s vs female: 2.89 ± 1.07s), 16 y (male: 2.28 ± 0.99s vs female: 2.89 ± 1.30s), 17 y (male: 2.03 ± 0.94s vs female: 2.37 ± 0.82s), 18 y (male: 2.07 ± 1.02s vs female: 2.44 ± 1.43s).

Discussion: The results demonstrated significant differences in relation to static balance only at 11 years of age, where better balance was demonstrated in females compared to males. A different pattern of results emerged for dynamic balance, from 12 to 18 years of age, where statistically significant differences with regard to gender were identified for all age groups. All values for dynamic balance were greater in males compared to females. It is known that static balance is related to muscle strength, and dynamic balance to coordination. More research is needed to understand why so few differences exist between males and females from 4 to 18 years of age for static balance

THE BALANCE-MEASUREMENT-DISC: A NEW APPROACH TO STUDY POSTURAL CONTROL?

LIPPENS, V., NAGEL., V.

UNIVERSITY OF HAMBURG

Introduction: We consider balance to be understood as dexterous postural control in specific situations to facilitate suprapostural tasks (cf., e.g. Stoffregen et al. 2007). It is functional integrated as part of a broader information-movement coupling (Bootsma, 1998). Our experimental setting is founded on a review of studies under different approaches of postural control investigations (moving-room, moving-platform, multi-tasking, multi-link).

Method: In general, our experimental settings in investigating balance performance are similar to those of Stoffregen et al. (e.g., 2007), except that we prefer the more challenging postural control conditions on the balance disc (e.g., Lippens et al., 2008). The utilised data fusion employs the same principle as used in integrated navigation systems, e.g. of airplanes: It comprises a Kalman filter estimating the three Euler angles of the disc and sensor calibration values (Wagner et al., 2003). The dependend variables (tbal., n./RMSxyz) are proofed in an ANOVA.

Analysis/Discussion: On the basis of confirming results in experiment series (2005-2008) we are able to state: Postural sway on the balance-measurement disc is reduced to facilitate perceptual tasks. The adaptive coordination mode depends on specific constraints of person, task and environment (Newell, 1986). The conclusion of our research approach so far (cf., Adler et al., under review) will be discussed under the topics of quasi-static vs. dynamic demands, performance of younger vs. older adults, suprapostural- vs. dual-task, general ability vs. skilled adaptation. Finally, in an outlook we consider the aspects of advanced methods of data analysis (Gottschall et al., 2009).

PHYSICAL ACTIVITY RELATED TO CLUSTERED RISK FOR CVD IN CHILDREN

DENCKER, M., THORSSON, O., KARLSSON, M.K., LINDÉN, C., WOLLMER, P., ANDERSEN, L.B.
UNIVERSITY HOSPITAL MAS

Background: It is biologically plausible that risk factors for CVD cluster in an individual. This study evaluate if accelerometer measured physical activity predicts clustering of risk factors for CVD in children aged 8 to 11 years.

Methods: Cross-sectional study of 156 (81 boys and 75 girls) children aged 8-11 years, recruited from an urban population-based cohort. Total body fat mass (TBF) and abdominal fat mass (AFM) were measured by Dual-energy x-ray absorptiometry. Body fatness was expressed as TBF percentage of total body mass (BF%). Body fat distribution was calculated as AFM/TBF. Maximal oxygen uptake (VO2PEAK) was assessed by indirect calorimetry during a maximal exercise test and indexed for body mass (ml/min/kg). Blood was sampled and analysed for lipoprotein (LDL, HDL and total cholesterol) and triglycerid (TG) concentrations. Resting heart rate (HR), systolic and diastolic blood pressures (SBP and DBP) were measured. Daily physical activity was assessed by accelerometers for four days and daily accumulation of moderate and vigorous physical activity (MVPA) were calculated (defined as above 3500 counts/min with the actigraph accelerometer). Maturity was evaluated according to Tanner. Z-scores (Value for the individual-mean value for group)/SD were calculated. Sum of z-scores for BF%, AFM, AFM/TBF, SBP, DBP, HR, LDL, HDL, LDL/HDL quotient, total cholesterol, TG, and -VO2PEAK were calculated in boys and girls, separately, and used as an indices of clustered risk.

Results: Boys performed significantly more minutes of MVPA per day compared to girls (46±21 vs. 35±13, P<0.001). Person correlation between MVPA versus indices of clustered risk was for boys (-0.15, NS) and for girls (-0.31, P<0.05). Boys and girls were divided according to tertiles of MVPA. One-way ANOVA analysis indicated significant differences in sum of z-scores between tertiles of MVPA, in girls (P=0.006), whereas no significance could be observed for in boys (P=0.40, NS).

Conclusion: In this population-based cohort of children aged 8 to 11 years accelerometer measured minutes of moderate and vigorous physical activity per day predicted clustering of risk factors for CVD in girls aged 8-11 years, no such pattern could be observed in boys, which could be attributed to a higher physical activity level.

GENDER DIFFERENCES IN PHYSICAL ACTIVITY PATTERNS OF CHILDREN AGED 7-9 YEARS

NOTTLE, C., MCGALL, S.
WAIKATO INSTITUTE OF TECHNOLOGY

Introduction: With a decreasing opportunity for children to exercise a contributing factor for childhood obesity [1]; and previous reports of gender differences in activity patterns of children [2], the current investigation examined differences in physical activity patterns of New Zealand girls and boys aged 7-9 years. Activity patterns were examined during a period where the same opportunities to be active were present, and during a period of habitual activity.

Methods: Physical activity data was collect over 5 consecutive school days using Actigraph GT1M accelerometers (60 s epochs). Data from 24 girls and 25 boys recruited from two primary schools was obtained. Total activity counts for the break periods while at school (80 minutes) represented a period of equal opportunity to perform physical activity. Total activity counts for the 120 minute period immediately following school represented a period of habitual physical activity. Total minutes of activity performed for these time periods were determined for the thresholds counts: sedentary (<100), light (101-2999), moderate (3000-5200) and vigorous (>5200) activity [3]. Differences (p<.01) for total activity, and minutes spent in each threshold were assessed between genders (independent) and time periods (paired) using t-tests. All results are reported as means±SD.

Results: Significant differences between genders for total activity counts during the break and after school periods were recorded, with greater counts occurring during school breaks (boys: 1357±341; girls: 1024±320) compared with the after school period (boys: 885±361; girls: 683±224). Threshold analysis revealed gender differences for moderate activity only for both the school (boys: 7.6±4.1; girls: 4.9±3.2), and after school (boys: 5.5±4.7; girls: 2.8±1.9) periods. Sedentary activity was significantly lower and, light and moderate activity significantly higher for both genders while at school with compared with habitual activity after school. On average 9 and 15 minutes (5 and 8%) of the 200 minutes available was spent engaged in MVPA for females and males respectively.

Conclusions: The current results indicated that opportunity to perform activity while at school increased the total activity performed by children compared with habitual activity, with boys performing significantly more moderate activity than girls in both situations. Despite this however, less than 10% of the time available to be active was spent performing MVPA. Therefore, only a fraction of the 60 minutes of MVPA recommended for obesity prevention and a healthy lifestyle was performed in the time available.

THE RELATIONSHIP BETWEEN AGE, GENDER, BODY COMPOSITION AND CARDIO RESPIRATORY FITNESS IN STUDENTS AGED 8 – 11 YEARS BY USE OF FFMI – FMI REGRESSION MODEL

DELFAN, M., AGHA ALINEJAD, H., MIRZAEI RABAR, M., LOTFI, SH.

SHAHID BEHESHTI UNIVERSITY

Introduction: Age, gender, body composition and genetic affect on cardio respiratory fitness. Variability of physiological responses to exercise in children cause to different interpretation of the effective parameters (Welsman & Armstrong 1996).The aim of the present study was to investigate the association between cardio respiratory fitness and age, gender, body composition as solid, average or slender in students aged 8–11 years.

Methods: This cross sectional study was performed on 685 students (347 boys and 338 girls). Subjects were selected via a multi – level cluster sampling. After adjustment for differences in age, gender and body mass by FFMI – FMI regression model that Fat free mass index(FFMI)(dividing fat free mass to squared stature) predicted by fat mass index(FMI)(dividing fat mass to squared stature) stratified 3 group; Normal , Solid (higher amount of FFM than normal group) and Slender (lower amount of FFM than normal group)(Van Etten et al 1994). 20 m Shuttle run test used for estimation of maximal oxygen uptake (VO2peak) as an indices of cardio respiratory fitness that was expressed in absolute values.

Results: Our study showed solid group had upper values [(Boys: 8yrs =1/42; 9yrs =1/65; 10yrs =1/57; 11yrs =1/80 l/min)(Girls: 8yrs =1/27; 9yrs =1/54; 10yrs =1/44; 11yrs =1/51 l/min)] and slender group had lower values [Boys: 8yrs=0/98; 9yrs =1/05; 10yrs =1/26; 11yrs =1/23 l/min)(Girls: 8yrs =1/02; 9yrs =1/15; 10yrs=1/15; 11yrs =1/16 l/min)] in VO2peak even after controlling for age, gender and body mass($P<0.05$). There are positive significant association between age and VO2peak ($P< 0.05$) and boys were better than girls in cardio respiratory fitness (Boys=1/50 l/min; Girls=1/24 l/min)($P< 0.05$).

Discussion: The total FFM can be considered as the main functional mass which plays a keys role during physical activity (Goran et al 2000); Therefore increase in FFM/FM ratio cause to increase in VO2peak. Increasing VO2peak during growth in children can be explained by increasing muscle mass/body mass ratio and differing developmental stage of aspects of the oxygen transport system (Rowland 2005). Existing gender differences in VO2peak where boys had higher VO2peak than girls can be explained by differences in body composition, physical activity and heart size (Wilmor et al 2008; Fareed et al 2001).

ANTHROPOMETRIC PREDICTORS OF AEROBIC ENDURANCE IN 9-10 YEAR OLD SCHOOLCHILDREN

BODDY, L.M., STRATTON, G., HACKETT, A.F.

LIVERPOOL JOHN MOORES UNIVERSITY

Introduction: Levels of physical fitness in children have declined in recent years (Tomkinson et al., 2003). These declines may be mediated by the increased prevalence of obesity observed in children (Ortega et al., 2008). Conversely, in Liverpool, levels of aerobic endurance have declined in 9-10 year old children irrespective of BMI (Stratton et al., 2007). The aim of this study was to investigate the relationship between measures of body composition and a marker of aerobic endurance in 9-10 year old schoolchildren to further assess the relationship between measures of adiposity and fitness in children.

Methods: Body mass, stature, subscapular and triceps skinfold thicknesses, waist and hip circumferences, and performance on the 20 metre multi-stage shuttle runs test (20mMST) were collected using the SportsLinx (Taylor et al., 2004) field-based fitness testing sessions. 20mMST performance was used as a measure of aerobic endurance. Stature and body mass were used to calculate BMI. Data were available for 2675 (n = 1336 boys and 1339 girls) 9-10 year old participants. Multiple regression analyses were completed to assess the relationship between anthropometric variables and 20mMST separated by sex.

Results: For boys all anthropometric variables were negatively correlated with 20mMST performance (p≤ 0.01). Triceps (p≤ 0.01, B=-0.49 [S.E.= 0.11], β -0.08) and subscapular skinfolds (p≤ 0.01, B=-0.62 [S.E.= 0.13], β -0.22) were significant predictors of 20mMST performance and the model explained 24.6% of variance. For girls, all anthropometric variables were negatively correlated with 20mMST performance (p≤ 0.01). Triceps skinfolds (p≤ 0.01, B=-0.35 [S.E.= 0.08], β -0.17), subscapular skinfolds (p ≤ 0.01, B=-0.32 [S.E.= 0.08], β -0.17), and hip circumference (p≤ 0.05, B=-0.16 [S.E.= 0.08], β -0.1) were significant predictors of 20mMST performance in girls, the model explained 21.1% of variance. Waist circumference and BMI were not significant predictors of 20mMST performance in boys and girls.

Discussion: Declines in levels of cardiorespiratory fitness in children are often associated with increased adiposity. The findings of this study suggest that skinfolds are more important predictors of aerobic endurance, a marker of cardiorespiratory fitness, in 9-10 year old schoolchildren than BMI or waist circumference. Furthermore, the regression models explained a small proportion of variance, suggesting including variables other than anthropometrics may help improve the prediction of aerobic endurance in boys and girls.

STUDY ON LIFESTYLES OF A STUDENTS GROUP: "ACTIVE LIFE PLAN" UNDER EVALUATION.

MANZO, S., BORGOGNI, A., FALESE, L.

UNIVERSITY OF CASSINO

Introduction: The presentation is part of the study " Physical Activity and Active Lifestyle. A study on the relation between the practice of physical activity during the past (age 6 to 17) and current lifestyle; stimulus and crossing from "a completely inactive to an active lifestyle" .

The aim of the study is to investigates the current lifestyle and the practice of physical activity during the past (age 6 to 17) of a group of students of the University of Cassino and it is divided into two phases.

The aim of the presentation is to report some findings which emerge from a questionnaire submitted a group of 511 students and then to describe the process used in the second phase of the study.

Methods: The first phase involved students from some Faculties of the University; the questionnaire contains different sections, each of which treats a specific aspect (a lot of PA practice in the past and currently, the kind of PA and the perception relative to lifestyle and active lifestyle).

The second phase of the research consists of different steps and the aim is to build a Process called "Active life Plan" which may lead to an understanding of the perception of the current lifestyle and the individual approach to changes in lifestyle. This phase involved only a part of the students corresponding to the MET LOW profile emerging from IPAQ .

Each step was measured thanks to the completion of specific report cards relative to the aspects of the research

Results: Some of the findings which emerge from the questionnaire tend to show a correspondence between the continuity of activity (in school and outside school) in the past and the current perception of the level of health. The figures are significantly different for the higher levels of health (good and very good).

Relative to the second phase of the study, at the moment the data are being elaborated, but it is possible to highlight the perception relative to the strong motivation that every participant needed to have in order to follow the "Active life Plan".

Discussion: The data emerging from the firth phase of the research gives rise to study in depth about the theme of the study, useful for the realization of the Process.

The Process consists of different steps: in the first one, the student group was submitted to an evaluation of daily routine; in the second step, each aspect of daily routine was analyzed with the aim to develop a specific "Active Life Plan" for each person. The Plan consists of indications/advice on diet, everyday activity in relation to movement, and the achievement of small objectives like the numbers of the steps taken per day. In the third phase, the sample group had to carry out an evaluation of two weeks with the daily routine.

A COMPARISON OF ENDURANCE TESTS FROM 1982 TO 2007 FOR A COHORT OF NORWEGIAN ADOLESCENTS

DYRSTAD, S., KVINEN, C., BERG, T.

UNIVERSITY OF STAVANGER

Purpose: To compare results from a running test between 1982 and 2007 for high school students.Methods: Between 1982 and 2007 a total number of 1133 running tests were collected from one senior high school in Stavanger, Norway. The participants were 568 girls and 565 boys between 16 and 18 years, with the mean age of 17,0 years. The gravelled running trail was flat and 3050 m long. All tests were performed at the same time of year and collected by the same teacher. The test results were divided in three groups; tests from 1982-1989, 1990-1999 and 2000-2007. A one- way ANOVA test was used to reveal any difference between the groups. Results: The average running time for the girls was 16,32 (0,17 SE, n= 210); 16,39 (0,14 SE, n= 261); 17,21 (0,25 SE, n= 97) min in the 1980's, 1990's and 2000's respectively. The increase in running time from the 80's to the 00's was 5,5% ($p<0,01$). The average running time for the boys was 12,83 (0,11 SE, n= 244); 13,08 (0,14 SE, n= 184); 14,22 (0,22 SE, n= 137) min for the 1980's, 1990's and 2000's respectively. The increase in running time from the 80's to the 00's was 10,8% ($p<0,01$). In contrast to the girls, the boys had a greater difference in running time comparing the early 80's to the latest test years. Between 1982/83 and 2006/07 the increase in running time for boys was 13,3% ($p<0,01$, n=190). While 24% of the students in the 1980's did not carry out the test, the same number in 2000's was increased to 31%. The dropout number for girls and boys in the 2000's was 39 and 26%, respectively. Conclusion: The running time for the endurance tests for the boys in this cohort has increased around 11% for the last 25 years, which was twice the increase for the girls. The finding that the boys had a much greater increase in running time could be explained that the dropout number for girls were much higher compared to the boys. It might be the girls with the poorest endurance that missed the running test.

THE INFLUENCE OF MATURITY STATUS ON PRIMARY SCHOOL CHILDREN'S PHYSICAL ACTIVITY

FAIRCLOUGH, S.J.

LIVERPOOL JOHN MOORES UNIVERSITY

Gender differences in youth physical activity are commonly reported with boys accepted as being more active than girls (Riddoch et al., 2007). Usually these gender comparisons are made between boys and girls of the same chronological age or school grade. Recent studies have observed how gender differences in physical activity diminish between children and adolescents of the same biological age (Sherar et al., 2007). It is suggested that children's physical activity levels start to decline during the primary school years (Saris, 1986), but most studies of the effects of maturity status have focused on adolescents. The study purpose was to assess the influence of maturity status on primary school boys' and girls' self-reported and objectively measured physical activity.

One hundred and seventy five children (78 boys) aged 10.6 ± 3.1 y completed the PAQ-C and wore an ActiGraph GT1M accelerometer for 5 consecutive days (including two weekend days). Anthropometric measures were completed in order to estimate body composition and maturity status. Following initial exploration of gender differences in PAQ-C (t-test) and ActiGraph data (MANOVA), the analyses were corrected for maturity status using ANCOVA and MANCOVA.

Uncorrected analyses revealed that boys were significantly more active than girls according to the PAQ-C ($p < .0001$, $d = 0.67$) and ActiGraph (MPA: $p < .0001$, $d = 0.64$; VPA: $p < .0001$, $d = 0.91$; VVPA: $p = .002$, $d = 0.48$; MVPA: $p < .0001$, $d = 0.78$; cnt/min: $p = .006$, $d = 0.42$). After controlling for maturity status the differences in PAQ-C scores remained substantial ($p < .0001$, $d = 0.69$), but significant differences disappeared for ActiGraph data at all intensities ($p = .084$).

When the effects of maturity status were controlled there were no longer significant gender differences in objectively measured physical activity, but maturity status did not affect the PAQ-C data. Controlling for maturity status had the effect of reducing MPA, VPA, VVPA, and MVPA values in boys and increasing them in girls. Maturity status appears to influence objectively measured physical activity levels

among pre and peri-pubescent children and should be accounted for in the design of physical activity promoting strategies and initiatives.

COMPARISON BETWEEN SEOUL AND CHONAN CAMPUS'S RECOMMENDED LOCOMOTION ENERGY EXPENDITURE GUIDELINE OF SANGMYUNG UNIVERSITY

LEE, B.K., CHOI, D.H., KIM, J.H., IM, J.H.

1. SANGMYUNG UNIV, 2. SOGANG UNIV, 3. INJE UNIV, 4. KAIST

Purpose : The purpose of this study were to recommend locomotion energy expenditure guideline during walking and running at Seoul and Chonan campuses of SangMyung university.

Methods : The subjects(20 college students) were walked and run 2 rounds depend on their normal pace on Seoul and Chonan campuses. The length of Seoul campuses(585m), the one of Chonan campuses(1,235m) per rotation. The course of locomotion were decided for the circulation of campus. The subjects had been measured energy expenditure by accelerometer, heart rate by monitor(Polar), etc.

Results : The men's relative energy expenditure of Seoul campus were 0.070 kcal/kg/min on walking, and 0.180 kcal/kg/min on running. The ones of Chonan campus were 0.081 kcal/kg/min on walking, and 0.217 kcal/kg/min on running. The women's relative energy expenditure of Seoul campus were 0.071 kcal/kg/min on walking, and 0.182 kcal/kg/min on running. The ones of Chonan campus were 0.090 kcal/kg/min on walking, and 0.190 kcal/kg/min on running. In that case of normal Korean male college students(71kg) for 300 kcal, the walking, period was 60.4 minutes, and the rounds were 6.3 on Seoul campus. On normal Korean female college students(54kg) for 300 kcal, the running period was 29.2 minutes, and the rounds were 3.2 on Chonan campus. This recommendation should be adjusted depend on their weight.

Conclusion : The recommended locomotion energy expenditure guideline of University campus will be used for the composition of exercise and conditioning program.

LIFE-STYLE HABITS IN MALE AND FEMALE „WORLD GYMNAESTRADA" PARTICIPANTS

TAEYMANS, J., ZECH, S., DERIEMAEKER, P., AERENHOUTS, D., CLIJSEN, R., CLARYS, P., HEBBELINCK, M., CABRI, J.

1. UNIVERSITY COLLEGE PHYSIOTHERAPY

Aim: This study is a part of the "Gymnaestrada Health Project" (GHP), conducted at the „13th World Gymnaestrada" (Austria, 2007). The aim was to assess life-style habits (fruit and vegetables consumption (F&V), smoking (S) and physical inactivity (PI)) in „World Gymnaestrada" participants.

Methods: Out of 25000 gymnasts 325 males (M) and 948 females (F) volunteers were recruited during the one week event. F&V, S and PI were assessed using questionnaires. Daily F&V portions were summed. Participants were stratified in S and non-S groups. Time spent sitting per day was used as a proxy of PI. Parametric and non-parametric statistics were used for analysis. Significance was set at the 5% level.

Results: Although it was aimed to include subjects from all the participating countries, the majority of the volunteers came from German and English speaking countries. M (42.4±17.5 yrs) were younger than F (45.6±18.0 yrs) (p=0.005). Median daily F&V intake was 2.7 and 3.8 portions in M and F respectively (p<0.001). More than 5F&V portions a day were consumed by 20.0% of the M and 29.5% of the F. Low (0.07<Rho<0.11) significant correlations between age and F&V intake were observed in both genders.

A median time spent sitting of 4 hrs.day-1 was found in M and F (p>0.05).

Smoking frequencies in M and F were 17.0% and 12.4% respectively (p<0.001). Within and between gender groups, smokers had lower F&V intake than non-smokers (Medians: M(S)=2.0, M(non-S)=3.0, F(S)=3.0; F(non-S)=3.9) (all p≤0.004).

Discussion: To ensure healthy nutritional habits, a minimum intake of 5F&V portions per day has been proposed (1). About 20% of the M and 30% of the F participants met these recommendations. Compared to the 20% observed in a Swiss sample (M&F) (2), our findings indicated that more effort is needed to promote healthy nutritional habits even in a physical active population. Higher F&V in F than in M was also observed in the general population by other researchers (1). The positive relationship between age and F&V suggested that promotion of healthy nutritional habits should start already during childhood and adolescence.

Compared to the reference data of 2006 in Germany (M=43%, F=30%), smoking frequencies were considerably lower among GHP-participants (3). As in the general population we equally found a combination of unhealthy habits such as smoking and low F&V intake.

GHP-participants were importantly less inactive than the 74 M and 169 F adults of an Australian study (time spent sitting= 9.8±2.4 respectively 7.5±3.4 hrs.day-1) (4).

Conclusions: Compared to reference data GHP-participants (M & F) showed health enhancing life-style characteristics such as low time spent sitting, low smoking frequencies and somewhat higher F&V intake. However, further efforts are needed to promote F&V consumption to reach the "5-a-day" recommendations even in physical active individuals.

EVALUATION OF THE TRAINING CONCEPT "INHARMONY" ON RISK FACTORS FOR FALLS IN ELDERLY PEOPLE. A RANDOMIZED CONTROLLED TRIAL.

RUSTADEN, A.M., LOLAND, N.W., TORSTVEIT, M.K.

NORWEGIAN SCHOOL OF SPORTS SCIENCE

Introduction: Falls among elderly people are a serious and common problem. Several studies have shown that physical activity is one of the most important strategies to prevent falls, but the optimal type and dosage of activity still remains unclear (Gillespie et al. 2008). Therefore, the aim of this study was to determine whether the group-training concept "inHarmony" could reduce fall risk in elderly men and women over 65 years old.

Methods: The intervention, "inHarmony" with MBT-shoes, is a group-training concept with focus on dynamic balance, stability and strength. Sixty participants were recruited from the district Nordre Aker in Oslo, Norway, and randomized into the intervention group (n=30) or the control group (n=30) (walking). Both groups exercised 60 minutes twice a week for 16 weeks. Thirty-four participants completed the interventions; 20 in the intervention group and 14 in the control group. The main outcome variable was the short-form of PPA (Physiological Profile Assessment) (Lord et al. 2003), which provides a fall risk index score. Secondary outcome variables were dynamic balance and self-reported occurrence of falls.

Results: The intervention group and the control group experienced a 16,5 % (p=0,470) and 20,2 % (p=0,390) increased fall risk, respectively, after the intervention period. There were no significant differences in fall risk between the two groups after the intervention period (p=0,849). However, the control group obtained significant improvements in dynamic balance (p=0,006), while the intervention group had a tendency to improvements (p=0,052). There were no significant differences between the groups in dynamic balance (p=0,104). None of the groups experienced significant changes in fall occurrence, and there were no changes between the groups (p=0, 216).

Discussion: We found that "inHarmony" seem to have little influence on fall risk, dynamic balance or fall occurrence in elderly people. However, our participants may initially have been too active for the outcome variables. We also experienced a considerable drop-out, especially in the control group, which resulted in non-parametric analyzes. Furthermore, it would have been interesting to also include an inactive control group. Further studies investigating different types and dosage of activity are necessary.

RODRÍGUEZ-ROMO, G., GARRIDO-MUÑOZ, M., MAYORGA, J.I., LÓPEZ-DÍAZ, A.

TECHNICAL UNIVERSITY OF MADRID (UPM)

Introduction: For the design of strategies for overcoming barriers preventing physical activity, authors have declared the need to know the motivations for physical activity in the population (Booth et al, 1997; Sheppard et al, 2003). In the present work (Rodríguez-Romo et al, 2009) we analyze the motives and the barriers perceived by the population of the metropolitan area of Madrid for the practice of physical activity and/or sport in their free time. Also possible relationships are studied between the said motives and barriers and some of the sociodemographic variables that seem to have a greater incident on the physical activity practice levels and/or sport of the population of Madrid: gender, age and social status (Rodríguez-Romo et al, 2005).

Methods: For data collection a descriptive study with cross sectional design was used, utilizing a questionnaire administered through personal interview. The population studied consisted of residents of the metropolitan area of Madrid aged from 15 to 69 years. 625 people was selected, with a margin of error of the + 4% and a confidence interval of 95.5% for the whole population. The sampling was multistage and an ad hoc questionnaire was used. From the data a descriptive analysis and a non-parametric Chi-Square test were performed.

Results: Enjoyment (29.9%), maintenance of shape and condition (26.4%) and health (16.1%), were the motives for practice mentioned most frequently, showing differences according to participants gender [X2 (8) = 19.635; p = 0.009; IC95%: 0.007-0.011] and age [X2 (32) = 55.671; p = 0.006; IC95%: 0.005-0.008]. With respect to the abandonment of the practice, the family and labour demands (24.1%) and the lack of time (22.2%), were the most common causes. These causes were associated with age [X2 (24) = 36.955; p = 0.041; IC95%: 0.037-0.044] and, marginally, with gender [X2 (6) = 11.753; p = 0.069; IC95%: 0.063-0.074]. Finally, the most frequent motives for never having practiced were a lack of time (24.4%) and a lack of enjoyment (24.4%), these motives did not change with gender, age and social position.

Discussion: In our sample the practice of physical activity and sports was mainly recreational and however the maintenance and improvement of health and the acquisition of a good physical shape and condition was also important. The motives that control the practice of physical activity and to its abandonment are related to age and gender. On the other hand, the reasons for never having practiced are independent of the variables analyzed.

IMPROVED HEART RATE VARIABILITY AND ENDURANCE PERFORMANCE IN SEDENTARY SUBJECTS

NUMMELA, A., HYNYNEN, E., KAIKKONEN, P., RUSKO, H.

RESEARCH INSTITUTE FOR OLYMPIC SPORTS

Introduction: Recent studies suggest that the changes in heart rate variability (HRV) during night sleep could be used to evaluate the training load of the preceding day or cumulated training load of the preceding training period (Pichot et al. 2000; Hynynen et al. 2007). Furthermore, HRV changes may also be related to the changes in physical fitness (Hautala et al. 2004). The purpose of the present study was to investigate the individual performance and HRV responses to aerobic endurance training program in previously untrained subject.

Methods: Sedentary women (n = 12) and men (n = 12) trained four weeks three times per week at the average running intensity of 76 ± 4 % of their heart rate reserve. The R to R ECG-intervals were recorded and HRV indices including high frequency power (HFP) were calculated for the nights following the training days every week. Endurance performance characteristics were measured in incremental treadmill test performed before and after the 4-week training period. The subjects were divided into responders and non-responders according to the changes in the endurance performance (vVO2max). The responders were those subjects who improved vVO2max more than 0.5 km/h (n = 12) and the others were included in the non-responders (n = 12).

Results: The responders improved their vVO2max by 10.9 ± 4.6 % ($P < 0.001$) and no changes were observed in the non-responders (1.6 ± 3.0 %). In the responders nocturnal HFP was significantly higher during the fourth training week compared to the first training week ($P = 0.036$) but no changes were observed in the non-responders. Furthermore, a significant correlation was observed between the change in vVO2max and the change in nocturnal HFP ($r = 0.482$, $P = 0.042$).

Discussion: The 4-week endurance training program was enough to induce 11 % increase in endurance performance in the responders. Despite the same volume and intensity of training in all the subjects the individual training response in the vVO2max varied from -4 % to 21 %. The main result of the present study was that a relationship occurred between the changes in vVO2max and the changes in HFP during the 4-week endurance training period. It was concluded that similar training resulted in different performance responses, which were related to the changes in cardiac autonomic modulation during sleep. Monitoring nocturnal HRV seems to provide useful method in evaluating responses to endurance training and in building up a training program in sedentary subjects.

THE EFFECTIVENESS OF EXERCISE ON BODY COMPOSITION AND LUNG FUNCTION IN SEDANTARY WOMEN: CALLISTHENIC OR PILATES?

GUZEL, N.A., KARACAN, S., COLAKOGLU, F.F, BALTACI, G.

GAZI UNIVERSITY

Introduction: The aim of this study was to investigate that which type of exercise would be more effective either callisthenic or pilates to relationship between body composition parameters and lung functions including VC, FVC, FEV1, FEV1/VC, and FEV1/FVC in healthy sedentary women.

Methods

104 female participants were voluntarily participated for this study. 34 participants (mean age (X±SD): 41,7±7,8 years) were done callisthenic exercises 3 days/wk for six months, 26 participants (mean age (X±SD): 42,5±9,4 years) were done pilates exercise 3 days/wk for six months and 44 participants (mean age (X±SD): 40,9±7 years) did not take any exercises as control group. All subjects were evaluated pre-training, 3months, and post-training. Anthropometric and body composition (including fat mass (FM), fat free mass (FFM), and percentage body fat (%BF)) evaluated by using the skinfold methods and lung function was examined by using spirometry. 3rd and 6th months exercise periods differences were determined using One-Way ANOVA for repeated measures. Pearson correlation coefficient analyses were performed to analyze the relationship between dependent variables.

Results: There were significantly found a decrease in body weight, fat mass and body mass index values ($p<0.05$) after exercise period only callisthenic exercise group. Also there was significant increase of fat mass values of control group ($p<0.01$) Lung volume and capacity values (VC, FVC, FEV1, FEV1/VC, FEV1/FVC) of both exercise groups were increased significantly ($p<0.01$). There were negatively significant relationship between the body fat percentage and FVC and VC values of women ($p<0.05$, $r = -0.51$, $r= -0.42$) for pilates group; respectively. Also it was found that a negative correlation between BMI and FVC for pilates group ($r = -0.41$, $p<0.05$). There was only one negative correlation found between MVV and fat free mass for callisthenic group ($r = -0.40$ $p<0.05$).

Discussion: In conclusion, there were positive effects as evident on women lung volume and capacity both callisthenic and pilates exercises. This study showed that the decrease level of fat percentage, BMI and fat free mass after exercise would be affected the lung functions increment.

ARE GREEN ELEMENTS PRINCIPAL PULL FACTORS FOR PHYSICALLY ACTIVE COMMUTING?

SCHANTZ, P., WAHLGREN, L., STIGELL, E.

THE RESEARCH UNIT FOR MOVEMENT, HEALTH AND ENVIRONMENT

Purpose

The aim of this study is to further the understanding of how environmental factors relate to existing behaviours of walking between home and work/study place in urban settings. For this purpose physically active commuters rated their perceived experience of 10 environmental variables along their individual commuting routes. They also expressed whether the overall route environment stimulated or inhibited their commuting.

Methods: The commuters volunteered to participate in the study after being contacted through advertisements in two morning newspapers in Stockholm. A questionnaire was sent to 1950 persons. The response frequency was 93 %. 335 of the respondents walked in the inner urban area of Stockholm and constitute the basis for this study. The variables studied were exhaust fumes, noise, flow and velocities of motorized vehicles, respectively, congestion of pedestrians, incidence of conflicts between the individual and other road-users (including pedestrians), the extent of green elements, aesthetics, number of red lights, and the perceived distance. Semantic differential 15-point scales for responding were used. Whether the ratings of the environmental variables could explain to what extent the overall route environment stimulated or inhibited their commuting was tested with multiple stepwise regression analysis.
Results: The following variables were statistically significant in explaining variations in the ratings of whether the overall route environment stimulated or inhibited the respondents commuting: 1) aesthetics, 2) noise 3) green elements (nature, parks, trees, plantings). The multiple regression analysis built a regression equation of the form: Y = 5.78 + 0.52 x aesthetics – 0.18 x noise + 0.12 x green elements. The perceived levels of green elements correlated significantly with aesthetics (r=0.496).
Discussion/Conclusion: The present findings point to the importance of different environmental variables in stimulating/inhibiting bicycling commuting in urban areas. The fact that there was a strong correlation between green elements and aesthetics indicate that, to a great extent, green element may constitute the dimension of perceived aesthetics. In such case, green elements can be seen as a major pull factor for being physical active in this context.

LIFESTYLE AND HEALTH BEHAVIOURS OF UNIVERSITY STUDENTS

AL-NAKEEB, Y., DODD, L., NEVILL, A.
NEWMAN UNIVERSITY COLLEGE

Introduction: The onset of unhealthy behaviour is usually rooted during adolescence and young adulthood. The causes of premature morbidity and mortality are frequently attributed to risk behaviours such as inactivity, smoking, excessive drinking and unhealthy diet (Mokdad et al., 2004; World Health Organisation, 2002). It has been reported globally that university students engage in such behaviour (Steptoe et al., 2002). This study was designed to explore the prevalence and association of multiple risk behaviours among university students.
Methods: A total of 410 university students (mean age 22.8+5.8 years) from central England participated in a voluntary and anonymous survey in 2008. The study assessed students' actual health behaviours and perceptions regarding physical activity (PA), body satisfaction, smoking, illicit drug use, binge drinking, eating habits as well as socio-demographic variables.
Results: The prevalence of risk behaviours was high; over 81.7% did not exercise sufficiently, 66.3% ate less than five servings of fruits and vegetables, 56.9% reported binge drinking, 35% were regular or occasional smokers and 22% reported illicit drug taking. Based on Body Mass Index, a third of all students were classified as overweight or obese with half of the females and a third of the males reporting body dissatisfaction. Strong associations were evident between risk behaviours of inactivity, binge drinking, smoking and fatty diet. Generally, females showed slightly more positive patterns of behaviour than males and there were significant gender differences on binge drinking (Chi-Square=20.5; P<0.001), body dissatisfaction (Chi-Square=20.5; P=0.000) and PA (t=5.886, p=0.000). Males were more active than females and the most common form of PA was walking (75%). Although the average frequency of moderate and high level of PA reported over 7 days was just over twice a week, 65% of students considered themselves sufficiently active. This is below the recommended level of PA associated with health benefits (Haskell et al., 2007). While socialising appeared to be the main reason for risky behaviours like binge drinking, smoking and illicit drugs, time was the main barrier to exercise.
Discussion: Students tend to participate in multiple risk behaviours that appear to be associated strongly with socialising. Although unhealthy lifestyle is highly prevalent, it is disturbing to note that those students perceived their lifestyle and behaviours to be healthy. Addressing the health behaviours amongst student population requires programmes that promote behaviour modification, enhance healthy environmental conditions and target multiple risk behaviours.

RELATIONSHIP BETWEEN DAILY ENERGY EXPENDITURE AND BODY FATNESS, PHYSICAL FITNESS IN CHILDREN AGED 10-11 YEARS.

NAKAE, S., YAMADA, Y., KIMURA, M., SUZUKI, K., OZAWA, H., ISHII, K.
DOSHISHA UNIVERSITY

Introduction: The prevalence of childhood obesity is on the rise in many developed countries, and it has reached epidemic proportions. In Japan, an epidemiological annual survey revealed that prevalence of obesity in school children aged 6-11 y is approximately doubled over the last two decades. Moreover, physical fitness tests, which was authorized by the Ministry of Education, Culture, Sports, Science and Technology in Japan, disclosed that the overall physical fitness score of children have declined past two decades. Although environmental and cultural changes may be associated with physical inactivity in daily life, the causes of the current childhood obesity and low physical fitness epidemic are not clear. The purpose of this study was to examine the relationship between energy expenditure estimated by doubly labeled water (DLW) method and body fatness, physical fitness in children.
Methods: This research was performed on 30 healthy Japanese children (20 boys and 10 girls) in a public elementary school. The total energy expenditure (TEE) and % body fat were measured by the DLW method over a 6-day period. The physical activity-related energy expenditure (PAEE) was calculated as (TEE × 0.90) – predicted basal metabolic rate (pBMR) using the equation of the Recommended Dietary Allowances for Japanese (Health Promotion and Nutrition Division-Health Service Bureau Ministry of Health and Welfare 1995). The physical activity level (PAL) was also calculated as TEE/pBMR. The physical fitness tests consisted of grip strength, sit up, sit-and-reach, side steps, 20-m shuttle run, 50-m running, standing broad jump, and throwing a softball. Scores of each test were standardized, and total score was calculated as overall physical fitness score.
Results: The TEE was 8.41 ± 1.12 MJ/day (mean ± SD), the PAEE was 2.34 ± 0.85 MJ/day and the PAL was 1.61 ± 0.18. There were no significant relations between TEE, PAEE, PAL and % body fat. In contrast, TEE per weight (TEE/wt) and PAEE per weight (PAEE/wt) was significantly negatively correlated with % body fat ($r = -0.626$, $p < 0.01$; $r = -0.417$, $p < 0.05$, respectively). Most physical fitness tests scores

except for sit-and-reach test were positively correlated with TEE, TEE/wt, PAEE, PAEE/wt, and PAL. The PAEE/wt was most strongly correlated with overall physical fitness score ($r = 0.680$, $p < 0.01$).

Discussion: In this study, the significant negative correlation between body fatness and energy expenditure adjusted individual body size suggests that increasing energy expenditure is important for preventing obesity. Participants who were physically active showed high physical fitness scores. This result indicates that physical fitness tests may predict physical activity in children. It was suggested that physically active lifestyle would be necessary for childhood health.

TARGETED CAMPAIGN FOR MIDDLE-AGED MEN: THE ESSENTIAL ROLE OF RECRUITMENT

KINNUNEN, L., KOMULAINEN, J., SAARENTOLA, K., LÄHDESMÄKI, A., KAIVOSAARI, A.P., HAVAS, E.

LIKES RESEARCH CENTER FOR SPORT AND HEALTH SCIENCES

Introduction: The Fit for Life Program (KKI) inspires adults over 40 years of age to include physical activity in their daily routine. KKI planned and organized the Adventures of Joe Finn campaign to encourage sedentary Finnish middle-aged men to a healthy life-style. The campaign included a handbook of keeping fit, a website, physical training courses, combined courses on cooking and experimentation of different sports and, finally, the national Lorry Tour. The main partner of KKI was Etera Mutual Pension Insurance Company, which traditionally insures employees in branches dominated by men such as building trade. Among these men the risk of premature retirement due to disability is relatively high. It a great matter in which way then working class men could be recruited to health-enhancing programs.

Methods: Each Lorry Tour event took place at the market square being easily accessible. At KKI field lab the men (altogether 6100) had the test for the heart rate variation at rest, the hand compression force and body composition. There were 14 national cooperation partners offering additional health related information, material, advice and tests. Socio-economic status of men was verified by questionnaires.

Results: A magnificent amount of men (51 %) who participated in the Lorry Tours of the Joe Finn Campaign were working class employees of construction industry. These men received an invitation for the event from their employers, and they were allowed to attempt the event during their working hours. The men were slightly overweight having visceral fat too much and were strong enough.

Discussion: With regard to elements of targeted campaigns the following messages are important: 1) a low threshold to start exercise, 2) several advantages offered by sports and even minor physical activity is worthwhile and 3) the fun and adventure-aspect is emphasized rather than health aspects. The campaign managed to get targeted group into the events. The use of pension insurance company as a recruit tool was successful. Altogether, The Joe Finn campaign got ahold of planned population.

PHYSICAL ACTIVITY AND SPORT PARTICIPATION. A GENDER STUDY ABOUT OPPORTUNITIES AND THE INFLUENCE OF THE NEIGHBOURHOOD ENVIRONMENT

SILVA, P.,,3, BOTELHO-GOMES, P.,3, NOVAIS, C., PEREIRA, M., SANTOS, M.P.,2

1. UNIVERSITY OF PORTO - FACULTY OF SPORT

Introduction: Environmental factors may have an important influence on physical activity, but only recently have health researchers become interested in the environmental correlates of physical activity among adolescents. Several studies suggest that the decline of physical activity levels is more evident during adolescence, specially among girls, but little research has examined reasons for differences between boys and girls in commitments with physical activities and sports participation. The purposes of this study are to explore the potential presence of gender issues in the link between perceived neighbourhood environment and physical activity, and to verify the different opportunities for sport participation according to gender.

Methods: Semi-structured interviews were conducted with 54 adolescents from Porto (Portugal). Questions focused on boys and girls perceptions of neighbourhood environment in relation with sports and physical activity participation. All interviews were audio-recorded and transcribed verbatim. Data were analysed using content analysis after data being processed by the program QSRNVivo7.

Results: Participants reported that neighbourhood environment have to be pleasant and safe to promote participation in leisure-time physical activities. Moreover, adolescents that reported regular sports participation considered the quality of facilities and equipment available in the neighbourhood as a facilitator/inhibitor for physical activities. Adolescents also generate ideas about the existence of more opportunities for physical activity within the neighbourhood for boys, but the reasons pointed out by boys and girls were different. While girls reported a lack of opportunities for physical activity participation, boys considered that girls are less interested in sports and physical activity. Nonetheless, boys indicated that, when interested in physical activity and sports, girls might choose "female activities".

Conclusion: This study suggests the presence of gender difference in opportunities for sports and physical activity participation in the neighbourhood. Gender issues are related to adolescents' perceptions and with local community availability of physical activity programs and facilities.

This study was supported by grant FCT/PTDC/DES/72160/2006.

QUANTITY AND QUALITY OF PHYSICAL ACTIVITY IN 4TH GRADE STUDENTS.

IONA T., AMMENDOLIA, A., MINGANTI, C., CAPRANICA, L., PIACENTINI, M.F.

UNIVERSITY OF CATANZARO

Introduction: Physical activity in childhood is important as it may establish physical and psychological health benefits, but declines in children's physical activity are evident (Biddle 2004). The prevalence of overweight, measured by body mass index (BMI) at or above the 95th percentile for children, adolescents, and young adults of the same age and sex has increased dramatically, from 4% among those aged 6 to 11 years and 5% among those aged 12 to 19 years in 1963 to 1966 to 15% in 1999 to 2000 (Ogden 2002). Recommended physical activity guidelines (AAHPERD Publications 2004) differ according to age group: for children 5 and older (school-aged youth), children should accumulate 60 minutes to several hours of age-appropriate moderate to vigorous physical activity on 5 or more days of the week. The purpose of the present research was to study the quantity and quality of physical activity in 4th grade children of southern Italy and correlate it with anthropometric data, specific ability tests and rural or urban area's life.

Methods: One-hundred-ninety-six 8-9 years old Italian children engaged only in the 2-hr school (S) physical activity (n=96) or in additional extra-scholastic (n=100) sport (ES) activities were tested. Informed consent was obtained from each child and his/her parent(s) after explaining the purpose of the research and its contents. Anthropometric measures and EUROFIT and hip tests were collected following a standard protocol (Weiner and Lourie,1981). A MANOVA verified differences ($p<0.05$) between groups.

Results: No differences were observed in the test results between S and ES. However, MANOVA results showed that children who went in urban schools performed better than those who went in rural schools, (Wilk's Lambda (11;182)=3,284 p<0,001).In particular, the differences were observed in the tapping test, the shuttle run test and the standing long jump.

Discussions: The results of the present study show that 4th grade children who live in urban areas perform better than those who live in rural areas. Moreover, compared to children in the rural areas, the urban area children seem to perform less ES sport, meaning that school appears to be an important context for providing sports participation opportunities across metropolitan status therefore helping the children acquire the reported abilities. However, these data need to be implemented dividing children by typology of practiced sport.

CONTRIBUTION OF PHYSICAL ACTIVITY TO THE PREVENTION OR PROMOTION OF FALLS IN COMMUNITY-DWELLING ELDERLY

PEREIRA, C., BAPTISTA, F., INFANTE, P.

1. UNIVERSITY OF ÉVORA, 2. FACULTY OF HUMAN MOVEMENT, TECHNICAL UNIVERSITY OF LISBON, 3. UNIVERSITY OF ÉVORA

A fall could happen when demand of a particular task is higher than the person ability to perform it. In order to prevent falls, so frequently in elderly people, is essential to preserve or improve physical, sensorial and cognitive capacity to respond with success to task demands, even in hostile environment, or to reduce the number of tasks to accomplish, decreasing falls opportunity. However, an insufficient physical activity has a negative impact on health-related quality of life, including functional competence.Purpose: The main propose of this study was to analyze physical activity contribution to promote or prevent fall occurrence in older people. Methods: Participants were 506 community-residing old adults aged 50-89 yrs (390 women: 67.7±6.8yrs and 116 men: 69.6±6.6yrs), of which 31.2% were fallers. Body weight (BW) and height (BH), lower and upper body strength (LBS and UBS), lower and upper flexibility (LBF and UBF), agility (Ag), aerobic endurance (AE) and multidimensional balance (MB) were evaluated by the Fullerton batteries. Body fat mass percentage (BFM%) was evaluated by bioimpedence. Physical activity (PA), namely, vigorous, moderate, walking and total PA, was assessed by the International Physical Activity Questionnaire. Health status (HS), defined as the number of diseases and impairments, number of hazards environmental (HE), fear of falling (FES), educational level, and, falls occurrence in the last 12 months were estimated by questionnaire. A faller was identified as a person who felt at least once in the previous 12 months period.Results: Binary logistic regression identified the following predictors for falling: HE OR: 1.12, CI 95% (1.03,1.21); FES OR:1.13, CI 95% (1.05,1.21); HS OR:1.11, CI 95% (1.01, 1.23); MB OR: 0.94, CI 95% (0.91, 0.97); BFM% OR: 1.04, CI 95% (1.01,1.07); BW OR:0.98, CI 95% (0.97,1.00); vigorous PA OR: 1.051, CI 95% (1.016,1.087); total PA OR:0.981, CI 95% (0.966,0.997). Area under the roc curve was 0.745, CI 95% (0.700, 0.791). At a cut-off point of 0.30, sensitivity was 65.8% and specificity was 69.0%.Conclusions: HE, HS, MB, BFM%, BW, vigorous PA, total PA and FES were the most important predictors of fall occurrence. Total PA prevents falls occurrence, even in the presence of a high number of HE, a diminished HS, or a high BFM % and a low BW. Considering physical function, MB was a significant ability that contributes to decrease fall probability. Vigorous PA seems to increases fall probability, eventually due to demand elevation of performed tasks. This model based on tangible risk factors, was twisted by auto perception of the falling risk, evaluated by FES. A higher concerned about falling was related with a higher probability of falling. Thus, it appears that to be active in safety activities could prevent fall occurrence.

RESPIRATORY MUSCLE ENDURANCE TRAINING IN OBESE PATIENTS

VERGES, S., VILLIOT-DANGER, J.C., BOREL, J.C., WUYAM, B.

JOSEPH FOURIER UNIVERSITY AND GRENOBLE UNIVERSITY HOSPITAL,

Introduction. Obese patients frequently experience dyspnoea that is usually charged to extra respiratory muscle work, due to reduced chest wall compliance. However, little is known regarding the role of respiratory muscles in dyspnoea and exercise tolerance.

Objective. The aim of this study was to determine the effects of respiratory muscle endurance training (RMET) in obese patients.

Methods. We investigated 20 patients hospitalized who followed a low caloric diet and a physical activity program. Subjects were overweight with BMI > 30 kg.m-2, without respiratory or heart diseases, muscular and skeletal disorders and diabetes. The exercise group (EXP n=10) carried out 10±2 RMET sessions (30 min of voluntary normocapnic hyperpnoea) over 3.3±1.0 weeks. The control group (CON

n=10) did not perform specific respiratory muscle training. We measured before and after training BMI, dyspnoea (MRC questionnaire), lung function, respiratory muscle strength and endurance, exercise tolerance (6 min walking test) and quality of life (SF 36 questionnaire).

Results. Respiratory muscle endurance was significantly improved in EXP group (+52±27.3%; EXP vs CON p<0.001) while respiratory muscle strength did not change (p>0.05). Exercise tolerance was significantly improved in EXP group (+54±34.9 m; p<0.006). Dyspnoea was significantly reduced in EXP group (-1.9±0.9 pts; p<0.047). Quality of life was significantly improved in EXP group (+70±30 pts; p<0.001).

Conclusions. This preliminary study suggests that RMET improve respiratory muscle endurance, dyspnoea, exercise tolerance and quality of life in obese patients. RMET could complete nutritional readjustment and standard physical activity program but further studies are needed to confirm these data.

EFFECTS OF MAXIMAL STRENGTH TRAINING ON ROLLER SKI DOUBLE POLING PERFORMANCE IN TWO HIGHLY TRAINED ELDERLY, MALE CROSS-COUNTRY SKIERS

KRISTOFFERSEN, M., WELDE, B., INGVALDSEN, R.P..

1. DEPARTMENT OF SPORT AND PHYSICAL EDUCATION, BERGEN UNIVERSITY COLLEGE, BERGEN, NORWAY, 2. DEPARTMENT OF SPORT AND PHYSICAL EDUCATION, NORTH-TROENDELAG UNIVERSITY COLLEGE, LEVANGER; NORWAY

Introduction: The effect of maximal strength training with emphasis on improved 1RM on cross-country ski performance is reported (Hoff et al. 2002), but none has so far investigated this in highly trained elderly, male cross-country skiers. The aim of this study was to investigate the effects of maximal strength training in highly trained elderly male skiers on a) double poling performance at short and long distances on roller skis and, b) maximal and submaximal strength.

Methods: Two highly trained male cross-country skiers (60 yr, maximal oxygen uptake (VO2max) 58 and 50mL kg-1 min-1) participated in this study. The subjects had long experience with endurance training, but little experience with strength training. A pretest-posttest design was applied, with a nine week training intervention period between. Strength training and testing was carried out using a modified cable pulley, designed to simulate the double poling technique on roller ski. Force parameters were measured using a force tranducer. Strength training was performed three times a week for nine weeks. The endurance training during the experiment was the same as the last two months before the experiment. Tests performed in pre- and posttest were: 1) one repetition maximum (1RM) in the cable pulley, 2) peak force (PF80) and time to peak force (TPF80) with a workload at 80% of 1RM in pretest, 3) maximal number of repetitions with a workload at 60 and 80% of 1RM in pretest (rep60, rep80), 4) VO2max during treadmill running, and 5) performance tests on roller skis a) 50 m double poling, b) 1.5 km double poling and c) 7.8 km double poling . Accumulated oxygen uptake was measured during the last two roller ski tests. In posttest, PF, TPF, and maximal repetitions with a workload at 80% of 1RM in posttest were measured.

Results: 1RM improved with 35 and 20% in the two subjects. Rep60 improved from 305 to 463 and from 97 to 490 reps, respectively for the two subjects, and rep80 improved from 27 to 77 reps, and from 18 to 78 reps. Maximal repetition whit a workload at 80% of 1RM in posttest was 29 and 35. Minor changes in PF and TPF, as well as accumulated oxygen uptake, were found from pre- to posttest. There was no change in VO2max during treadmill running from pre to post-test. Both subjects had an improvement in all performance tests on roller skis: 50 m (0.47 and 0.21 sec), 1.5 km (6.5 and 8.0 sec), and 7.8 km (40 and 37 sec).

Discussion: It is concluded that maximal strength training with emphasis on improved 1RM, may improve endurance performance in highly trained elderly skiers without changes in VO2max or accumulated VO2. The improvements in strength, submaximal strength and the roller ski performance seemed to be related to the increased in strength per se, and not to changes in PF or TPF.

PEAK CARDIORESPIRATORY ASSESSMENT IN OVERWEIGHT PREPUBESCENT CHILDREN

FERNANDES, R., BRITO, J., CONCEIÇÃO, A., LOURO, H., MAGALHÃES, N., SILVA, A.,3

1. SPORTS SCIENCES RESEARCH LABORATORY, SPORT SCHOOL OF RIO MAIOR, POLYTECHNIC INSTITUTE OF SANTARÉM, PORTUGAL

Introduction: Over the past 30 years, the preponderance of overweight youth has increased (1), this, in part, has been attributed to a decline in physical activity among children and adolescents (2). In order to evaluate peak cardiorespiratory function and accurately prescribe endurance exercise, VO2max and Ventilatory Anaerobic Threshold (VAT), when available, should be assessed (4). The first one indicates the functional capacity of cardiorespiratory function and is often considered as the benchmark indicator of cardiorespiratory fitness (3) and the second one provides a better index of aerobic performance. The purpose of this study was to compare peak cardiorespiratory parameters during a treadmill test between groups of prepubescent children with different Body Mass Indexes (BMI).

Methods: The sample was composed of 33 children and was divided into three groups according to BMI cut-off points proposed by Cole et al. (2000): 11 Non Obese (age: 11,55 ± 0,52; weight: 42,60 kg ± 5,64; BMI: 18,22 ± 1,20), 11 Overweight (age: 11,27 ± 0,64; weight: 50,98 kg ± 5,82; BMI: 22,21 ± 1,05) and 11 Obese (age: 10,91 ± 0,54; weight: 58,49 kg ± 11,05; BMI: 27,96 ± 2,30). A maximal, progressive and incremental test using ergo-spirometry procedures (Cosmed® k4b2) was selected to tested in laboratorial context. Heart rate was measured with the Polar S610. The comparison and descriptive data was analyzed between the groups (SPSS, ver.15.0).

Results: All groups show significant differences in weight and BMI measures. Significant differences were observed for the VAT parameter between Overweight (OV) and Obese (O) group and for the VO2max/kg parameter between Non Obese (NO) and O groups. The VO2max/kg has an inversely relation to the BMI parameter in this groups (NO – 53,18 ml.kg.min-1; OV – 50,48 ml.kg.min-1; O – 46,90 ml.kg.min-1).

Conclusions

The cardiorespiratory condition inversely relates with the body mass and the BMI could be an indicator of the cardiorespiratory status of children.

MEASUREMENT OF CHILDREN'S PHYSICAL ACTIVITY FROM THE WRIST

VIRTANEN, P.
POLAR ELECTRO OY

According to questionnaires children's everyday physical activity has diminished. Objective measurements of children's physical activity as well as technical solutions are needed. Accelerometers have been used in several researches to evaluate oxygen consumption and physical activity. The researches have, however, so far focused on validating devices developed for the measurement of adults. The objective of this research was to create a method based on acceleration measurement on the wrist to evaluate 6-15 y old children's oxygen consumption and physical activity. We wanted to find out how accurately different intensities of children's physical activities could be recognized. Also the effect of children's demographics to the measured acceleration signals and parameters was examined.

Twenty 6-15 y old children were measured in twelve activities using uniaxial acceleration measurement. Simultaneously oxygen consumption was measured with portable analysator (Viasys, Oxygon Mobile). The activities were divided in three classes: 1) sitting activities (sitting on a chair, lego playing, pc playing and table icehockey playing – all activities lasted 5 min); 2) interrupted moving (backpack packing, rope jumping, football dribbling, basketball dribbling – all lasted 5 min); and 3) walking & running. Walking and running were both performed with two speeds on a treadmill. All measurements were performed in laboratory conditions. The acceleration data was transferred to Matlab software and transformed into MET units. The results were compared with those of the gas analysator.

Height of the children was the best demographic parameter to adjust the oxygen consumption evaluated from the acceleration signal. In the sitting activities the METs evaluated from acceleration were (mean±SD): sitting on a chair 1.3±0.0 MET, lego playing 1.5±0.2 MET, pc playing 1.3±0.0 MET, and table icehockey playing 1.5±0.6 MET. In the interrupted moving the MET values were: backpack packing 2.8±0.4 MET, rope jumping 6.7±2.3 MET, football dribbling 7.4±2.5 MET, and basketball dribbling 7.6±2.6 MET. In walking the values were on the average 3.1±0.6 MET and in running 7.0±1.4 MET. METs evaluated from the acceleration signal and calculated from oxygen consumption differed in sitting activities -0.03±0.36 MET. The correlation coefficient was 0.31. In interrupted moving the difference was -0.01±1.19 MET and correlation 0.91. In walking and running (results combined) the difference between evaluated and calculated MET values was 0.10±1.00 MET and correlation 0.91. When METs of all the twelve activities were taken into account, the difference between evaluated and measured values was

-0.07±0.092 MET and correlation 0.95.

It seems that measuring acceleration from the wrist and classifying the activities suits well to evaluate 6-15 y old children's oxygen consumption. Oxygen consumption evaluated from acceleration correlates well with the measured values.

SMOKING CESSATION SHOULD BE ACCOMPANIED BY LIFESTYLE INTERVENTIONS IN PATIENTS WITH RHEUMATOID ARTHRITIS

STAVROPOULOS-KALINOGLOU, A., METSIOS, G.S., KONTIS, V., JAMURTAS, A.J., KOUTEDAKIS, Y., KITAS, G.D.
UNIVERSITY OF WOLVERHAMPTON

Background: Rheumatoid arthritis (RA) is associated with altered metabolism leading to muscle wasting. In the general population cigarette smoking is known to affect body composition by reducing fat and inhibiting muscle synthesis. Even though smoking has been implicated in the pathophysiology and progression of RA, its possible effects on body composition of such patients have not been studied. This cross-sectional study aimed to identify potential associations of smoking with body weight and composition of RA patients.

Methods: A total of 392 patients (290 females) with RA were assessed for body mass index (BMI), body fat (BF), fat-free mass (FFM) and waist circumference. Erythrocyte sedimentation rate, C-reactive protein, Disease Activity Score-28 and Health Assessment Questionnaire were used to assess disease activity and severity. Smoking habit (current smoker: CS; ex-smoker: XS; never-smoker: NS) and intensity (pack-years) were also noted.

Results: CS (male: 25.8, 95% CI: 24.1 – 27.6; female: 26.1, 95% CI: 24.5 – 27.9) had significantly lower BMI compared to XS (male: 28.4, 95% CI: 27.3 – 29.5, $p<0.001$; female: 28.6, 95% CI: 27.4 – 29.7, $p<0.05$) and NS (male: 27.6, 95% CI: 25.9 – 29.2; female: 27.5, 95% CI: 26.6 – 28.4; $p<0.05$ for both genders). Similarly, BF of CS (male: 24.5, 95% CI: 21.1 – 27.9; female: 35.9, 95% CI: 33.4 – 38.3) was lower compared to that of XS (male: 28.8, 95% CI: 26.7 – 30.9, $p<0.001$; female: 39.2, 95% CI: 37.8 – 40.6, $p<0.05$) and NS (male: 27.8, 95% CI: 25.7 – 29.7, $p<0.001$; female: 38.1, 95% CI: 36.9 – 39.2, $p<0.05$). FFM did not differ between groups ($p>0.05$ in all cases). Finally, CS (male: 100, 95% CI: 95.4 – 104.6; female: 90.8, 95% CI: 86.8 – 94.8) had significantly smaller waist circumference only compared to XS (male: 106.2, 95% CI: 103 – 109.4, $p<0.001$; female: 98.6, 95% CI: 95.7 – 101.4, $p<0.05$). Following adjustments for age, disease duration and HAQ, smoking remained a significant predictor for BMI ($p<0.001$), BF ($p<0.05$) and waist circumference ($p<0.05$). Pack-years were inversely correlated with BF ($r=-0.46$; $p<0.001$) and heavy smokers exhibited significantly lower FFM ($p<0.05$) compared to all other participants.

Conclusions: Within the limitations of a cross-sectional study, it appears that cigarette smoking associates with reduced BMI and BF in patients with RA and heavy smoking associates with lower muscle mass. Smoking cessation appears to associate with increased BMI, BF and waist circumference in these patients. These results should be confirmed in prospective studies. Given the numerous adverse effects of smoking on general health and RA, patients should be actively advised against it. However, smoking-cessation regimes in RA may need to include more general lifestyle counselling particularly about weight control.

WHAT IS THE CLINICAL COURSE OF ACUTE ANKLES SPRAINS? A SYSTEMATIC LITERATURE REVIEW

VAN RIJN, R.M., VAN OS, A.G., BERNSEN, R.M.D., LUIJSTERBURG, P.A., KOES, B.W., BIERMA-ZEINSTRA, S.M.A.

ERASMUS MC

BACKGROUND: Ankle sprains are one of the most common musculoskeletal injuries. In order to evaluate the effectiveness of therapeutic interventions and to guide management decisions, it is important to have clear insight of the course of recovery after an acute lateral ankle injury and to evaluate potential factors for nonrecovery and re-sprains.

METHODS: A database search was conducted in MEDLINE, CINAHL, PEDro, EMBASE, and the Cochrane Controlled trial register. Included were observational studies and controlled trials with adult subjects who suffered from an acute lateral ankle sprain that was conventionally treated. One of the following outcomes had to be described: pain, re-sprains, instability, or recovery. Two reviewers independently assessed the methodological quality of each included study. One reviewer extracted relevant data.

RESULTS: In total, 31 studies were included, from which 24 studies were of high quality. There was a rapid decrease in pain reporting within the first 2 weeks. Five percent to 33% of patients still experienced pain after 1 year, while 36% to 85% reported full recovery within a period of 3 years. The risk of re-sprains ranged from 3% to 34% of the patients, and re-sprain was registered in periods ranging from 2 weeks to 96 months postinjury. There was a wide variation in subjective instability, ranging from 0% to 33% in the high-quality studies and from 7% to 53% in the low-quality studies. One study described prognostic factors and indicated that training more than 3 times a week is a prognostic factor for residual symptoms.

CONCLUSIONS: After 1 year of follow-up, a high percentage of patients still experienced pain and subjective instability, while within a period of 3 years, as much as 34% of the patients reported at least.

THE EFFECT OF 6 WEEKS OF WHEELCHAIR EXERCISE ON FUNCTIONAL RECOVERY AND HEALTH-RELATED QUALITY OF LIFE IN STROKE PATIENTS

SONG, W.

SEOUL NATIONAL UNIVERSITY

The purpose of this study was to investigate the effects of wheelchair exercise on functional recovery and health-related satisfaction in stroke patients.

Subjects for this study were stroke patients at a chronic stage (more than 10 months since onset of stroke) and they were divided into 2 groups. Control group was composed of 5 patients who participated in a central nervous rehabilitation program which was routinely applied for stroke patients and the wheel chair exercise group was composed of 12 patients who participated in a wheelchair exercise as well as central nervous rehabilitation program.

Body composition and the functional recovery factors consisted of muscle strength (grip strength), muscle endurance (chair stand test and arm curl test), flexibility (chair sit-and-reach test), agility (reaction time) and PASS (Postural Assessment Scale for Stroke) have been measured. The health-related satisfaction factors were also measured using SF-36 which tests self perceived changes in health. The wheelchair exercise carried out at a seated position was composed of aerobic and resistance exercise with music and thera-band, respectively. The exercise program was composed of warm up (10 min), main exercise (40 min) and cool down (10 min) and performed 5 days per week for 6 weeks. The intensity of exercise was 60~70% of HRR (Heart Rate Reserve) and RPE (Rate of Perceived Exertion) 11~13. All exercise session throughout entire intervention period was carefully monitored and supervised by clinical exercise physiologist.

All the data were analyzed by 2 x 2 ANOVA with repeated measures using SPSS (Version 14.0) and the statistical significance was accepted at the level of $P<0.05$.

Our results showed that there was no significant difference in body composition including muscle mass, fat mass, and visceral fat mass between 6 weeks of wheelchair exercise group and control group. However, most of the functional recovery factors such as muscle strength ($p=0.023$), muscle endurance ($p=0.021$), flexibility ($p=0.028$), and PASS ($p=0.022$) were significantly improved in wheelchair exercise group compared to control group. In addition, among the factors of SF-36 as a measurement of health-related satisfaction, emotional health was significantly improved ($p=0.031$) in wheelchair exercise group compared to control group and most of other factors including energy, social functioning, and general health showed the tendency to increase after 6 weeks of wheelchair exercise participation although statistically not significant due to the limited numbers of participants.

In conclusion, our current findings suggest that 6 weeks of wheelchair exercise improves functional recovery including muscle strength, muscle endurance, flexibility, and PASS as well as health-related satisfaction in chronic stage stroke patients.

SELF-RELATED HEALTH, PHYSICAL ACTIVITY, BMI AND MUSCULOSKELETAL COMPLAINTS - A COMPARISON BETWEEN FOREIGN AND SWEDISH HIGH SCHOOL STUDENTS

ALRICSSON, M., KAHLIN REICHARD, Y., WERNER, S.

SWEDISH WINTER SPORT RESEARCH CENTRE

Background: Physical activities during leisure time and school hours as well as nutritional habits have changed over the past years by adolescents being less physically active and adopting a sedentary life-style. Aim The aim of the present study was to investigate possible differences between foreign and Swedish high school students in terms of self-related health, physical activity, overweight and possible complaints from the musculoskeletal system.

Methods: 1090 high school students, 450 with foreign background and 640 with Swedish background, aged 16-26 years answered a questionnaire.

Results: A higher percentage of students with foreign background reported poor self-related health compared to students with Swedish background (p= 0.038). Students with foreign background were to a greater extent more physically inactive than students with Swedish background (p= 0.003). There were no differences between students with foreign background and students with Swedish background regarding musculoskeletal complaints. Students with foreign background were more often overweight than students with Swedish background and overweight was more frequent among males than females. Physical activity (moderate and high level) was concluded to be a factor with significant positive effect on self-related general health (moderate level p= 0.042, high level (p< 0.001) and musculoskeletal complaints were
negative factors on self-related general health (p< 0.001).
Conclusion: Based on these results it is suggested that adolescents with foreign background should participate in physical activity in order to prevent overweight and thereby improve physical health.

STRENGTH TRAINING AND THE MENSTRUAL CYCLE: EFFECTS OF FOLLICULAR- AND LUTEAL PHASE-BASED TRAINING ON MUSCULAR STRENGTH AND MUSCLE DIAMETER IN SUBJECTS WITHOUT ORAL CONTRACEPTION

SUNG, E., HAN, A., HINRICH, T., PLATEN, P.
RUHR-UNIVERSITY BOCHUM

Purpose: The follicular and the luteal phase of the menstrual cycle (FO and LU) are characterized by a certain profile of different hormones. Menstrual cycle specific regulation of many hormones is not clear so far. This is especially true for the interaction between estradiol (E2), hGH, and IGF-1, all of them possible anabolic hormones on the level of the muscular cell and therefore important supporting factors during strength training. We, therefore, investigated possible different effects of follicular phase-based versus luteal phase-based strength training (FT and LT) on strength parameters and muscle volume.
Methods: 16 healthy eumenorrheic untrained or moderately trained women (age: 24.9 ± 4.8 yrs, height: 162.5 ± 5.3 cm, weight: 56.7 ± 5.1 kg) completed a strength training program of the m. quadriceps femoris for each leg on the Leg Press for 3 menstrual cycles (approx. 12 weeks). The subjects were divided into group A and group B. Group A performed FT with the right leg and LT with the left leg and vice versa for Group B. FT was organized 4 times a week in FO and once in LU, and LT was organized 4 times a week in LU and once a week in FO. Blood samples were taken on 11th day in FO and on 25th day in LU of menstrual cycle to analyze values of E2, progesterone (Prg), FSH, LH, total testosterone (tT), free testosterone (fT), IGF-1, DHEA-S and hGH. Maximum isometric force (Fmax-iso) was measured for each right and left leg prior to, during (2 times per cycle), and after training. Muscle diameters (Mdm) were measured by means of ultrasound for M. quadriceps prior to and after training, and sum of Mdm of M. rectus femoris, M. vastus intermedius and M. vastus lateralis was calulated.
Results: LH, FSH, tT and fT were significant higher in FO as compared to LU, Prg was higher in LU, and E2, DHEA-S, hGH, and IGF-1 were not significantly different between the two phases. Fmax-iso increased significantly by 26.1 ± 11.6 kg (+43.9 %) after FT and by 19.3 ± 10.3 kg (+32.9 %) after LT. The increase of Fmax-iso after 3 month of follicular-based strength training (FT) was significantly greater than the increase after luteal-based training (LT). We found a clear trend (p=0.07) for a higher increase of Mdm after FT as compared to LT (+0.67 ± 0.55 cm (+ 11.7 %) vs. +0.46 ± 0.38 cm (+7.7 %) after FT and LT, respectively).
Conclusions: FT clearly showed more pronounced effects on muscle strength and muscle diameter as compared to LT. This is probably due to the specific hormonal milieu during each phase of the cycle. Further studies including detailed analysis of the hormonal profile though the menstrual cycle are needed in order to understand the underlying mechanisms on the cellular and molecular level of the skeletal muscle.
The study was supported by BISP, Bonn (IIA1/070110/08).

ASYMMETRIES IN MUSCLE RECRUITMENT PATTERNS IN ACLR AND HEALTHY SOCCER PLAYERS DURING HIGH INTENSITY RUNNING

PATRAS, K., ZIOGAS, G., RISTANIS, S., TSEPIS, E., STERGIOU, N., GEORGOULIS, A.D.
ORTHOPAEDIC SPORTS MEDICINE CENTER, UNIVERSITY OF IOANNINA

BACKGROUND: In response to accumulating metabolic fatigue there is a change in muscle recruitment pattern resulting in enhanced EMG activity. Muscles increase their EMG amplitude and/or shift their EMG frequency content towards higher frequencies [1, 2]. However, recent studies have shown that the neuromuscular response to fatiguing exercise, following ACL reconstruction is altered [3].
PURPOSE: The aim of the present study was to evaluate the time course of EMG variables indicating muscle recruitment patterns in a group of ACL reconstructed and healthy soccer players.
METHODS: We evaluated 14 ACL reconstructed soccer players 1-3 years post-operatively and 14 healthy control soccer players. ACLR players had anterior tibial translation difference between reconstructed and intact leg less than 2mm, Tegner activity score 8 and Lysholm score 99. Athletes performed a 10 minute run at intensity ~90% of their VO2max with expired gas analysis. Blood lactate was measured at baseline and at end-exercise. EMG data were recorded at the 3rd, 5th, 7th, and 10th minute from muscles vastus lateralis and biceps femoris bilaterally with a telemetric EMG system. The dependent variables examined were the peak EMG amplitude and the total energy of the high frequency components (>90Hz, HE) of the power spectrum. Repeated measures ANOVA's were used to compare the time course of the EMG variables between legs.
RESULTS: ACL reconstructed group run at 87.6(4.4) %VO2max and control group at 88.7(3.1) %VO2max. End-exercise blood lactate values were 7.6(1.7) mM and 7.9(1.6) mM respectively. For vastus lateralis muscle peak EMG amplitude increased for both the control and intact leg but not the reconstructed leg (F=4.26, p=0.008 and F=6.74, p=0.001 respectively). HE tended to increase for both the control and intact leg but not the reconstructed leg (F=3.97, p=0.011 and F=2.81, p=0.052 respectively). For biceps femoris muscle there was an increase in peak EMG amplitude only when the ACL reconstructed group was considered (F=4.26, p=0.011). HE increased significantly for each of the tested legs and there was no significant interaction.
CONCLUSION: While for both the control and intact leg there was an enhanced EMG activity in order to compensate for the accumulating fatigue, the reconstructed leg shows an inability to alter muscle recruitment patterns. This may indicate greater fatigability for the vastus lateralis of the reconstructed leg. For biceps femoris, both groups showed signs of enhanced EMG activity but this was more pronounced only for the ACL reconstructed group. This may indicate the presence of a protective mechanism under metabolic fatigue.

THE CLINICAL COURSE AND PROGNOSTIC FACTORS OF ACUTE ANKLE SPRAINS DURING ONE-YEAR FOLLOW-UP

VAN MIDDELKOOP, M.
ERASMUS MC - UNIVERSITY MEDICAL CENTER ROTTERDAM

Background: Ankle sprains are the one of the most common musculoskeletal injuries. About 40% of the patients with such an ankle sprain report persistent complaints after 3 months. About 80% of these patients still report persistent complaints after 12 months follow-up. Factors predicting persistent complaints for ankle sprains are largely unknown.
Aim of the study: Evaluate prognostic factors for incomplete recovery, instability and re-sprains during one-year follow-up in patients who consulted primary care for acute ankle sprains.
Methods: Patients consulting their general practitioner or a first aid department for an acute ankle sprain were invited to participate in this prospective cohort study. Possible prognostic factors assessed at baseline and 3 months follow-up: demographic factors, clinical factors, ankle load factors and factors from the physical examination at 3 months follow-up. Outcome measures assessed at 3 and 12 months follow-up were self-reported recovery, re-sprains, instability and pain intensity. Possible prognostic factors were identified by multivariate logistic and linear regression models.
Results: A total of 102 patients were included in this study. At 3-months follow-up 65% of the patients reported instability and 23% reported one or more re-sprains. After one-year follow-up, still 27.5% reported instability and more than 50% regarded themselves not completely recovered. Baseline factors related to incomplete recovery at 12 months follow-up were not found. Furthermore, prognostic factors from the physical examination for the non-recovered patients at 3 months follow-up could not be identified. However, re-sprains and self-reported pain in rest at 3 months follow-up were related to incomplete recovery for the non-recovered patients at 3 months follow-up.
Conclusion: A physical examination at 3-months follow-up for the non-recovered ankle sprain patients seems to have no additional value in the prognosis for the 12-months outcomes. However, self-reported pain in rest at and re-sprains during 3 months follow-up seem to have a prognostic value for recovery at 12 months follow-up.

MENSTRUAL STATUS DIFFERENCES OF ELITE TURKISH FEMALE ATHLETES FROM VARIOUS TEAM SPORTS

KARACAN, S., COLAKOGLU, F.F., ERSÖZ, G.
SELCUK UNIVERSITY

Introduction: The aim of this study was to compare the menstrual state of professional Turkish female athletes who compete in different team sports.
Methods: 133 female athletes (33 football, 29 basketball, 27 handball and 44 field hockey players) from different sports branches who take place in the Turkish Premier League and Turkish Super League by random sampling method participated to this study. The physical characteristics including age, weight and height of the subjects were detected and given in order as following; in handball 23.62±3.04 years and 60.74±5.13 kg, 168.92±6.74 cm in football, 22.21±3.33 years, 54.87±5.75 kg, 164.30±6.29 cm in field hockey 19.93±3.87 years, 52.31±6.25 kg, 164.95±5.56 cm and in basketball 22.72±2.85 years, 64.82±7.21 kg, 177.03±5.38 cm. As a data gathering tool, a questionnaire that was made up of 37 questions was applied to the participants, and the questions were asked face to face to each athletes. One-way ANOVA and Chi square tests were used for statistical analysis.
Results: Although there was not found a significant relation between the menstrual status and the sports branches (χ2=3.893, p>.05), there was a significant relation between the sports branches and sports activities' changing the length of the menstrual period (χ2=12.165, p<.05). Among all the female athletes who pointed on their menstrual irregularity complaints out, the average was 8.3 %. There was not found significant relation between training frequency and menstrual cycle irregularity (χ2=1.178, p>.05). A significant relation was found between sports branches and the effects of menstruation on the sports activities on behalf of the female athletes who pointed out that they were psychologically affected by menstruation (χ2=15.53, p<.05).
Discussion: As a result, menstrual irregularity was detected among Turkish Elite female athletes. This study showed that menstrual period would be significantly affected the performance in terms of psychological aspect. Therefore, this was explained that the length of the menstrual period might be affected the performance during sports activity.

EFFECTS OF EXERCISE-INDUCED MUSCLE DAMAGE ON NEUROMUSULAR AND SENSORIMOTOR PERFORMANCE IN BOYS

TSAKIRIS, A., GLEESON, N., ESTON, R.
UNIVERSITY OF EXETER

Optimal functioning and timely activation patterns of the musculature facilitates dynamic stabilisation and protection of synovial joints. Exercise-induced muscle damage (EIMD) detracts from neuromechanical performance and sensorimotor performance capabilities in adults. The effects of EIMD on children's sensorimotor performance is unknown and while neuromuscular performance may be affected to a lesser extent compared to adults, little is known of EIMD's effects on muscular activation in children at functional knee joint angles that are proximal to the extreme of the joint's range of motion. The aim of this study was to assess the effects of EIMD on sensorimotor and neuromuscular performance in boys.
Peak force, electromechanical delay, sensorimotor performance (force error (relative to a 'blinded'-target)) and descriptive markers of EIMD (perceived muscle soreness; passive hip flexibility) were assessed in ten boys (age: 12.7 ± 1.3yr; height: 1.56 ± 0.08m; body mass: 46.5 ± 8.7kg (mean ± SD)) prior to and at 0.5h, 24h, 48h, 72h following a strenuous exercise protocol incorporating six sets of 10 isokinetic eccentric contractions of the ipsilateral knee flexors. Neuromuscular and sensorimotor assessments were recorded at 30 degrees of knee flexion.
Results showed that while performance remained constant during the control period and in the contralateral control leg, the EIMD intervention provoked reduced performance of the involved leg compared to pre-intervention levels in peak force (17.3%: 157 ± 45.3 N versus 129.8 ± 34.8 N (pre- versus post-0.5h); $F(4,36) = 3.9$; $p < 0.05$), passive hip flexibility (25.8%: 0.163 ± 0.071 m vs. 0.121 ± 0.065 m (pre- vs.

post-48h]; F[4, 36] = 9.23; p <0.005) and increased delayed onset muscle soreness (DOMS) (1 ± 0.0 vs. 4.33 ± 1.1 m [pre- vs. post-48h]; F[4, 36] = 21.8; p <0.001). Performance capabilities recovered substantially by 72 hours after the damaging protocol (P<0.05). The EMD and sensorimotor performance were preserved throughout the experiment.

The decrease in peak force, passive flexibility and the increase in DOMS indicated that the children in this study experienced exercise-induced muscle damage as a result of the eccentric exercise protocol, but there were no impairments in sensorimotor performance and muscle activation.

ELECTROMYOGRAPHIC ACTIVITIES OF THE VASTUS MEDIALIS OBLIQUE AND MEDIALIS LONGUS MUSCLES DURING SUSTAINED FATIGUING ISOMETRIC CONTRACTIONS

HEDAYATPOUR, N., FALLA, D., ARENDT-NIELSEN, L., FARINA, D.

CENTER FOR SENSORY-MOTOR INTERACTION

Introduction: Strengthening of the vastus medialis oblique (VMO) muscle during training programs is an important part of protocols for rehabilitation of patellofemoral disorders (Wise et al., 1984). This study evaluated the activation of this muscle in comparison to the vastus medialis longus (VML) during sustained isometric exercise.

Methods: Multi-channel surface and fine-wire intramuscular EMG signals were concurrently recorded from VMO and VML of the right leg of 9 healthy men during 70-s isometric contractions at 10%, 20% and 30% of the maximal force.

Results: Mean power frequency (MPF), muscle fiber conduction velocity (MFCV), and average rectified value (ARV), computed from the surface EMG (Farina et al., 2004) significantly increased with contraction intensity for both VMO and VML muscles (P < 0.05). However, the rate of change over time in MPF, MFCV, and ARV were significantly greater for VMO than VML (P < 0.05).

Discussion: The changes in EMG features with fatigue were greater in the VMO than VML during isometric contractions. This result can be interpreted as due to greater activity of the VMO (Sczepanski et al., 1991) to stabilize the patella during fatiguing contractions. Therefore, submaximal sustained isometric exercise can be used as part of a training program for strengthening VMO muscle in order to prevent lateral dislocation of the patella.

MOTOR SKILLS OF PRIMARY SCHOOL GIRLS

SZABÓ, E., FARMOSI, I., GAÁL, S., KERESZTESI, K.

SEMMELWEIS UNIVERSITY FACULTY OF PHYSICAL EDUCATION AND SPORT SCIENCES

Introduction: There are several scientists, who studied the motor performance, however, there are limited publications about birth season, age effect and division of children.

The aim of this study was 1) to evaluate the physical development and motor performance according to birth season and age; 2) to use percentile tables to separate the sport talented, the average and the children of limited ability.

Methods: During the study body height and body weight, 20 m dash, standing board jump, 6 minutes continuous running, throws with stuffed ball and obstacle race-test of 148 seven-, 191 eight- and 87 nine year old, altogether 426 school girls were evaluated. Unitrate analyses of variance, correlation analysis moreover percentile values and 't' test were used applying SPSS programme.

Results: The overall mean value and standard deviation of the three age group school girls were as follows: body height 128.61±9.11 cm; body weight 26.87±6.33 kg; 20 m dash 5.33±1.13 sec; standing board jump 117.47±23.46 cm; 6 minute continuous running 797.14±254.14 m; throws with stuffed ball 3.94±1.29 m; obstacle race test 23.12±6.79 sec.

According to the results the children group in body height was quite homogenous (cv%<10%), however in body weight (cv%>20-30%), and in case of all motoric test results was heterogeneous (cv%>21.20-32.79). Significant (P<0.05) age and birth season effect was found in most of the motor performances. Older girls were better developed, and generally had better motor performance than younger ones.

The physical development and motor performances of the summer and autumn born school girls were generally better than of those born in winter or spring, except the obstacle race-test. Loose or medium relationships were found between different developmental and motor performance traits. It means that sport performances of older, or better developed school girls were generally better than those of younger or underdeveloped ones. Children who were better at some performances than their schoolmates had generally better results in other sport activities, too.

According to the results of percentile analyses, the 5% of the children with worst motor performance can be considered as limited ability children while the 5 percent with best results the talented children.

Discussion: According to the results both the physical development and the motor performance were influenced by the age and birth season of the children.

The results obtained by percentile values there were big differences between the advanced, average and underdeveloped children.

Percentile values seem to be a useful indicator for the selection of children. With using this method the talented, the average and those children of limited ability can be separated at young age.

THE EFFECTS OF BLOOD LACTATE, BODY COMPOSITION, HEART RATE, AND THE AMOUNT OF EXCRETIONS OF MOUNTAIN BIKER ON THE DRINK TYPES'

KOH, S.M., KIM, J.H., CHOI, M.K., KIM, B.R., LEE, D.K., OAK, J.S., LEE, B.K., CHOI, D.H.

INJE UNIVERSITY, 1. CHANG WON UNIV., 2. SEOUL NATIONAL UNIV. OF EDUCATION, 3. DANKOOK UNIV., 4. SANGMUNG UNIV., 5. SOGANG UNIV.

This study was conducted on five male mountain bikers of a amateur club for four weeks. The research took place once a week at a mountain bike stadium. Its process was as follows: 1) providing them with 300 ml drinks such as sports drinks, red ginseng drink, water or no beverage ahead of the game, 2) with 300 ml drinks by 75 ml four times in four sections (300 m, 1.1 km, 2.4 km, 3.6 km) during playing game, 3) with 300 ml drinks six times after the game. The players drove a bike at the level of 80~85% of their heart rate maximum(HRmax) in the total distance of 19.2 km (4.8 km x 4 times). It was examined the change in body composition variables, heart rate, blood lactic acid concentration and the amount of urinary and excretions before and after the game depending on whether players drink or not and what types of beverages they drink.

In the change in body composition, the result showed that the body weight was affected by correlation between timing and groups. In addition, the greatest weight loss was seen in the no beverages, followed by water, sport drinks and korea red ginseng drink. A significant difference was also found depending on timing. In body fat mass, there was a correlation between timing and groups, but no significant difference occurred in a post investigation.

Depending on timing and groups, there was significant difference in heart rate, but there was no significant difference in the post investigation. Significant difference was shown depending on timing and drinking water were proven to be more effective than having sports drink only during rest in the comparison of the time zone of a day.

In terms of blood lactic acid concentration, no significant difference was found depending on timing and groups, but not having beverage was found to be more effective than having sports drinks in the post investigation, There was a significant difference in timing and having water was more effective than sports drink during rest and no beverage was the most effective followed by sports drinks and water 20 minutes after recovery in the comparison of the time zone of a day.

No significant difference was found in the amount of urinary and excretions. Based on the overall results, sports drinks were found to be the most effective. Not having beverages was more effective in losing weight than having drinks and it is believed that a higher blood lactic acid concentration means a higher fatigue of muscle. Consequently, since there is a great loss of electrolyte in high intensity exercises like mountain bike racing where average heart rate during exercise reaches as much as 90% of the heart rate maximum, we believe that sports drinks would be more effective in enhancing performance of players than ordinary beverages, water or no beverage to maintain physical balance.

ROLE OF THE INTERMITTENT PHYSICAL EXERCISE ON THE FLOW-MEDIATED VASODILATION IN ELITE VOLLEYBALL PLAYERS

AMMENDOLIA, A., CARÈ, I., FERRAGINA, A., MICELI, S., IAMUNDO, M., IONA, T.

UNIVERSITY OF CATANZARO

Introduction: In literature there are a lot of studies that report the importance of the physical exercise to improve cardiovascular functions (1). Recently, the development of new technologies made possible the not invasive study of vascular functional parameters like the flow mediated vasodilation, valuable only since few years (2). The aim of this study was to evaluate the changes of the flow mediated vasodilatation and of the diameter of the brachial artery, after a programmed training, in a group of young elite volleyball players.

Methods

We enrolled 8 young elite athletes (men, average age 20+6). After informed consent, we have undergone them to the complete cardiovascular evaluation with echocardiographic measurement of the diameter, of the brachial artery of both upper limbs, in diastole before the beginning of the pre-championship training and at the middle of the championship. The measurement of the flow mediated vasodilatation has been performed by the digital pulse volume amplitude (PVA) during reactive hyperemia. The statistical analysis was conducted using t-test, considering significant $P<0.05$.

Results: At the middle of the championship we observed a not significant reduction of the cardiac frequency (59+13/min vs 54+7/min; p=0.102), a significant increase of the systolic blood pressure values (111+6 mmHg vs 121+7 mmHg; p=0.045), a significant increase of the diameter of the brachial artery in the right limb (0.31+0.04 cm vs 0.37+0.04 cm; p=0.016) and in the left limb (0.30+0.03 cm vs 0.38+0.07 cm; p=0.019) and a significant increase of flow-mediated vasodilation (1.7+0.2 vs 2.3+0.8 cm; p=0.038). No significant changes of the diastolic blood pressure were observed.

Discussion: Previous studies have demonstrated a higher flow-mediated vasodilation levels in athletes after aerobic exercise (3-4). Our data, for the first time, demonstrate that also the habitual intermittent physical exercise increases the flow-mediated vasodilation and the diameter of the brachial artery, improving the vascular adaptation.

EFFECT OF EPS® 7630 IN IMMUNE SYSTEM OF RUNNERS

VAISBERG, M., LUNA JR, L.A., BACHI, A.L.L., BRITO, R.R.N., EID, R.G., OLIVEIRA, P.W.B., SUGURI, V.M., GREGÓRIO, L.C.
FEDERAL UNIVERSITY OF SÂO PAULO

High-intensity exercises may compromise the immune response as revealed mainly by upper respiratory tract infections. This effect may be related to the decrease in secretory immunoglobulin A in the upper airway mucosa and/or changes in the profile of systemic cytokines as well as local cytokines of the upper respiratory tract. Extract of Pelargonium sidoides (EPs® 7630) is currently used to treat infections that affect the upper airways. The aim of the present study was to evaluate the action of EPs® 7630 extract on the immune response of athletes submitted to an intense running session by analyzing the production of immunoglobulin A in their saliva and of cytokines both locally and systemically, using a placebo as control. The results show that secretory immunoglobulin A levels were increased significantly in EPs® 7630 extract group [213(129.2-1436) ug/mL] in relation of placebo group [41.16 (16.06-85.28) ug/mL] ($p<0.05$), while levels of serum interleukin-15 [94.62(78.59-100)pg/mL, EPs® 7630 extract group and 104.9(100-130.5)pg/mL), placebo group], serum interleukin-6 [82.47(63.67-100)pg/mL, EPs® 7630 extract group and 103.6(100-122.2)pg/mL, placebo group] and interleukin-15 [90.18(69.64-178.1)pg/mL, EPs® 7630 extract group and 122.8(91.85-231.8)pg/mL, placebo group] in the nasal mucosa were decreased ($p<0,05$). Based on this evidence, we suggest that extract of Pelargonium sidoides (EPs® 7630) can exert a strong modulating influence on the immune response associated with the upper airway mucosa in athletes subjected to intense physical activity.

EVALUATION OF KNOWLEDGE AND ATTITUDE LEVEL OF TEACHERS AND SPORT COACHES REGARDING AIDS

MATINHOMAEE, H.
ISLAMIC AZAD UNIVERCITY CENTERAL BRANCH OF TEHRAN

Background & Aim: According to Unaids report, young people(under 25 years old) account for half of all new HIV infect.Furthermore,The probability of exploration of new drug or vaccine isn't possible in the near future so we have to focus on prevention.
Methods: This descriptive and analytical study was carried out on 212 coaches , 186 teacher and 275 general people(that they are occupied other job).Samples were randomly selected and then their knowledge and attitude was determined by questionnaire. level of knowledge and attitude and The relationship between knowledge and attitude were determined by X2 and Chi-square test and Pearson correlation coefficients.
Findings: This results indicated that all groups obtained information on Aids and most of them obtained information only from media and most frequency of knowledge related to weak level in general people and average level in teachers and coaches.60.2% of coaches and 61.5% of teachers and 51.4% of general people had neutral attitude(Neither agree nor disagree).There was a direct relationship between knowledge level and attitude.
Conclusion: teachers and coaches don't have enough knowledge about Aids.It must be given more information to them and suggested to consider this information as a course.

SURVEY OF WORKLOAD ON HEART FROM THREE MAXIMAL AEROBIC POWER TESTS WITH CALCULATION OF DOUBLE PRODUCT

MATINHOMAEE, H., MORADI, F.
ISLAMIC AZAD UNIVERCITY CENTERAL BRANCH OF TEHRAN

Purpose: The product of systolic blood pressure (SBP) by heart rate (HR), the double product (DP), is an index on workload on heart. The purpose of this study was to Survey of workload on heart from three maximal aerobic power tests with calculation of double product.
Methods: For this purpose, 13 subjects randomly were selected from the physical education students at Urmia University. They had at least 3 years experience in regular physical activity and sport participation. Measurements were made during four consecutive days (every day from 2 p.m. to 4 p.m.). At 1st day, age (24.7±2.3 yr), height (176.5±2.6 cm), weight (69.4±3.7 kg), rest HR (63.4±2.8 beat/min) and rest SBP (119±4 mmHg) were measured. Subjects did PWC195 test, Katch-McArdle step test and Astrand ergometer test at 2nd, 3rd and 4th days, respectively. For calculating of test's DP, HR and SBP were recorded at end of each test. Finally, DP values (rest and tests) compared by one-way ANOVA. Statistical significance was accepted at $P<0.001$.
Results: Analysis of data detected that there were statistically significant differences between mean DP values of rest and tests (rest: 7636.2±209.1, PWC195 test: 38045.5±1121.8, Katch-McArdle step test: 17092.6±441.5, Astrand ergometer test 21821.7±672.9 mmHg.beat/min, $P=0.000$. $F=4215.582$(.
Conclusion: According to main differences between sport tests at workload on heart, it seems to be logical recognizing of subject's cardiovascular fitness before testing. It is possible to use DP values for determination of exercise limits for patients (particularly cardiovascular diseases) and survey of athlete's cardiovascular response to physical activities.

EXERCISE TRAINING REDUCES INFLAMMATION IN DIABETICS RATS

HATANAKA, E., BELOTO, M.F., VINOLO, M.A.R., RODRIGUES, H.G., CURI, R., PITHON-CURI, T.C.,2
1. POST-GRADUATE PROGRAM IN HUMAN MOVEMENT SCIENCE, CRUZEIRO DO SUL UNIVERSITY, 2. DEPARTMENT OF PHYSIOLOGY AND BIOPHYSICS, INSTITUTE OF BIOMEDICAL SCIENCES, UNIVERSITY OF SAO PAULO

Chronic inflammation is a key player in the pathogenesis of diabetes which is characterized by increased plasma levels of Serum Amyloid A (SAA) and pro-inflammatory cytokines such as tumor necrosis factor-alpha (TNF-α), interleukin 1beta (IL-1β), interleukin-6 (IL-6) and cytokine-induced neutrophil chemoattractant in inflammation 2 alpha/beta (CINC-2α/β) [1]. This inflammatory mediators lead to inappropriate activation of neutrophils and macrophages and contribute to tissue damage as well as increased susceptibility to invasive microorganisms [2]. Exercise has beneficial health effects due to anti-inflammatory actions [3]. Regular exercise practice is recommended to diabetic patient, however, the symptoms of vasculopathies, neuropathy and retinopathy decrease the acceptance to exercise by diabetic's persons. The effects of a three week moderate aerobic-training programme at treadmill (50% of VO2 max, 30 min/day, 5-folds per week) on CINC-2αβ, IL-1β, TNF-α and IL-6 serum levels in diabetic rats were investigated. The number of peritoneal resident macrophages and neutrophil migration were evaluated as soon as the ratio of necrosis and apoptosis of these cells. We also evaluated the serum levels of creatine kinase (CK) and lactate dehydrogenase (LDH). Exercises decreased the serum levels of TNF-α (6%), CINC-2αβ (9%), IL-1β (34%), and IL-6 (86%) in diabetic group as compared with diabetic sedentary rats. In both, control and

diabetic, exercise decreased the oyster glycogen induced-neutrophil migration as compared with no exercised group. No alterations were observed in neutrophil and macrophage necrosis and apoptosis ratio in all groups studied. Serum activities of CK and LDH were not modified in the conditions studied. We conclude that exercise training exerts marked anti-inflammatory effects in diabetic rats, suggesting that this may be an important mechanism for exercise to improve insulin sensitivity and to protect against vascular complication in diabetic patients. Supported by Fundação de Amparo a Pesquisa do Estado de São Paulo (FAPESP) and Conselho Nacional de Desenvolvimento Cientifico e Tecnológico (CNPq).

EFFECT OF A 1000M KAYAK SPRINT ON REDOX STATUS, MUSCLE DAMAGE AND INFLAMMATION MARKERS IN ELITE MALE KAYAKERS

TEIXEIRA, V.H., VALENTE, H., CASAL, S., MARQUES, F., MOREIRA, P.

UNIVERSITY OF PORTO

Introduction: Sprint kayaking is a demanding exercise that can generate reactive oxygen species (ROS) to a level that surpasses body's antioxidant capacity causing oxidative stress and damage. This study aimed to determine the response of plasmatic antioxidants and markers of lipid peroxidation, muscle damage, inflammation and physiological stress to a 1000m flatwater kayaking simulated race in elite kayakers.

Methods: Superoxide dismutase (SOD), glutathione reductase (Gr), glutathione peroxidase (GPx) and creatine kinase (CK) activities and levels of uric acid, alpha-tocopherol, alpha-carotene, beta-carotene, lycopene, lutein + zeaxanthin, total antioxidant status (TAS), thiobarbituric acid reactive substances (TBARS), interleukin-6 (IL-6), cortisol, lipoproteins and hematologic parameters were determined in 15 male kayakers before and 15min after the kayak bout. Post-exercise measurements were corrected for hemoconcentration.

Results: Both enzymatic and non-enzymatic antioxidants were unaffected by exercise, with the exception of alpha-carotene which decrease (0.22 to 0.18 mmol/L; P = 0.013). The exercise bout caused a decline in TAS (1.46 to 1.13 mmol/L; P = 0.001) and an augment in CK (256 to 304 IU/L; P = 0.023), uric acid (5.0 to 5.4 mg/dL; P = 0.016), TBARS (5.4 to 9.0 mmol/L; P < 0.001) and IL-6 (1.8 to 2.4 pg/mL; P = 0.028). Post-exercise TBARS and TAS were inversely correlated (r= -0.569, P = 0.027). Cortisol levels were not altered by kayaking (188 and 193 nmol/L; P = 0.824).

Discussion: The stability of alpha-tocopherol after kayaking suggests that it was not consumed or mobilized from adipose tissues, which is consistent with the maintenance of triglycerides levels. Also, the lack of change in carotenoids agrees with the maintenance of their main carrier (LDL). The increased post-exercise uric acid likely resulted from the enhancement of purine metabolism or the inhibition of its renal clearance by lactate. Therefore, the observed decrement in TAS after the kayak bout may reflect a compromised status of other aqueous antioxidants, such as ascorbic acid (not measured). This lowering in antioxidant status was associated with an increase in lipid peroxidation following exercise. The augmented post-exercise TBARS reflect the efflux of peroxides from muscles into plasma. ROS attack of polyunsaturated fatty acids increases the permeability of cell membranes causing the efflux of miocellular CK. However, no correlation between TBARS and CK was detected. The modest rise in CK may be explained by the concentric nature of kayaking and the familiarization with the exercise by athletes. The slight augment in IL-6 after exercise may be due to the type (concentric) and duration (234.0 ± 5.8 sec) of the exercise or to the subjects' training status. Our data indicate that a single 1000m kayak bout impair antioxidant status and induce lipid peroxidation, muscle damage and inflammation even in high-level kayakers.

SPERM AND HORMONAL DIFFERENCES BETWEEN PHYSICALLY ACTIVE AND SEDENTARY SUBJECTS.

VAAMONDE, D., DA SILVA-GRIGOLETTO, M.E., GARCIA-MANSO, J.M.

UNIVERSITY OF CORDOBA

INTRODUCTION: It has been previously shown that high-load training, whether intensity or volume, might be detrimental for sperm parameters [1,2]. However, it seems that a less demanding physical activity does not promote any sperm alterations. Moreover, we hypothesize that a physically active lifestyle might result in a more favorable environment for fertility-related processes and might improve or, at least, prevent degradation of hormonal and sperm parameters. Sperm velocity is one of the key parameters for male fertility, since sperm need to move in order to reach the egg and for conception to be able to occur [3]. Thus, the aim of this study was to compare sperm and hormone values of sedentary and physically active subjects.

METHODS: Sperm and hormonal values of 16 physically active subjects (PA; VO2max=45.2±4.2 ml/min/kg, age=19.0±1.8yr) and 15 sedentary subjects (SE; VO2max =34.6±3.9 ml/min/kg, age=19.2±1.9yr) were assessed. The exclusion criteria were any factors interfering with semen production. The inclusion criteria were: not having any exclusion criteria, a practice of 2-4 hs/w (at least in two different days) for PA, and not practicing any physical activity for SE. Sperm velocity was assessed after 3-6 days of abstinence (type "a" velocity is ≥20 micron/sec; type "b" is ≥ 5 and < 20 micron/sec; type "c" is < 5 micron/sec; type "d" is 0 micron/sec, static sperm). Hormonal assessment was performed after an overnight fast with subjects refraining from any physical activity during 3 days before the testing.

RESULTS: No significant differences were found for either type "a" or type "c" velocities. However, the percentage of sperm with type "b" velocity was significantly greater ($p<0.05$) in PA than in SE (27.4±7.2 vs. 21.8±6.8, respectively); moreover, the percentage of static sperm (type "d" velocity) was significantly lower ($p<0.05$) in PA than SE (30.6±4.9 vs. 34.8±5.7, respectively). Likewise, the T/C ratio showed significant differences ($p<0.05$), being higher in PA than in SE (0.46±0.11 vs. 0.32±0.07, respectively).

DISCUSSION: The main finding is that PA subjects seem to have both better sperm velocity and hormonal values than SE. PA showed higher values of type "b" velocity and lower values for "d" velocity (static); this seems to be supported by the greater T/C observed. Therefore, it can be concluded that PA may have a healthier microenvironment for the sperm production process.

USE OF MEDICATION AND NUTRITIONAL SUPPLEMENTS IN TRACK AND FIELD ATHLETES

TSCHOLL, P., ALONSO, J.M., JUNGE, A., DOLLE, G., DVORAK, J.
FIFA MEDICAL ASSESSMENT AND RESEARCH CENTRE

Introduction: High use of medication and nutritional supplements has been reported in several sports. Athletes participating in team sport events seem to have a higher use of painkilling agents than in individual sport events, whereas higher use of nutritional supplements and beta-2-agonists has been reported in individual sport athletes. Several authors have raised the question whether prescription practice corresponds to medical indication. Detailed analysis in track and field athletes is scarce, especially concerning different age groups and disciplines. This study focuses on the use of prescribed medication and nutritional supplements of track and field athletes depending on their sports discipline with special regard to gender, age, and geographic origin.

Methods: 3'887 doping control forms were analysed undertaken during twelve IAAF World Championships (2003 – 2008) and one entire out-of-competitions season (2007) in track and field athletes.

Results: 6'523 nutritional supplements (1.7 per athlete) and 3'237 medications (0.8) were reported by the athlete. Non-steroidal anti-inflammatory drugs (NSAIDs; 0.27, n=884), respiratory drugs (0.21, n=682), and alternative analgesics (0.13, n=423) were used most frequently. Medication use increased with age (0.33 to 0.64 per athlete) and decreased with increasing duration of the event (from sprints to endurance events) (0.11 to 0.60). African and Asian athletes reported using significantly fewer supplements (0.85 versus 1.93) and medications (0.41 versus 0.96) than other athletes. Compared with middle distance and long distance runners, athletes in power and sprint disciplines reported using more NSAIDs, creatine and amino-acids, and fewer antimicrobial agents. The final ranking in the championships was unrelated to the quantity of reported medications or supplements taken.

Conclusions: The use of NSAIDs in athletics is less than that reported for team-sport events. However, nutritional supplements are used more than twice as often as they are in international football competition. Significant differences were found between the different disciplines regardless of geographic origin. Nevertheless, African and Asian athletes seem to receive lesser pharmaceutical support by their team physicians than other athletes. Whether some of the athletes are over-medicated or others under-supplied due to lower financial resources needs special regard in the future. Both over-medication and under-medication may have detrimental effects not only for the athletes' health status but also for their sports performance. It therefore is absolutely essential that an evidence-based approach to the prescribing of medication and nutritional supplements is adopted, to protect the athlete's health and prevent them from testing positive in doping controls.

EFFECTS OF ENDURANCE TRAINING AND ONE SESSION OF EXHAUSTIVE EXERCISE ON ACTIVITY OF PLASMA GOT<AST>,GPT<ALT> ENZYMES AND TAC IN RATS

KHOSRAVI, N., NASIRI ZAHED, M.
ALZAHRA UNIVERSITY

The aim of this study was to determine the interaction effect of 8 weeks of endurance training and one session of exhaustive exercise on hepatic injury in rats. Methods :Three week-old male wistar rats (n= 24) were randomly divided into two groups 1)endurance training (n=12), and untrained group (n=12) .The first group participated in 8 weeks training program, 5 day/week ,consisted of treadmill running with the beginning speed of 8 m/min for 10 min/day which gradually increased to 32m/min for 1.5 h/day at the 8th weak. At the end of endurance exercise both groups were divided randomly into two subgroups. One of the two subgroups in every group performed exhaustive exercise while the others were given rest and their blood samples were taken after 14 hours resting time. The program of exhaustive exercise was to run on treadmill with the beginning speed of 20 m/min for 10 min while the speed was gradually increased to 35m/min and kept constant until the rats were exhausted. Blood samples of the exhaustive training groups were collected immediately after the end of exercise .The activity of (GOT/AST)(GlutamicOxaloaceticTransaminase), (GPT/ALT)(GlutamicPyrovicTransaminase) and TAC in plasma were measured .The one way ANOVA method with repeated measure at 0/05 significance level was utilized to analyze the data. Results: The results indicated that the level of plasma GOT and GPT enzymes activity in exhaustive group were significantly higher than control group (P<0/05) while no significant increase in the activity of these enzymes in endurance and (endurance+ exhaustive) groups was observed (P>0.05). There was a significant difference in TAC between endurance and control groups as well (P=0/001) while there was no significant difference between endurance and (endurance+ exhaustive) groups (P=0.916).Also there was a significant difference in TAC between (endurance + exhaustive) and exhaustive groups (P=0.024).Conclusion: Findings of current study indicated that increase in activity of GOT and GPT enzymes were observed in exhaustive group while no alteration was seen in trained group. Also body temperature elevation and consequent formation of Heat Shock protein after endurance training has a inhibitory effect on the increase of plasma GOT and GPT enzymes activity after one session of exhaustive exercise in endurance trained group. In this research total antioxidant capacity (TAC) were not altered in exhaustive group .This study showed that endurance training could have inhibitive effect on increase of main hepatic cells injury markers in rats.

THE STATE OF THE ART OF SCIENTIFIC RESEARCH IN COMBAT SPORTS

DISTASO, M., MAIETTA, A., GIANGRANDE, M., VILLANI, R.

UNIVERSITY INSTITUTE OF CASSINO - MOTOR SCIENCES FACULTY

Introduction: The aim of the study is to analyse the current situation of the scientific research in combat sports. The study was conducted considering the number of publications and their topics for each discipline. We compared the publications submitted to the ECSS congresses over the last 9 years, to trace the state of the art of scientific research in combat sports and in every specific discipline.

Methods: The research was carried out considering all the abstracts books of ECSS congresses of the last 9 years (1999-2008). Each publication on combat sports was catalogued in specific grids in order to collect data divided into discipline, publication chronological order and lastly scientific type (physiology, refereeing, regulations, tests, training, technique and tactics, etc..).

We analysed statistically the grids by comparing the publications divided into discipline and topic. We calculated percentages and reliability

Results: The total number of articles about combat sports from 1999 to 2008 at ECSS congresses is 171. The majority of the articles deals with Judo (64; 37%;p> 0,01), follow TKD (22; 13%;p>0,01), karate (20; 12%; p>0,01), boxe (n.17; 10%; p>0,01) wrestling (13; 8%;p>0,01), kick boxing (10; 6%;p>0,01), muay thay (4; 2%; n.s.), thai chi chuan (4, 2%; n.s.), sanda - kung fu (2; 1%; n.s.), shoot boxe and MMA (2; 1%; n.s.), and lastly capoeira, kendo and thai boxe with a little percentage of published articles. (1; 1%; n.s.).

We pointed out a significant growth in the number of experimentations in combat sports, in spite of a fair variability in the studies carried out from 1999 to 2008 (1999: 7; 2000: 2; 2001: 23; 2002: 14; 2003 :11; 2004: 18; 2005: 27; 2006: 26; 2007: 17; 2008: 26). From 1999, in effect, ECSS congresses had been showing an ever growing interest in combat sports.

With regard to the topics, the physiological state was dealt with more often (34; 22%), follows the psychological state (16; 11%), injuries and traumas (15; 9%), technique and tactics (14; 9%) , dietary habits (12; 7%), strength tests (10; 6%), athletic training (9; 6%), balance test (8; 5%), athletes comparison (7; 4%), supplements (7; 4%), biomechanics tests (6; 4%), competitions and matches(5; 3%), trainer's methods (4; 2%), endurance tests (4; 2%), speed tests (10; 6%).

Conclusions: We can state that the number of publications in the field of combat sports is rather limited when compared with the publications about other sports. This trend, however, contrast with the high number of athletes who practise such disciplines. The low interest in combat sports showed by researchers can be put down on the lack of funds assigned to research in that field or to the low popularity of martial arts and combat sports in the academic area. Our research group "Combat Sport Study and Research Center" has been working for over 7 years trying to fill the lack of scientific studies in such disciplines.

Abstract books of the ECSS Congress (from 1999 to 2008)

THROWING VELOCITY DIFFERENCES IN TRAINING VS. EUROPEAN CHAMPIONSHIPS IN THE WATER POLO SPANISH FEMALE NATIONAL TEAM

ALCARAZ, P., FERRAGUT, C., ABRALDES, A., VILA, H., ARGUDO, F., RODRÍGUEZ, N.

UNIVERSIDAD ALFONSO X EL SABIO;UNIVERSIDAD CATÓLICA SAN ANTONIO DE MURCIA; UNIVERSIDAD DE MURCIA; UNIVERSIDAD AUTONOMA DE MADRID

INTRODUCTION: The velocity component of accurate, overhead water polo throws, especially in the act of goal shooting, is an important ingredient of successful scoring ability. It seems that when a tactical situation (goalkeeper) is included the speed has been smaller. However, there are no studies that presents if differences are found in performance between training or real play situations. PURPOSE: To compare the throwing velocity differences in training vs. European championships in the Water Polo Spanish female national team. METHODS: Eleven healthy woman sub-champions of Europe (22.5 ± 2.9 years; 65.0 ± 8.0 kg; 171.7 ± 7.5 cm) were tested at training (pre-competitive period), or at the Europe Championships (competitive period), always in a indoor swimming pool. For the training test, a radar, placed ten meters behind the goal, and aligned with the penalty line, registered two throwing at maximum intensity from the penalty line. The shooting was carried out with a goalkeeper. The best shot was selected for the analysis. For the championships test, the same position of the radar was allowed. We analyzed all the shots carried out from the penalty line in the last five matches. T-test for dependent samples was used (P ≤ 0.05). RESULTS: There were no between-situations differences. The data confirm that the throwing velocity was similar in the training situation (15.46 ± 1.15 m•s-1), when they were compared to the championship condition (15.55 ± 2.24 m•s-1). CONCLUSION: The throwing velocity is similar when a water polo player performs a shot from the penalty line with goalkeeper, independently the situation: training vs. international championship. In this sense, the control of the throwing velocity over the training can be a very reliable method of the championships shots velocities. REFERENCES: 1. Bloomfield J, Blanksby BA, Ackland T, et al. ANALYSIS OF REFEREES' DECISIONS DURING THE FIFA WORLD CUP 2006

TESSITORE, A., MINGANTI, C., LUPO, C., BENVENUTI, C., MARINELLI, L., CAPRANICA, L.

UNIVERSITY OF ROME

Introduction: During World FIFA Championships media, sponsors, and nationalism create a relevant pressure on teams and referees. Despite this environment, top-class referees need to officiate processing information accurately and reacting with appropriate decisions (MacMahon et al. 2007). Differently from team sports that make use of technology for offside decisions, during a football game the referee has individual decision-making responsibilities, which reflect both his personality to apply the football rules and different "national refereeing styles". The aim of this study was to describe the profile of the referees' decisions during the World Soccer Championship 2006.

Methods: The referees' decisions from the 64 matches of the 2006 FIFA World Championship were analyzed by means of the following indicators: 1) Direct Free Kick (D), i.e. kicks or attempts to kick an opponent, charges an opponent, handles the ball deliberately, etc.; 2) Indirect Free Kick (I), i.e. offside, plays in a dangerous manner, etc.; 3) Disciplinary Sanctions (S), i.e. delaying the restart of play, deliberately offence versus referee, etc. Data were analyzed in relation to the entire match, the two halves, the different time periods (0-15, 15-30, 30-45, and overtime) of each half, and the tournament's phase (qualifying, quarter-finals, semi-finals and finals).

Results: During the 1st half, the occurrence of D, I, and S was 81%, 14%, 5%, respectively. The relative picture during the 2nd half was 75%, 20%, 5%. Regarding D, decisions per match were 9±4 for kicking an opponent, 5±3 for charging an opponent, and 10±4 for pushing an opponent, respectively. The relative picture for I indicators was 5±3 for the offside and 1±1 plays in a dangerous manner. In relation to the game periods, yellow cards occurred most frequently during the last 15 min of the two halves (19%). While red cards showed the highest frequency during the first 15 minutes of the 2nd half (29.2%), 12.5% and 8.3% occurred during the 1st and 2nd overtime periods, respectively.

Discussion: In general, the low occurrence of D, I, and S during a match indicates that teams participating in FIFA World Cup 2006 mostly engaged in a fair playing. However, a more aggressive play occurs during the last fifteen minutes of each half and the first period of second half when the players are more likely to receive yellow cards. The surprisingly occurrence of red cards during the overtime periods could be attributed to the players' attempt to catch the last chances to score a goal.

POSSIBLE EFFECTS OF NEW REGULATION IMPLEMENTATION ON POLE VAULT EVENT

THEODOROU, A., SKORDILIS, E., PARADISIS, G.

UNIVERSITY OF ATHENS

Introduction: According to the Athletics European Team Championships new regulations, which are to be introduced in June 2009, each pole vault event competitor shall be entitled to a maximum of 4 fouls only throughout the whole event. The purpose of the present study was to examine the possible effects that the implementation of the new regulations, would have had on the conduction of the event for males and females.

Methods: Male and female pole vault finals official results in Olympic Games, IAAF Outdoor World Athletics Championships and European Outdoor Athletics from 2000 onwards, were analysed.

Results: Male pole vaulters (N=102), start the competition at a mean height of 551.29cm (SD±7.96) and conclude at 568.31cm (SD±15.57), with a mean height difference of 17.02cm (SD±12.49). During the event they perform a mean of 6.85 attempts (SD±2.16), classified as either successful (M=2.41, SD±1.15) or failed (M=4.44, SD±1.38). Following the fourth foul 40.20% of them perform failed attempts (M =1.80, SD ±0.98 attempts) and 10.78% successful ones (M=1.36 SD ±0.67 attempts). If the new regulations were applied, athletes would achieve a mean height difference of 15.83cm (SD±4.82) between start and finish.

Female pole vaulters (N=93), start the competition at a mean height of 424.19cm (SD±16.46) and conclude at 450.56cm (SD±19.71), with a mean height difference of 26.37cm (SD±13.35). During the event they perform a meane of 8.01 attempts (SD±2.48), classified as either successful (M=3.47, SD±1.59) or failed (M=4.52, SD±1.48). Following the fourth foul 50.54% of them perform failed attempts (M=1.68, SD±1.23) and 12.90% successful ones (M=1.50, SD±0.67 attempts). If the new regulations were applied, female athletes would achieve a mean height difference of 24.91cm (SD±4.82) between start and finish.

Discussion: Data demonstrate that the new rules would have resulted in a decrease in the event final performance (6.99% and 5.53% for males and females respectively), due to a mean attempt restrain of 11.13±4.76 and 12.13±6.64, in each final, for males and females respectively. No data however was available for variables such as the time duration of the event and our statistical analyses were based exclusively on the results recorded with the current regulations. Therefore, further research is required before drawing permanent conclusions regarding possible effects on the pole vault event duration and athletes' tactics.

POSSIBLE EFFECTS OF NEW REGULATION IMPLEMENTATION ON HIGH JUMP EVENT

THEODOROU, A., SKORDILIS, E., PARADISIS, G.

UNIVERSITY OF ATHENS

Introduction: According to the Athletics European Team Championships new regulations, which are to be introduced in June 2009, each high jump event competitor shall be entitled to a maximum of 4 fouls only throughout the whole event. The purpose of the present study was to examine the possible effects that the implementation of the new regulations, would have had on the conduction of the event for males and females.

Methods: Male and female high jump finals official results in Olympic Games, IAAF Outdoor World Athletics Championships and European Outdoor Athletics from 2000 onwards, were analysed.

Results: Male high jumpers (N=102), start the competition at a mean height of 218.63cm (SD±2.70) and conclude at 228.07cm (SD±4.93), with a mean height difference of 9.44cm (SD±4.83). During the event they perform a mean of 7.28 attempts (SD±1.91), classified as either successful (M=3.15, SD±1.40) or failed (M=4.10, SD±1.17). Following the fourth foul 37.25% of them perform failed attempts (M=1.39,

SD±0.59 attempts) and 1.96% successful ones (M=1.50, SD±0.70 attempts). If the new regulations were applied, athletes would achieve a mean height difference of 9.34cm (SD±4.82) between start and finish.

Female high jumpers (N=105), start the competition at a mean height of 184.11cm (SD±2.38) and conclude at 195.02cm (SD±5.19), with a mean height difference of 10.90cm (SD±5.00). During the event they perform a mean of 8.21 attempts (SD±2.34), classified as either successful (M=3.90, SD±1.76) or failed (M=4.30, SD±1.14). Following the fourth foul 37.14% of them perform failed attempts (M=1.54, SD±0.75 attempts) and 5.71% successful ones (M=1.17, SD±0.40 attempts). If the new regulations were applied, female athletes would achieve a mean height difference of 10.71cm (SD±4.82) between start and finish.

Discussion: Data demonstrate that the new rules would have resulted in a decrease in the event final performance (1.05% and 1.74% for males and females respectively), due to a mean attempt restrain of 7.00±4.00 and 8.50±3.85, in each final, for males and females respectively. No data however was available for variables such as the time duration of the event and our statistical analyses were based exclusively on the results recorded with the current regulations. Therefore, further research is required before drawing permanent conclusions regarding possible effects on the high jump event duration and athletes' tactics.

THE ANALYSIS OF DIFFERENCES IN TEHNICAL AND TACTICAL ELEMENTS OF JUDO BASED ON THREE WOMEN BALKAN'S CHAMPIONSHIPS

TORLAKOVIC, A., KAJMOVIC, H., RADJO, I., KAPO, S.

INTERNATIONAL BURCH UNIVERSITY, SARAJEVO

Introduction: The objective of this research was conducted in order to determine the differences in technical and tactical elements of women judo fights on Balkan's Championships and to compare levels of differences in using tactical and technical elements during competition activities. A sample of 137 judo matches on three Balkan's Championships was used (2001/2002 and 2006).

Methods

In the purpose of analysis, we must introduce technical and tactical variables. For this research canonical discriminated analysis was used to determine the differences in particular situations (Rc, Wilk's Lambda, Barttler's test, Test of functions, Structure, Matrix, Chi-square).

Results: The result of this analysis show that there are statistically significant differences between matches on Balkan's Championships 2001/2002 and 2006. Summary of canonical discriminate functions show one isolated discriminated function.

The x2 (Chi Square) test was used to determine the differences between indicators for situational efficiency. The results show statistically important differences between fights on tree Balkan's Championships for:

Place of attack on the tatami ($x2 = 25.5$; $df = 1$; $p = 0.000$)

Technical points and penalties ($x 2 = 27.0$; $df = 8$; $p = 0.001$)

Elapsed time ($x2 = 9.36$; $df = 1$; $p = 0.002$)

Grips configuration ($x2 = 7.75$; $df = 2$; $p = 0.021$)

Discussion: Main reason for those differences is changing of judo rules during 2002-2006 periods, made by IJF. According to them, there is no red square on tatami, penalties and match duration for women are changed and "gold point" is introduced. These parameters were gathered concerning real fight at the highest competitive level. Also, regarding all analyzed matches, the differences were noticed in frequency of used techniques between NAGE WAZA and KATAME WAZA groups. Given results might be used for programming and training process control improvement in judo for senior female fighters in Bosnia and Herzegovina and wider.

RACING STRATEGY IN BMX COMPETITION

SMIT, A.

*NETHERLANDS OLYMPIC COMITTEE*NETHERLANDS SPORT FEDERATION*

Introduction: Theories based on time trial studies indicate an advantage of a fast start for short and middle distance cycling events. However, when competing at the same time against other competitors, tactics also plays a role in pacing and winning. The main purpose of this study was to determine which racing strategies elite riders use to distinguish themselves from sub-elite riders.

Methods: The measurements were done during a European Championship round of Bicycle Motocross (BMX). The course was 358m long and divided in 6 sections (S1-S6), with the aid of the start, 5 strategic points (T1: after 10m; T2-T5 after each straight) and the finish (TF). With use of multiple video cameras, time and rank on T1-T5 and TF were recorded during the semi-finals of this race in the category Elite Men. From this, split-time, section-speed, normalized split-time, and final-time were determined. Split-ranking and final ranking was also determined. A Student's t-test was used to determine differences between elite riders (top 5) and sub-elite riders (11-16).

Results: Elite riders have a higher normalized split-time ($p<0.01$) than sub-elite riders on T1 (5.14% vs 4.97%) and T2 (21.77% vs 20.94%). The speed-distance profile shows a declining speed from S2-S6 for sub-elite riders. Elite riders have the same profile, but accelerate on S4. Elite riders ride a significant faster speed (11.09 vs 9.89 m/s) on S4 ($p<0.01$) than sub-elite riders. Split-times for elite riders was significant faster on T4, T5 and TF. Most rank changes occur on S2-S4 (10, 12 and 9 rank changes respectively), while few rank changes occur on S5-S6 (6 and 4 changes respectively).

Discussion: Elite riders in this study distinguish themselves from sub-elite riders in that they use a different racing strategy. Elite riders have a relative faster start and are able to accelerate on S4 where sub-elite riders cannot. This gives elite riders a tactical advantage in the last part of the race, where few rank changes occur. Koning et al. (1999) indicate that an all-out strategy is the best strategy on distances shorter than 1000m, based on a energy-flow model. The speed-distance profile in this study though, resembles more the pattern of a 1500m simulated time trial, as found by Hettinga et al. (2007). One explanation is the influence of tactics on the race strategy (Jones &

Whipp, 2002), which is absent in a simulated time trial. Another explanation for the finding is the used gear ratio, which is quite small in BMX, resulting in a quicker acceleration and achieving peak power and peak speed earlier than on a race bike and therefore requiring a more evenly paced strategy as power is generated more quickly resulting in a faster fatique.

ANALYSIS OF FREE-THROW QUOTAS OF LEFTHANDED AND RIGHT-HANDED ELITE BASKETBALL PLAYERS

PAPADOPOULOS, P., LINDNER, M., ERGEC, D., STAFILIDIS, S., GOEBEL, R., BAUM, K.

INSTITUTE OF EUROPEAN SPORT DEVELOPMENT AND LEISURE STUDIES

Introduction: Research in the domain of handedness in sports showed that a tactical advantage is attributed to left-handed athletes in many sports (Brooks et al., 2003; Wood and Aggleton, 1989). There are only a few studies which analysed performance of sport-specific motion sequences of right- (RH) and left-handed (LH) athletes (Grondin et al., 1999). The aim of this study was to examine whether LH elite basketball players have a better free throw quota than RH elite basketball players.

Methods: The free throw performance of 299 players who participated in the season 2006/2007 of the NBA was evaluated statistically. The data were taken from the NBA website. The players were classified depending on position and handedness (right-hander: n=280, left-hander: n=19). The handedness was identified using the official list of LH players of the Association for Professional Basketball Research. In addition an online search of photos of all players was made. In order to discover significant differences between the free throw quota of all LH and RH basketball players and those playing the same position the Mann-Whitney-U-test was used.

Results: The free throw quota of the LH players was significantly higher (p= 0.034*). The highest significant result (p= 0.011*) was shown on the guard position. For the forward and center position no significant difference respectively no representative finding was obtained. There were over two times more LH players (26.3%) than RH players (12.1%) reaching a free throw quota over 85%. On the other hand, almost two times more RH players (19.3%) than LH players (10.5%) were found reaching a free throw quota under 65%.

Discussion: In contrast to other studies the strategic advantages, which were considered to be the reason for the superior performance of left-handers, are excluded in the free throw situation. The better performance of left-handers has been attributed to neurological benefits (Anzola et al., 1977; Geschwind and Galaburda, 1985). These benefits are often associated with better visual and spatial abilities (Nass and Gazzaniga, 1987) and could explain the results of this study and the findings of other examinations (Dane and Erzurumluoglu, 2003; Stöckel et al., 2007). Further studies examining different motor skills, a greater number of subjects and the reasons for the phenomenon found should be conducted.

SPEED ADAPTATION IN CYCLE DURATION AND EMG DURING RUNNING ON DIFFERENT GROUND SURFACES AMONG ORIENTEERS

GJERSET, A., JOHANSEN, E., NILSSON, J.

THE NORWEGIAN SCHOOL OF SPORT SCIENCES, OSLO, NORWAY AND THE SWEDISH SCHOOL OF SPORT AND HEALTH SCIENCES, STOCKHOLM SWEDEN

Introduction: Orienteering is a sport that is extremely demanding, not only with respect to work load, but also with respect to running techniques that has to be performed on different surfaces at different speeds. The change in surface from hard to soft and from even to extremely uneven etcetera will impose a challenge to the neuromotor system to execute an optimal movement for the specific demands. From a motor control point of view it would be beneficial to use a similar basic movement pattern over the whole velocity range and on different surfaces. The purpose was to study how important stride parameters such as the cycle duration, electromoygraphical (EMG) burst duration and activation level change with speed and with change in running surface.

Methods: In total six male elite orienteers, mean (range) age, height and weight; 25 (19-32) years, 1.80 (1.74-1.88) m and 71(67-75) kg, participated in the study. EMG was recorded with surface electrodes on m. vastus lateralis (VL) on the right leg. Angular displacement of the hip joint of the right leg was recorded by means of an electrogoniometer and used to determine the cycle duration. The participants ran on four different horizontal ground surfaces; gravel stone road, forest terrain, timber felling and wet moss. The recordings were done during running in four different constant self determined speeds: slow, medium, fast and maximum speed. The actual mean speed in the recording intervals performed by the orienteers were determined by means of an ultra sound based timing system (Time it, Eleiko AB, Sweden).

Results: The cycle duration decreased in a similar manner with speed during running on all the tested surface conditions. The burst duration of the knee extensor m. vastus lateralis shows the same trend as the change in cycle duration with speed. The same increasing trend in mean EMG activation level with speed is seen on all running surfaces. Surface related differences in cycle duration, burst duration and EMG amplitude were present.
Discussion: The clear trends in cycle duration and EMG during running on different surfaces with speed indicate that the neuromotor system tend to adapt the control of locomotion with a similar basic pattern in the studied parameters. Despite the similar generic trends a running surface like the wet moss may limit the speed range, elongate the EMG burst duration and demand a higher EMG activation level for a given speed. This is important information in endurance and strength training design and for the acute route choices in an orienteering race.

ACCURACY OF SHOOTING RESULTS IMITATION WITH AN OPTOELECTRONIC TRAINING SYSTEM

KOROSTYLOVA, Y., ZANEVSKYY, I.

LVIV STATE UNIVERSITY OF PHYSICAL CULTURE, LVIV, UKRAINE; CASIMIR PULASKI TECHNICAL UNIVERSITY, RADOM, POLAND

Controlling of postural and weapon stability is a distinctive feature in the sport of shooting [1]. Optoelectronic training systems provide a shooter with data and graphical information on the aiming line cross point coordinates on a target [2]. The SCATT system indicates a prognostic result of a real shot taking into account the period of time from triggering up to the instant when a pellet leaves a barrel and also a lateral motion of a muzzle because the pellet having left the barrel continues moving in the same direction as the muzzle [3].
The aim of the research is to compare pellet coordinates on a target with coordinates of the SCATT system imitation trace.
The method of study includes shooting with Steyr LP-10 air pistol and 4,49 mm Finale Match pellets using simultaneous recording on the SCATT system and shooting with the pistol held in a vice and pellets from the same box. A research hypothesis is that coordinates of the imitation and pellet's coordinates on a target are equal. Relative coordinates of the SCATT system point and the pellet mark on a target were calculated to avoid systematic errors caused with non-focus of its axis and a barrel axis on a target, and a gravitational displacement of a pellet. A statistical hypothesis is that a dispersion of the relative coordinates equals a dispersion of pellets hit coordinates shot with the viced pistol.
A highly qualified female shooter made 10 shots from a 10 m distance. An initial speed of pellets (M±SD=162.2±0.6 mps) was measured with a chronoscope Combro cb-625мk4. A shot moment (0.0031 s) was calculated as a time of pellet motion along a barrel (0.25 m) assuming a constant acceleration during the time. A distance between pairs of the pellet and imitated points in the relative coordinates was 2.52±0.72 mm. A radius from a centre of 10 shots executed with the viced pistol was 1.36±0.76 mm. Normal distribution of the two samples was accepted using Shapiro-Wilk test ($p>0.1$). With Fisher-Snedecor criterion, the statistical hypotheses about equal variances was accepted ($p>0.620$). T-test showed a large difference in the mean distances ($p<0.003$), i.e. the SCATT system imitation of the pellet mark on the target is not relevant enough. This could be caused by non-correct modelling of a muzzle trajectory as the trace imitation because angular motion of a barrel relative to the muzzle falsifies calculation of its lateral speed. The SCATT system measures one kinematical parameter in the sagittal and one in the transverse plane. They are vertical and horizontal coordinates on a target simulation. A relevant model of a barrel motion needs one more parameter in both of the planes, e.g. angles of the barrel axis relative to a normal line to the target plane.

ESTIMATION OF CARDIORESPIRATORY FITNESS AMONG YOUNG MEN WITHOUT EXERCISE TEST

TANSKANEN, M., KYRÖLÄINEN, H., TAMMELIN, T.

UNIVERSITY OF JYVÄSKYLÄ

Cardiorespiratory fitness is accurately measured by exercise testing, which is time consuming and not suitable for large group of subjects. Previous studies suggest that self-reported exercise habits may be useful in developing non-exercise prediction models for maximal oxygen consumption (VO2max) among adult population (1). However, simple methods are needed to estimate VO2max of young male conscripts before they enter compulsory military service. It would be useful to divide conscripts into different fitness groups in order to optimize the volume and intensity of physical training.
PURPOSE: To develop and estimate the validity of non-exercise method to predict VO2max among conscripts.
METHODS: Before military service, 50 males (age 19.7±0.3 years) reported their physical activity by international physical activity questionnaire (IPAQ)(2). In addition, Jackson's non-exercise method (1) was used to estimate their VO2max. During the first week of military service, VO2max (ml/min/kg) was directly measured in a maximal treadmill test. Body weight and height were also measured, and body mass index (BMI) was calculated. Subjects were randomly divided into two groups for further analyses. The results of the first group (N=25) were used to develop a regression equation to estimate cardiorespiratory fitness of young men based on IPAQ questions and anthropometric measures (CF method). The results of the second group (N=25) were used to evaluate the validity of this new developed CF method and Jackson's non-exercise method. VO2max estimates by these two methods were compared to directly measured VO2max by Bland and Altman plot (3).
RESULTS: Jackson's method overestimated VO2max so that mean difference between directly measured and estimated VO2max was -5.2 ± 4.6 ml/kg/min ($p<0.001$). Furthermore, Jackson's method overestimated VO2max to a higher degree among males with good cardiorespiratory fitness. New CF-method (regression equation including IPAQ's question of vigorous exercise and BMI) explained 71% of conscripts' VO2max (SEE 4.0 ml/kg/min). Mean difference between directly measured and estimated VO2max was non significant (-1.8 ± 5.7 ml/kg/min). There was neither significant correlation ($r = 0.22$, $p<0.28$) between the mean values and the difference of the CF and VO2max.
CONCLUSION: These findings indicate that CF method estimates VO2max equally well among males with high or low cardiorespiratory fitness. The present results suggest that VO2max of conscripts can be estimated with reasonable accuracy by body weight, height and self-reported participation in vigorous intensity physical activity. In practice, these findings suggest that CF method can be used as a tool to divide conscripts into different fitness groups in the very beginning of their military service.

THE EFFECTS OF RESISTANCE TRAINING INTENSITY ON PHYSICAL FITNESS GAIN IN THE OBESE ELDERLY WOMEN

KYUNG-RYUL, C., SA-YUP, K., CHUNHO, C., GYU SEOG, H., JUN HO, H., GI DUCK, P.
KOREA INSTITUTE OF INDUSTRIAL TECHNOLOGY

Introduction: This study was designed to investigate how resistance training intensity affects muscular strength and body composition change responses in the obese elderly adults over a 12-week training period.
METHODS: Thirty-nine volunteers (obese elderly women) were divided into the following three groups; high-resistance (60~70% of 1RM, age 69.75±2.83, percent body fat 35.15±4.95), mid-resistance (40~50% of 1RM, age 68.64±3.2, percent body fat 34.78±5.32), low-resistance (20~30% of 1RM, age 70.92±3.86, percent body fat 33.82±5.29) training group. Exercise regimens consisted of three sets of arm curl, shoulder press, chest press, lat pull-down, abdominal, leg extension, leg curl, leg press, and hip adductor, 12 repetitions/set, 3 sets, 3 days/week. Each exercise program contains five minutes of warm-up session using cycle ergometer, main exercise using nine kinds of adjustable resistance exercise machine, and five minutes of cool-down session with stretching and belt massage. Dynamic muscle strength evaluated by 1RM on the nine exercises, senior fitness test (30s chair stand, 6-minute walk, functional reach, arm curl, grip strength, chair sit-and-reach), and body composition (body fat and percent body fat) were measured at 0, 6, and 12 weeks.
RESULTS: 1RM strength for all nine exercises increased significantly ($p<.05$) between groups according to period of exercise, and especially in 12th week, higher increase of 1RM occurred in the high-resistance and mid-resistance groups than in the low-resistance training group between-period without shoulder press. In the body composition, even though there was no meaningful difference between groups in terms of strength of exercise, it was noted that body fat and percent body fat reduced, and muscle mass increased after 6th week. Senior fitness test had statistically meaningful differences ($p<.05$) between period analyses on the all test items.
CONCLUSIONS
Following 12 weeks of strength training all three groups improved in the 1RM strength, senior fitness test, and body composition (in between-period analysis), but there were no differences in between-group (exercise intensity analysis) at any measurement factor in the 1RM strength, senior fitness test, and body composition.

MONITORING TRAINING IN ELITE SPRINGBOARD DIVERS.

MINGANTI, C., MEEUSEN, R., CAPRANICA, L., DE PERO, R., PIACENTINI, M.F.
UNIVERSITY OF ROME

Introduction: Monitoring training is critical to the process of quantifying and correctly planning training, especially in the periodization of elite athletes. Session RPE method has proven to be successful in monitoring training load during steady state, high-intensity and multiple types of exercises (Foster C.,'96, '98, 2001, Minganti C. 2008). Divers practice basic skills, basic dives and optional dives from different heights (both springboard and platform); dryland workouts are also scheduled to work on specific skills and to improve strength and flexibility. No previous studies were conducted to evaluate the session RPE method in this sport Therefore, the aim of the present study was to evaluate the ability of the session RPE method to quantify training during diving practice.
Methods: Six elite divers, three males (age=25,7±6,1yrs; height= 171±6,1 cm; weight=66,7±1,2 kg) and three females (age=25,3±1yrs; height= 163,3 ±4,7 cm; weight=58,3±4 kg) participated in the present study. Each subject was monitored during two different training sessions (1 and 3 meters springboard) with a Heart Rate (HR) monitor (Polar Team System), and the RPE rating was obtained using the 10 cm VAS (Visual Analogue Scale). The subjects were asked to provide a rating of the overall difficulty of the training session 30 minutes after the end of the session. An exercise score for each training session was computed by multiplying the duration of the training session by the RPE (Session RPE). As an objective reference method for quantifying each training session the summated HR zone method (Edwards S.,'93) was used. The HR monitors were downloaded using software that allowed evaluation of the accumulated time in each of 5 HR zones based on 50-60%, 60-70%, 70-80%, 80-90% and 90-100% of theoretical HR peak (220-age). Time in each zone was used to calculate the training score (TRIMP) by multiplying the accumulated duration in each HR zone by different factors (50-60%=1; 60-70%=2; 70-80%=3; 80-90%=4, 90-100%=5) and summating the Results: Results: Pearson's correlation coefficient was used to evaluate the relationship between TRIMP scores (TRIMP =96±18,18) generated using the summated HR zone method and the session RPE (Session RPE =2372±882,28) method of monitoring the training session. Results (r= 0,88; p<0,05) shows a high correlation coefficient between the two Methods: Discussion: Results of this study are consistent with previous observations of a strong correlation between session RPE and the summated HR zones methods of evaluating training sessions.
Our results suggest that the session RPE method may be used as an easy method of creating a TRIMP score for evaluating exercise training in diving as well.

EFFECTS OF COMBINED RELAXATION AND SHOOTING TRAINING ON SHOOTING PERFORMANCE IN BIATHLON

LAAKSONEN, M.S., AINEGREN, M., LISSPERS, J.
MID SWEDEN UNIVERSITY

Applied Tension Release (ATR) training has been successfully used in different clinical contexts in order to enhance the ability to decrease unwanted and unnecessary tension and arousal in everyday life situations (Öst 2002; Lisspers&Almén 2008). To some degree correspondingly, in biathlon, which consists of cross-country skiing and shooting, sportsmen must recover fast after the high intensity skiing bout just before the shooting and moreover, needs to have a ability to focus on shooting under a high external (e.g. public, other com-

petitors) but also internal stress. In one earlier study, Groslambert et al (2003) have shown that 6 weeks of shooting training combined with imagery training improved the stability of rifle at standing position in biathletes. However, there are only few studies considering shooting performance or shooting training in biathlon. Therefore, totally 20 biathletes at high national level (age 20+-4 yr, VO2max 60+-7 ml/kg/min-1, 1-13 (range) years in biathlon) were recruited to the study. First, VO2max and shooting performance at rest and immediately after two sub-maximal exercise intensities (75% and 90% of VO2max) were measured. Thereafter, subjects were randomized into experimental (EXP) and control (CON) groups. During 11 weeks intervention, the EXP group performed specific ATR-training 6 times per week, first with help of specific CD-ROM program (weeks 1-2). Thereafter, ATR training was successively combined with holding and "dry firing" training, with a goal that during the last two weeks of the intervention, ATR was integrated into all shooting training. CON continued their usual shooting training. Shooting performance was measured by SCATT prof. shooting training system® based on laser light, and was determined as a group size (mm) and stability of aiming (mm) for 20 shots at rest, and for 10 shots per each exercise intensities, but also as a total shooting accuracy which was calculated as a total sum of group size and stability of aiming at rest and during both exercise intensities. The exercise mode in all measurements was roller skiing on the treadmill. Totally 12 subjects (EXP n=7, CON n=5) completed the study. No change in VO2max was observed in EXP or CON group. EXP group showed decrease in group size at 75% of VO2max ($p<0.05$). In addition, stability of aiming was enhanced at rest and at 75% of VO2max ($p<0.05$) in EXP but also at 90% of VO2max ($p<0.05$) in CON. The total shooting accuracy was significantly improved (11%) in EXP compared to CON ($p<0.05$). Therefore, ATR training combined with shooting training enhances the shooting performance, and therefore, if these results can be replicated in further studies, it can potentially be recommended for the biathletes.

THE IMPACT OF PHYSICAL ACTIVITY ON THE BEHAVIOUR OF RODENTS BY USING A DEXAMETHASONE-INDUCED RAT MODEL OF DEPRESSION.

HELMICH, I., LATINI, A.L., BUDDE, H.

INSTITUTE OF SPORTSCIENCE, HUMBOLDT UNIVERSITY BERLIN

The antidepressive effect of physical exercise is of important interest, because the prevalence of depression, the economic burden and the need for more effective treatment options are enormous. The time delay in therapeutic response of antidepressants led to the theory that neural adaptations are required to induce a relief of depressive symptoms. The upregulation of neurotrophic factors seems to play an important role in the therapeutic response [1]. Exercise also induces the upregulation of neurotrophic factors [2]. In this study we tested the effect of physical activity on the behaviour of rodents that were treated with dexamethasone to induce depressive-like behaviour. Materials and methods: The studies were carried out on 32 adult male Wistar rats that were randomly divided into four groups. The "control group" (C), "control and exercise group" (CE), "dexamethasone control group" (DC) and the "dexamethasone and exercise group" (DE). The exercise consisted of a swimming exercise (1 h / day, 5 days / week) for 4 weeks (20 exercise training days), with an overload of 5 % of the rats body weight [3]. Every day rats were injected with either dexamethasone (DC / DE) or a saline solution (C / CE). It is known that these constant high concentrations of dexamethasone are able to induce depression-like behavior in rats [4]. The depressive-like behavior has been tested by using the Sucrose preference test SPT [5] that was performed twice before, after 7, 14, 21 and after the 4-week-swimming-period. Results: The SPT did not show differences between the groups on both tests before, on day 7 and 14 days of exercise. On day 21 and after the training period the DC group differed significantly from all other groups showing depressive-like behavior. All other groups including the DE group showed on day 21 and after the training non-depressive-like behavior. Conclusion: The results demonstrate in an animal model of depression the antidepressant effect of exercise in the SPT matching with the time delay observed in other therapeutic responses. To affirm these results the levels of neurotrophic factors will be measured.

31P MRS AND MOTOR PERFORMANCE TESTS DISPLAY DIFFERENCES IN SKELETAL MUSCLE PROPERTIES OF SPRINT-TRAINED AND ENDURANCE-TRAINED SUBJECTS

PESTA, D., MESSNER, H., BURTSCHER, M., SCHOCKE, M.

MEDICAL UNIVERSITY INNSBRUCK

Introduction: Until recently, assessment of muscle metabolism was only possible via biopsy sampling, which is an invasive procedure. 31P-Nuclear magnetic resonance spectroscopy (31P-NMRS) nowadays offers a feasible way to study aerobic and anaerobic muscle metabolism non-invasively. Therefore, the aim of the present study was to assess muscle fibre properties of sprint-trained and endurance-trained athletes by 31P MRS and appropriate motor performance tests.

Methods: Ten competitive athletes, stratified according to their discipline and activity into five sprint-trained (SG) and five endurance-trained (EG) athletes, participated in the present study. Each athlete completed a 31P MRS assessing high energy phosphates, intracellular pH and muscle volume, a Wingate test (WAnT) measuring peak power (PP), mean power (MP), fatigue index (FI) and a countermovement-jump measuring jump height. Additionally, lactate was taken 3 minutes after the end of the WAnT.

Results: Lateralis PCr content of the EG was significantly higher than in the SG during the second recovery phase of MRS. PCr concentration of the lateralis muscle in the second recovery phase and MP.kg-1 correlated negatively: r = -0.728 (p ≤ 0.05). Muscle volume of the m. quadriceps was significantly greater in SG than in EG (2406 ± 250 cm3 and 2866 ± 339 cm3, p ≤ 0.05). The SG exhibited significantly higher values for PP, MP, FI and lactate as well as for jump height (p ≤ 0.01). Lactate post WAnT correlated significantly (p ≤ 0.01) with jump height (r = 0.97). T-Tests for independent variables and a logistic regression analysis were carried out.

Conclusion: Skeletal muscle reveals considerable differences between endurance and sprint athletes. 31P MRS in combination with motor performance tests therefore seems to be a suitable tool to display differences in skeletal muscle properties of subjects with a supposed difference in their muscle fibre distribution.

PHYSIOLOGICAL INDICES OF IRANIAN ELITE FEMALE KAYAKRRS IN TWO DIFFERENT TESTS ON TREADMILL & ARM ERGOMETER

MIRAKHORI, Z., AGHA ALINEJAD, H., MOLANOURI SHAMSI, M.

TARBIAT MODARES UNIVERSITY

Introduction: Testing is the beginning of the implementation of a training program and it will provide direction and purpose to the planning of training. Aerobic and anaerobic power are the main factors of optimal performance in kayakers (Bishop D., 2000). One of the most important points in choosing tests for measurement of physiological characters in sport sciences's studies is the principle of specificity. Upper body muscles are often involved in kayaking. It seems that it is more valid the using of tests that upper body muscles are more involved in them (Bishop et al., 1998). This study was conducted to evaluate physiological indices of Iranian elite female kayakers in two different tests on tredmill & arm ergometer.

Methods: Twelve Iranian elite female kayakers (age: 16.5±2 yrs; height: 166.7±4.4cm; body mass: 57.89±7.3kg; %BF: 20.33±6 percent) participate in this study. VO2max, lactat threshold, lactat threshold VO2, VO2 pulse and ventilation measured by two incremental tests on treadmill and arm ergometr with gas analizing. Body percent and muscle mass evaluated by body composition analyzer. Antropometric characteres such as height; sitting height; arm span; arm, thigh and leg lengths; arm, thigh, sholder and pelvise breadths; and arm, thigh, chest, hip and leg girths are masured. Subject's performance evaluated by 12 kilometer kayaking test (K12t).

Results: VO2max values measured by the arm ergometer was lower than VO2max values measured by treadmill. There was significant correlation between VO2max values measured by two tests (r=0.68,p=0.015). Negetive correlation attained between both VO2max values with K12t time that was significant only with arm ergometer VO2max values.There were no significant correlation between body composition and anthropometric measurments with both K12t time and VO2max values in two tests. There was high correlation between VO2max, VO2 palse and VE values in two tests.

Discussion: An important determinant in the measurement of VO2max is the quantity of the muscle mass stressed when performing the task or mode of exercise used to elicit maximal oxygen uptake (Midgley et al., 2007). VO2max values measured by specific test in kayakers(arm ergometer), had lower than non-specific (treadmill) test that is explainable by low used muscle mass in this test. Significant negative correlation between K12t and arm ergometer can refer to specific test of upper body like kayaking.

EFFECTS OF THREE DIFFERENT WHOLE-BODY VIBRATION TRAININGS ON KNEE EXTENSOR MUSCLES STRENGTH AND JUMP PERFORMANCE.

PETIT, P.D., TESSARO, J., HÉBRÉARD, L., PENSINI, M., COLSON, S.S.

UNIVERSITY OF NICE-SOPHIA ANTIPOLIS

Introduction: Whole-body vibration (WBV) has been recently employed as a means of strength training in healthy humans (Luo et al., 2005). Most likely, the effectiveness of WBV training programs might be dependent of the wide possible combination of parameters (peak-to-peak displacement of the platform and vibration frequency) characterizing a WBV training session. To date, only one study has attempted to determine the optimal vibration frequency for increasing muscle strength after WBV training (Savelberg et al., 2007), but the effect of the displacement of the platform remain uninvestigated. Therefore, the purpose of this study was to compare the effects of 3 different combinations of WBV parameters on knee extensor muscles strength and jump performance.

Methods

33 physically active male students were randomly allocated to 3 groups: i) a low frequency and low displacement (30Hz, 2mm, n=10; G2F30), ii) a low frequency and high displacement (30Hz, 4mm, n=11; G4F30) and, iii) a high frequency and high displacement (50Hz, 4mm, n=12; G4F50). Three times a week, the WBV training consisted of maintaining unloaded static squatting positions over a 6-week period. Maximal voluntary isometric, concentric and eccentric torque, jump performance (squat jump; SJ and countermovement jump; CMJ), knee extensor muscles activation and contractile properties evoked by percutaneous neurostimulation were assessed before and after the training period.

Results: Whatever the variable analyzed before training, no significant differences were observed between groups. After training, a significant group x time interaction was found for SJ and CMJ. Jump performance was increased for both G4F30 and G4F50 groups ($P<0.05$). A significant increase (time effect) was observed for: i) the maximal voluntary torque produced during isometric, concentric and eccentric contractions and, ii) the single and paired twitches evoked at rest. Knee extensor muscles activation and post-contraction potentiation were not significantly modified after the training period.

Discussion: This study desmonstrate that training protocols performed with high displacement (4 mm) were more effective than the one realized with a low displacement to increase jump performance. Regarding the vibration frequency, no conlusions can be drawn after the present study. This result is consistant with the previous report of Savelberg et al., (2007), however these authors have only assessed frequencies under 35Hz. Although significant increased were found, further research is required to ascertain the exact influence of displacement and vibration frequency on isometric and dynamic strength. In conclusion, our 6-wk WBV training programs realized with a high displacement were effective to improve jump performance. These enhancements might be attributable to peripheral adaptations.

VALIDITY AND RELIABILITY OF THE SINGLE-TRIAL LINE DRILL TEST OF ANAEROBIC POWER IN BASKETBALL PLAYERS

JAMURTAS, A.Z., FATOUROS, I.G., KATRABASAS, I., CHATZINIKOLAOU, A., KAMBAS, A., TEXLIKIDOU, E., AGGELOUSIS, N., LEONTSINI, D., SOTIROPOULOS, A., GOURGOULIS, V., KELIS, S., TAXILDARIS, K.

DEMOCRITUS UNIVERSITY OF THRACE, DEPT. OF PHYSICAL ADUCATION & SPORT SCIENCES

Introduction: Although numerous tests have been used for anaerobic power and endurance assessment in basketball, questions arise regarding their movement and metabolic specificity (Ben Abdelkrim et al., 2007). The aim of the present investigation was to evaluate the single-trial form of the Line Drill Tet (SLDT) by measuring its concurrent validity, reliability, and sensitivity not only on the basis of performance output but also on blood lactate concentration following testing.

Methods: Twenty-four volunteers were assigned to either a control (C, N=12) or an experimental (BP, N=12 basketball players) group. Following familiarization, participants performed the SLDT, WAnT, and VJT in a random order to determine concurrent validity of SLDT. Subjects had their mean (MP) and peak power (PP) in the Wingate test (WAnT), mean height and MP in the 30-sec vertical jump test (VJT), and time-to-complete the SLDT measured. Blood lactate concentration was measured at rest and immediately after each test. Test-retest reliability was determined by computing the intraclass correlation coefficients (ICC) on time and blood. SLDT's sensitivity was determined by one-way ANOVA between the two groups

Results: Kendall's tau correlation analysis revealed significant (P<0.05) correlations between SLDT time and WAnT's PP (τ=0.78) and MP (τ=0.56) and VJT's MP (τ=0.85) and height (τ=0.90). SLDT lactate concentration was moderately (P<0.05) correlated with the respective lactate values of WAnT (τ=0.40) and VJT (τ=0.66). However, SLDT time in BP correlated (P<0.05) with VJT's MP (τ=0.80) and height (τ=0.90) but not with performance variables in WAnT. In contrast, SLDT lactate responses in BP were moderately (P<0.05) correlated with WAnT's PP (τ=0.54) and VJT MP (τ=0.68), height (τ=0.65), and lactate concentration (τ=0.65). Test-retest reliability ICCs for time and lactate were 0.92 and 0.93, respectively (P<0.05). In all tests, BP demonstrated higher (P<0.05) performance levels compared to C indicating an adequate sensitivity for SLDT.

Discussion: Previous research suggests that the LDT may be an acceptable field test for assessing anaerobic power in basketball (Hoffman et al., 2000). Our results show that the single-trial LDT demonstrates moderate to high concurrent validity compared against two criterion tests such as the WAnT and the VJT. Furthermore, the SLDT exhibited satisfactory reliability and sensitivity. This notion empowers basketball coaches to use the SLDT for measuring anaerobic power in their day-to-day practice since it is time- and movement-specific, inexpensive, allows the simultaneous measurement of several athletes.

UPPER BODY STRENGTH AND MUSCULAR ENDURANCE IN SPORT CLIMBERS

BALAS, J., STREJCOVA, B.

CHARLES UNIVESITY

Introduction: The upper body strength and muscular endurance are limiting factors of performance in sport climbing. Suitable tests to evaluate climber's performance are still to be introduced in training practice. The aim of this study was to evaluate muscular strength measured by grip dynamometer and muscular endurance measured by bent-arm hang and finger hang on 2.5cm ledge in sport climbers.

Methods: The testing was realised with 145 climbers on artificial climbing wall. We have analysed the relationship between tests results and climbing performance RP (red point) using Pearson correlation coefficient. Tests results represented dependent variables in multivariate analysis of variance (MANOVA) with the independent factors sex and climbing performance. Climbers performance was divided in four levels (3/5; 6a/6c; 6c+/7b; 7b+/8b of French scale).

Results: The correlation coefficients between climbing performance and finger hang was 0.750, bent-arm hang 0.720, grip strength relative to body weight 0.591. The results for finger hang:

men: 10.8±6.7s; 32.2±11.9s; 50.1±16.8s; 71.7±8.2s; women 4.8±5.6s; 28.9±30.2s; 40.2±16.7s; 38.4±2.2s, for bent-arm hang: men: 25.4 ±17.6s; 45.1±15.9s; 53.8±12.4s; 77.8±25.7s; women 13.2±9.9s; 31.0±18.2s; 52.4±16.8s; 55.9±5.3s, for relative grip strength: men: 0.59±0.13; 0.68±0.10; 0.73±0.09; 0.76±0.08, women: 0.45±0.08; 0.52±0.45; 0.56±0.03; 0.67±0.13.

Discussion: Muscular endurance of upper limb and fingers is the main strength predictor of climbing performance. The used tests seem to be suitable to evaluate upper body endurance in sport climbers. The maximum grip strength is a strong predictor only when related to body weight. The use of grip dynamometry is controversial because of using the thumb and different muscle groups in the test (Schweizer& Furrer, 2007; Grant et al., 2001; Grant, Hynes, Whittaker, & Aitchison, 1996). Despite these facts, our results suggest that the simple grip dynamometry is an appropriate test for maximal finger strength evaluation in sport climbers.

THE MODIFIED LOUGHBOROUGH INTERMITTENT SHUTTLE TEST <LIST>: A PERFORMANCE TOOL FOR USE WITH GAMES PLAYERS

ALI, A., GANT, N., FOSKETT, A., MOSS, C., LYNCH, C.

MASSEY UNIVERSITY

Background: The Loughborough Intermittent Shuttle Test (LIST)1 was developed as a tool to reliably and accurately simulate the physiological demands of multiple-sprint sports such as soccer. The LIST protocol primarily involves periods of variable-intensity activity but since the sub-maximal exercise intensities are pre-determined and controlled by an audible signal it is not possible to examine self-selected aspects of running performance. Thus, it is not possible to assess fatigue-related decrements in exercise performance or whether any interventions increase 'work output'. Therefore, the aim of this study was to investigate the reliability of a modified version of the LIST that included self-paced running for use as a performance tool. Methods: Fourteen male games players performed the protocol on two separate occasions with at least 7 days recovery between trials. The LIST comprises 6 x 15-min blocks of 'prescribed' variable-intensity exercise (walking, sprinting, brief recovery, running and jogging) where participants exercise in time to audible signals. The modified test comprised 4 x 15-min blocks of 'prescribed' activity followed by 2 x 15-min blocks of 'self-paced' running (i.e. no audible signals). Participants were instructed to replicate the relative intensities of the prescribed exercise during the self-paced period. Various performance indicators were recorded during the protocol. Body mass (BM) was measured pre and post exercise while heart rate (HR) and blood lactate ([La]) were examined routinely. Participants were given 3 ml•kg-1 BM water during the 3-min rest periods between exercise blocks. Results: A correlation of r = 0.82 (P<0.01) and coefficient of variation (CV) of 1.7% for distance covered indicate good relative and absolute reliability. However, participants covered 1.4 ± 1.7% greater distance in Trial 1 (12.85 ± 0.26 km) vs. Trial 2 (12.67 ± 0.37 km, P=0.01). Distance covered was significantly less during the self-paced running period relative to prescribed activity (P<0.05). Percentage time spent in each activity was not different between trials (P>0.05) but average running velocity was higher in Trial 2 (P=0.01). Sprint performance was similar between trials (P=0.38) with a CV of 5.6%. There was no difference in BM loss (P=0.84) or mean HR (P=0.98) between trials but mean [La] was higher in Trial 1 (P=0.01). Conclusions: Incorporating self-paced exercise within the existing LIST test appears to be a sensitive means of quantifying key performance variables, provided participants are adequately familiarised with the exercise protocol. The protocol successfully detects the decay in running performance that occurs during the latter stages of exercise.

PREDICTORS FOR MEASURED VO2MAX DURING A 20-METER SHUTTLE RUN TEST IN YOUNG SCHOLARS

SILVA, G., OLIVEIRA, N., MOTA, J., OLIVEIRA, J., RIBEIRO, J.C.

FACULTY OF SPORT - UNIVERSITY OF PORTO

Purpose: The purpose of this study was to verify witch are the best predictors for the VO2max directly measured during a 20-meter shuttle run test (20mSRT) in Portuguese young students aged 13-17 years considering sex, age, height, weight, body mass index and 20mSRT running parameters [number of total laps (LAPS), last half-stage completed (HSTAGE) and maximal running speed (MRS)].

Methods: Sixty-two subjects were randomly selected from 4 schools of Porto district and analyzed. All subjects performed a 20mSRT wearing a portable gas analyser to measure the VO2max directly. VO2max was considered when a detection of a plateau in the VO2 curve, defined as an increase of VO2 less than 2 ml/kg/min with a concomitant increase in speed stage. However, it is known that the classical VO2 plateau is absent in many young subjects. So, if that was the case, VO2peak was taken as the highest oxygen uptake achieved during the 20mSRT and defined as VO2max. In the present study 8.1% of the subjects didn't achieved the VO2 plateau. Exhaustion was confirmed when (1) subjects desire to stop or demonstrate inability to maintain the required running pace despite strong verbal encouragement, (2) maximal heart rate was greater than 85% of the age-predicted maximal heart-rate (220-age) and/or (3) respiratory exchange ratio was greater than 1.0. Linear regression analysis by stepwise method was calculated using a significance level of 5% in the SPSS version 15.0.

Results: Sex, age, height, body mass index, LAPS, HSTAGE and MRS were significant related with VO2max ($p<0.05$). Linear regression analysis presented statistical significant results for the prediction model of the observed VO2max ($R=0.757$; $R^2=0.573$; Adjusted $R^2=0.559$; Std. Error of the Estimate=5.807; $F=9.069$; $p<0.05$). The analysis of regression coefficients indicates that only sex and MRS appear as significant predictors for measured VO2max ($p<0.05$).

Conclusions: As possible predictors, linear regression analysis indicates sex, weight and last half-stage completed in the 20mSRT.

DEVELOPMENT AND CONTROL OF SPECIAL STRENGTH ABILITIES BY ALPINE SKIERS IN PRECOMPETITIVE PERIOD

BACHEV, V., DIMITROV, D., DIMITROV, A.

NATIONAL SPORTS ACADEMY, BULGARIAN SKI FEDERATION

Introduction: The high level of physical abilities of alpine skiers is a basic of good performances. This is a reason of annual planning and control of that field. The concrete content of the programs and system usually is a question of discussion.

Goal

The goal of research is to establish and integrate training system of planning and control of special strength abilities by alpine skiers in pre competitive period

Methodic of research included

Modeling as a method of establishment of training program which combine macro- , mezzo- and micro cycles. Literature review and expert evaluations were methods composed of a group of control tests as: length jump, three different triple jumps, fivefold and tenfold triple jumps, complex tests from maximal high jumps and multiple jumps over strength measurements platform

Objects of research

Alpine ski competitors – Bulgarian National Team members

Results and Discussion: The percent distributions of volume of training for physical abilities establish directions and influences of the training program. For development of very one of the strength abilities forms - dynamic, explosive, speed, agility, endurance the system of special exercise was selected. The analyses of control tests results show significant absolute and relatively improvements by all of the competitors. The analyses of individual dynamics of data for each tested person gives opportunity special strength level to be characterized. For example, the high for 60 contiguous maximal high jumps of the skier S.G. stays constant after his second performance (33±1 cm). This is a good target for good rating. On the other hand of the length jump by men and junior skiers the differences were found. By men the improvement between two control test procedures was average 8 ± 3cm. (PT -0,96) and by junior was average 14±4 cm (PT = 0.99).

Conclusions

-The establishing and experimented methodic for development of special strength by alpine skiers seems to be effective

-There were found significant improvements of the special strength abilities, which are forming an objective basics for successful competitive realization

-The presented system of planning and control is a priority factor of rational management of training process by alpine skiers.

TEST-RETEST RELIABILITY OF FITNESS AND SKILL TESTS IN ELITE MALE YOUTH BASKETBALL PLAYERS

PETERS, D.M., BALCIUNAS, M., STONKUS, S.

1. UNIVERSITY OF WORCESTER, 2. UNIVERSITY OF AGDER, 3. LITHUANIAN ACADEMY OF PHYSICAL EDUCATION

Purpose: To assess reliability of fitness and skill tests in elite youth basketball. Players (n=368) from 8 teams in Lithuania (U17 n=25; U16 n=21; U15 n=39; U14 n=57; U13 n=57; U12 n=37; U11 n=70; U10 n=58) completed 2 trials of 4 fitness tests: 20 metre sprint (Sprint); countermovement standing vertical jump (CMJ); standing vertical jump from squat (SVJ); side-step (SST) and two skill tests: ball dribbling (BD); & jump shot (JST), according to Balciunas et al., (2006). Change in mean & 95% confidence intervals, intra-class correlation coefficient, and log-transformed coefficient of variation were calculated (Hopkins, 2000) and correlated with age group. Results: Sprint: Cohort decrease in performance (mean diff .03secs, p<.001, 95% CI .04 & .01, ICCr .92, CV% 2.1); decrease for U17 (mean diff .04secs, p<.05, 95% CI .01 & .08, ICCr .74, CV% 1.9) and U10 (mean diff .06secs, p<.05, 95% CI .11 & .01, ICCr .71, CV% 3.2); ICCr range .71 to .89, CV% range 1.9 to 3.2 across years. CMJ: No cohort difference (mean diff .18cm, 95% IC .61 & -.26, ICCr .87, CV% 11.9) or year groups (mean diff range -.79 to .74cm, ICCr range .46 to .79, CV% 4.2 to 16.5); correlation between increasing age group and CV% (rho -.79, p<.05). SVJ: No cohort difference (mean diff .33cm, 95% CI .71 & -.04, ICCr .86, CV% 11.7); decreased performance for U16 (mean diff -1.44cm, 95% CI -1.6 & -2.73, p<.05, ICCr .70, CV% 6.1) and increased performance for U13 (mean diff .63cm, 95% CI 1.25 & .0, p<.05, ICCr .85, CV% 6.1) and U11 (mean diff 1.13cm, 95% CI 2.08 & .19, p<.05, ICCr .71, CV% 14.1); ICCr range .50 to .85, CV% range 4.7 to 15. SST: Cohort improvement (mean diff -.27secs, 95% CI -.21 & -.33, p<.001, ICCr .87, CV% 4.9) and all year groups (mean diff range -.15 to -.45secs, p<.05 to p<.001, ICCr range .72 to .90, CV% range 3.2 to 5.3) except U11; correlation between increasing age group and CV% (rho -.83, p<.05). BD: Cohort improvement (mean diff -.23secs, 95% CI -.17 & -.29, p<.001, ICCr .83, CV% 5.6) and all year groups (mean diff range -.19 to -.34, p<.05 to p<.001, ICCr range .62 to .91, CV% range 2.2 to 5.2) except U13. JSP: Cohort improvement (mean diff .72pts, 95% CI 1.04 & .41, p<.001, ICCr .45, CV% 54.5), with unacceptable ICCr (-.04 to .65) and CV% (28.5 to 77.1) ranges also in each age group. Conclusions: Cohort test-retest differences were deemed 'practically' unimportant with acceptable ICCr (>.70) except for JSP (ICCr .45). Trends for reduced CV% with increased age group reached statistical significance for the CMJ and SST suggesting increased variability in younger players. Apart from JSP, all tests are reliable for use with elite male youth players.

ESTIMATING THE VELOCITY ASSOCIATED WITH THE MAXIMAL OXYGEN UPTAKE FROM THE 20M SHUTTLE RUN TEST IN ADOLESCENTS

TSIARAS, V., PATRAS, K., MANOU, V., GEORGOULIS, A., KELLIS, S.

UNIVERSITY OF IOANNINA

Introduction: The 20m shuttle-run test (1) is widely used for the assessment of aerobic power and the prediction of maximal oxygen uptake. The limitation of the 20m shuttle run test is that it does not provide information for the velocity which is associated with the achievement of maximal oxygen consumption (vVO2max). However, vVO2max is a variable which is widely used in prescribing intensities for interval endurance training (2). Therefore the aim of this study was to develop an equation for the calculation of the vVO2max using the 20m shuttle-run test.

Methods: Sixty male adolescent athletes performed a maximal exercise test on a treadmill to assess the actual vVO2max and a 20m shuttle-run test. The incremental exercise protocol started at 8 km/h and the speed was increased by 1km/h every 2min until exhaustion. The vVO2max was defined as the velocity at which the VO2max occurred and was sustained for at least 1 minute. Then, the subjects were randomly divided into a derivation (n=30; age=14.9±1.5 yrs.) and a cross-validation (n=30; age=15.2±1.5 yrs.) groups. Multiple-regression analysis was used to develop the equation from the derivation group using as independent variables the total runs, the stage achievement and the velocity at the end of the field test. The derived equation was cross-validated using: correlation coefficient (Rcross-validation) between the actual and predicted vVO2max, constant error (CE=actual vVO2max – predicted vVO2max), standard error of estimate SEE, total error TE (3), and the Bland-Altman plot for the agreement between the actual and the predicted vVO2max.

Results: The following equation best attained the above criteria and most accurately estimated vVO2max: vVO2max (km/h) =9.625 + (0.058 x Runs), R=0.84, SEE=0.7 km/h.

The cross-validation statistics showed a correlation coefficient between actual and predicted vVO2max, Rcross-validation=0.86. The mean difference was CE=0.1 km/h. The SEE and TE were, 0.5 km/h (3.5%) and 0.7 km/h (4.5%) respectively. Bland-Altman, 95% limits of agreement ranged from (-1.38 to 1.23 km/h).

Conclusions

The velocity at the end of the shuttle run test was about 1.5-3.5 km/h lower than the actual vVO2max. The cross-validation statistics showed that the equation of this study accurately predicts vVO2max in 12-18 yrs. males demonstrating low values of CE, SEE, and TE. In

conclusion, the equation of this study can be used for the estimation of vVO2max, so as to use this variable for the prescription of interval endurance training.

RELATIONSHIP BETWEEN MAXIMAL ISOMETRIC STRENGTH AND MUSCLE ENDURANCE

NIEMI, J., VAARA, J., OHRANKÄMMEN, O.,3, SANTTILA, M., HÄKKINEN, K., FORSSTEN, A.S., KYRÖLÄINEN, H.,2

1. NATIONAL DEFENCE UNIVERSITY, 2. UNIVERSITY OF JYVÄSKYLÄ, FINLAND, 3. TRAINING DIVISION OF DEFENCE COMMAND

Introduction: Good levels of both aerobic and neuromuscular fitness are of great importance in order to ensure sufficient physical performance of soldiers. Thus, it is essential to further develop field fitness tests which are valid to measure the true aerobic and neuromuscular performance. The purpose of the present study was to examine how well the present muscle fitness tests can evaluate maximal strength of different muscle groups. More specifically, our interest was to examine the relationships between bilateral isometric maximal strength of the arm and leg extensors and muscle endurance of the respective muscles.

Methods: Bilateral isometric maximal strength of the arm and leg extensors, grip strength, muscle endurance (recording of the number of repetitions in one-minute push-up, sit-up and squat actions) and VO2max were measured from a total of 783 reservists. Their mean age was 24 ± 2.8 yrs., height 1.80 ± 0.06 m, body mass 80.3 ± 13.5 kg, and percentage of body fat 17.8 ± 7.2 %. Muscle fitness index (MFI) was calculated from the results of muscle endurance tests. Overall physical fitness index (PFI) was further calculated from MFI and VO2max.

Results: Mean (±SD) bilateral isometric strength was 2917 ± 868 N for the leg extensors and 898 ± 201 N for the arm extensors, and that of grip strength 53 ± 9 kg. The number of reps/min was 38 ± 10 in sit-ups, 28 ± 12 in push-ups and 43 ± 8 in squats. Mean VO2max was 41.6 ± 8.1 mlkg-1min-1. Significant correlations were found between maximal strength of the arm extensors and repeated push-ups ($r = 0.58$, $p < 0.001$) as well as between repeated squats and VO2max ($r = 0.55$, $p < 0.001$). Bilateral isometric maximal force of the arm extensors correlated significantly with MFI and PFI ($r = 0.51$, $p < 0.001$; and $r = 0.47$, $p = 0.001$, respectively). No significant relationships were observed between maximal isometric strength of the arm or leg extensors and that of VO2max as well as between grip strength and MFI or PFI.

Conclusion: The present study demonstrated that in a large group of subjects with great interindividual variation in physical fitness, the present muscle endurance tests seem to measure not only the level of muscle fitness, but also to some extent that of maximal strength. The relationship between maximal strength and muscle fitness was found in push-ups but not in repeated squats. However, the performance in repeated squats was related with VO2max, whereas that of push ups did not. Thus, it seems that muscle fitness measured by push-ups also relies on maximal strength, while the level of aerobic capacity contributes to performance in repeated squats. This may be explained by a higher relative load (body weight) of maximal strength in push-ups than in repeated squats. In conclusion, the present muscle fitness tests seem to measure rather well the overall fitness profile of soldiers, and the contributive role of maximal strength could be indentified for the arm but not for leg extensor muscles.

THE VALIDITY OF POLAR FITNESS TEST IS ASIAN POPULATION

LAUKKANEN, R., KANG, S.

UNIVERSITY OF OULU, SANG MYUNG UNIVERSITY

THE VALIDITY OF POLAR FITNESS TEST IN ASIAN POPULATION

Raija Laukkanen*,** & Suhjung Kang***

*Polar Electro Oy, Finland, ** University of Oulu, Finland, ***Sang Myung University, Seoul, Korea

Introduction: Polar Fitness Test (PFT) is a simple method to predict cardiorespiratory fitness. PFT predicts maximal oxygen uptake (VO2max) based on age, gender, height, weight, resting heart rate and heart rate variability measurements and amount of physical activity. The test has been developed and validated in Caucasian population (Väinämö 1996, Kinnunen 2000). The purpose of this study was to examine the validity of PFT in predicting the VO2max in Asian (Korea) population.

Methods: Sixty volunteer 20~49 years old female (n=30) and male (n=30) subjects participated in this study. All subjects were healthy and they did not use any medication. The mean(SD) of weight and height for the groups were: male 72.8 (8.4) kg, female 58.6 (9.4) kg and male 174.7 (5.9) cm, female 162.6 (5.6) cm.

Prior to maximal stress test, PFT was tested using Polar FT60 training computer (Polar Electro Oy, Finland). Activity level was classified according frequency and intensity of weekly exercise during past 3 months. The subjects resting HR and R-R intervals were recorded during quiet lying on the bed for 5 minutes.

Maximal stress test was performed using Bruce protocol. At each stage during the stress test, expired gases were collected and analyzed continuously (Trueone2400, USA). Criteria for attaining VO2max were as follows: heart rate at least 85% of the age-specific maximum (220-age), respiratory quotient (RQ) over 1.1, and voluntarily maximum (RPE higher than 17).To exam the mean differences of PFT and VO2max from laboratory test in each group, paired t-test was used. Also, the data was analyzed using the principle presented by Bland & Altman, and the total error of the prediction (E) was calculated.

Results: The mean(SD) values and E of PFT and VO2max by the laboratory test in ml/kg/min are as follows. Male: PFT 43.3 (7.8), VO2maxlab 43.5 (7.0), (E 12.3), Female: PFT 34.3 (4.4), VO2maxlab 35.7 (6.7), (E 10.4). The mean differences by two methods in male (t=-.182, Sig=.857) and female (t=-1.258, Sig=.218) were not significantly different.

Discussion: Measurements during exercise are the most common methods used to predict cardiorespiratory fitness. However, the current results showed that measurement from resting can be used to predict cardiorespiratory fitness. Our results show that PFT is a valid test to predict cardiorespiratory fitness in Koreans. However, in some individuals PFT may under-or overestimate the laboratory VO2max. The results of this study should be confirmed in other Asian populations and in individuals with various ages and activity status.

IMPROVED MEASURING PROTOCOL FOR DETERMINING THE HUMAN POWER SPECTRUM: REPLACEMENT OF THE WINGATE TEST BY THE SPRINT POWER AND THE TRANSITION POWER TESTS

MÜLLER, W.

UNIVERSITY OF GRAZ

Introduction: A test series capable of determining the human power spectrum, i.e. the maximum out-put power in all time domains of relevance (parts of a second to hours), has been introduced recently (Müller and Schmölzer, 2006; Müller und Hofmann, 2008).

Jumping power (squat jump force plate measurement) is used for the sub-second time domain.

For the domain of seconds the Sprint Power Test was developed (Müller and Fürhapter-Rieger, 2006). Pmax determined this way is substantially higher than what is called 'peak power' in the Wingate Test.

For determination of Pmax over 30s (immediate, non-oxidative, and oxidative energy modes) a new test protocol, termed Transition Power, is introduced here. Alternatively, 20s can be used.

For endurance power a maximal cycle ergometer step test is used (Hofmann et al., 1994; Müller and Hofmann, 2008).

It was the aim of this study to search for a relation between the load at maximum sprint power and the load for highest value of the 30s-mean power.

Methods: The sprint power measurement (2s) at loads between 4% and 16% of body weight considered the rotational energy of the fly-wheel. Instead of the Wingate Test, the Transition Power Test protocol was used for determining all-out power over 30s. This protocol avoids problems associated with maximum pedal frequency at the start: peak power cannot be obtained at or close to maximum pedal frequency (Hill AV, 1938), and measurement procedure is easier.

15 male and 10 female sport students participated in the study.

Results: The mean of the maximal 2s Sprint Power values (n=25) was 12.7 ± 2.4 W/kg (mean rpm:112), the mean of the power values (n=25) over 30s was 9.6 W/kg (85rpm), and the mean of the maxima during the 30s tests was 11.3 W/kg (107rpm).

Maximum sprint power of different individuals was significantly correlated (Kendall's tau=0.65; p=3.1e-5) with higher weight on the ergometer.

Surprisingly, in the 30s Transition Power Test there was no significant correlation (tau=0.28; p=0.08); the highest power was obtained at 11.3 % load (of body weight) and standard deviation was only 1.2 %.

Max. 2s sprint power ranged in the group from 8.4 W/kg to 16.9 W/kg and 30s transition power from 6.9 W/kg to 12.2 W/kg.

Discussion: For the determination of maximum power in the time domain of a few seconds (Sprint Power Test) a series of measurements at various resistances is necessary, whereas in the 30s time domain a single test using a weight of 11 % of body weight appears to be sufficient, according to the study results.

ENERGY EXPENDITURE AND SUBSTRATE UTILIZATION DURING AND 30 MINUTES POST HIGH INTENSITY INTERVAL VERSUS CONTINUOUS EXERCISE BOUTS

HETLELID, K., HEROLD, E., SEILER, S.

UNIVERSITY OF AGDER

Purpose: There is a focus in the fitness industry on exercising to achieve high energy expenditure (EE) and especially high fat oxidation (FO). The purpose of the study was to compare exercise EE, early recovery EE (REE), and total FO during "hard aerobic interval" vs. "talking intensity" continuous exercise bouts typical of fitness industry exercise sessions constrained to about 45 minutes effective exercise time.

Methods: After preliminary testing, 9 regularly active males (28 ± 6 yr, VO2max 55 ± 5 ml•min-1•kg-1) performed 10 min warm-up followed by a self-paced high intensity interval session (INT) consisting of six, 4 min work bouts interspersed by 2 min recovery periods (34 min total exercise time) with continuous gas exchange measurement during exercise and 30 min post exercise. During INT, subjects were instructed to maintain the highest average work intensity they could for the 6 bouts. Responses were compared with those measured during a steady state, time matched (TM), and a steady-state distance matched (DM) exercise bout. The intensity of the steady state sessions was prescribed as "talking intensity". INT and TM sessions were performed in randomized order, with the DM session performed last. EE, REE, and FO were estimated from continuous measurements of respiratory gas exchange corrected for RER over 1.0 time segments. Fat oxidation calculations are considered minimum estimates due to presumed contamination of CO2 production with CO2 release due to H+ buffering.

Results: The INT (during work periods) vs. TM and DM session elicited higher heart rate (171 ± 14 vs. 154 ± 15, and 160 ± 11 $p<0.05$), blood lactate concentration (6.5 ± 2.8 vs. 2.1 ± 1.1, and 2.3 ± 1,1 mmol•L-1, $p<0.05$), and RPE (17 ± 1 vs. 12 ± 1, and 12.4 ± 0.9 $p<0.05$). EE during INT was ~12 % higher (555 ± 75 vs. 495 ± 68 kcal, $p<0.01$) and REE was 23% higher (89 ± 15 vs. 72 ± 9 kcal, $p<0.01$) when compared to the TM steady state session. No differences in EE were found between INT and DM, but REE were higher in INT than in DM (89 ± 15 vs. 76

± 16 kcal, p<0.01). FO tended to be lower during INT vs. TM and DM (9.4 ± 3.1 vs. 13.0 ± 5.3 and 12.4 ± 5.6 g, n.s.). FO during the 30 min post exercise period was higher after INT (4.5 ± 1.4 g) vs. TM (2.6 ± 1.3g) or DM (2.5 ± 1.3g, p<0.05). Total FO (34 min exercise + 30 min recovery) was similar in INT, TM and DM exercise sessions (13.0 ± 3.7, 15.5 ± 6.4, 15.0 ± 6.4 g, n.s.).

Conclusions: In this study, we have attempted to simulate two exercise prescriptions typical of the time constraints and intensity goals of "1 hour fitness classes" and compared this to a distance matched exercise session. Our results suggest that for the same time investment, self-paced interval training results in significantly greater total energy expenditure and similar total fat oxidation than continuous exercise performed at "talking intensity."

PERFORMANCE CHANGES IN TOP-LEVEL ATHLETES DURING A BLOCK-PERIODIZED TRAINING CYCLE

GARCIA-PALLARES, J., SANCHEZ-MEDINA, L., CARRASCO, L., DIAZ, A.

UNIVERSITY OF MURCIA

Introduction: The rigorous demands of modern sport led prominent coaches to propose alternatives to traditional periodization. One representative model among these new trends is block periodization (BP). The main theoretical benefits of BP are: a) better possibilities to design multi-peak preparations; b) reasonable reductions of total training volume; c) ways to avoid negative interactions between different fitness components; and d) increased control over residual training effects (Issurin, 2008). Unfortunately, there are very few studies that have explored the effects of contemporary periodization and even less that have done so using elite athletes. Therefore, it was the purpose of this study to examine changes in selected physiological and performance variables in a group of top-level athletes across a 10-wk training cycle using a BP approach.

Methods: Fourteen top-level kayakers underwent a battery of tests, being assessed three times across two 5-wk training blocks. On each occasion, subjects completed an incremental test to exhaustion on the kayak ergometer for the determination of maximal oxygen uptake (VO2max), second ventilatory threshold (VT2), peak lactate (Lapeak), paddling speed at VO2max (PSmax) and at VT2 (PSVT2), stroke rate at VO2max (SRmax) and at VT2(SRVT2). One-repetition maximum (1RM) and mean velocity with 45% 1RM load (V45%) were assessed in the bench press (BNP) and prone bench pull (PBP) exercises. The main training goals of each block were: B1, anaerobic threshold and muscle hypertrophy; and B2, aerobic power and maximal strength.

Results: The BP training approach resulted in significant increases in VO2max (12.7%), VO2 at VT2 (8.1%), PSmax (3.0%), PSVT2 (5.0%), 1RM in BNP (9.3%) and PBP (10.2%), with no significant changes for Lapeak, SRmax, SRVT2 and V45% in BP and PBP.

Discussion: Changes in VO2max in only 10-wk of training are of similar magnitude to those described in previous studies with high-level kayakers (Bunc and Heller, 1994; Tesch et al., 1976), although the latter were accomplished after considerably longer training. The high values for strength and endurance parameters found in this study are in agreement with those reported by other investigators that studied high-level kayakers (Tesch et al., 1983) and demonstrate the great requirements of muscle strength and aerobic power of Olympic canoeing. Prioritizing the development of fitness components (one endurance and one strength component per block), by selectively concentrating load on 5-wk training blocks, seems to be an effective strategy for improving physiological and performance markers of highly trained top-level athletes with great requirements of both, strength and endurance.

EFFECTIVENESS OF THE MONITORING THE TRAINING FOR THE SUBJECTIVE PERCEPTION OF TIREDNESS AND PERFORMANCE IN BASKETBALL PLAYERS

LEITE, G., BORIN, J., PADOVANI, C.

NOVE DE JULHO UNIVERSITY; STATE UNIVERSITY OF CAMPINAS, STATE UNIVERSITY OF SÃO PAULO

Introduction: The present study aimed at evaluating and comparing the effects of adult basketball players´ training in different moments of periodisation.

Methods: Eight men took part in this study, with ages from 19 to 30 years, all of them athletes participating in the São Paulo basketball championship in the special division. The macrocycle analyzed encompassed 19 weeks and was divided into the periods: preparatory, competitive I and II (with four, six and nine weeks, respectively). The athletes were daily evaluated as to subjective perception of tiredness (Borg, 1982) and the load of applied training, that was the multiplication product of the volume in minutes by the intensity, obtained by perception scale of adapted effort (Foster, 1998). At the beginning and end of each microcycle, was evaluated the vertical jump (nine first weeks) and medicine ball throw (19 weeks). For the different comparisons, it was used in the technique of the parametric or not parametric analysis of variance for the model with a factor in repeated measures, complemented with the bonferroni´s multiple comparisons test. All the discussions here were accomplished considering the 5% significance level.

Results: Principal results point out to a variation of the tiredness self perception measure after training (13.7 ± 1.3a; 14.7 ± 1.5b and 14.6 ± 1.2b, for $p < 0.005$, respective for PP, CI and CII). Variables quantified by Foster's (1998) method also presented a variation during the period, as monotony (2.5 ± 2.0a; 2.1 ± 1.6a and 1.18b ± 0.4, for $p < 0.001$, respective for PP, CI and CII), and strain (9887 ± 9097a; 7360 ± 6272a and 4144 ± 2768b, for $p < 0.001$, respective for PP, CI and CII). Weekly total load not altered in periods. For the performance tests, the vertical jump not altered into periods (PP and CI), but medicine ball throw decrease in initial and end week in CII (initial: 3.80 ± 0.4a; 3.86 ± 0.3a and 3.59 ± 0.3b, $p < 0.005$ and end: 3.85 ± 0.3a; 3.89 ± 0.3a and 3.58 ± 0.3b, $p < 0.001$, respective for PP, CI and CII).

Discussion: The results found for the group of players analyzed show to effectiveness of monitoring athlete's load and tiredness through the proposed method to help planning the whole training, once athlete's status and applied load are monitored. The athlete's performance control showed the need to monitor their training in a more effective way, that is, weekly, once it was possible to obtain the exact moment of the rapid force performance decrease using an available simple method.

THE EFFECT OF HYPOXIC TRAINING REGIMENS ON PULMONARY FUNCTION

AMON, M., KERAMIDAS, M.E., DEBEVEC, T., KOUNALAKIS, S.N., MEKJAVIC, I.B.

1. JOZEF STEFAN INSTITUTE, LJUBLJANA, SLOVENIA, 2. JOZEF STEFAN INTERNATIONAL POSTGRADUATE SCHOOL, LJUBLJANA, SLOVENIA

Introduction: Hypoxic training results in respiratory adaptations, namely increased resting hypoxic ventilatory response (Schoene et al., 1990), and altered exercise breathing pattern (Mekjavic et al., 1991). The present study investigated the effect of three different hypoxic training regimens on pulmonary function, and on normoxic and hypoxic exercise ventilation (VE).

Methods: Thirty-six healthy male subjects (mean+SD age = 22.1 ± 3.5 yrs; height = 180.6 ± 5.5 cm; body mass = 73.6 ± 7.8 kg; VO2max = 50.8 ± 9.4 mL•kg-1•min-1) were equally assigned to four different training groups: "live low-train high" (LL-TH; n=9), which lived at 300m above sea level and trained at a simulated altitude (FIO2=12%); "sleep high-train low" (SH-TL; n=9) sleeping at a simulated altitude ranging fro 2800 to 3200 metres above sea level (FIO2=12%) and training at sea level; daily intermittent hypoxic exposures at rest (IHE; n=9) (7 cycles of 5-min hypoxia: 3-min normoxia) and training at 900 metres above sea level; or Control (Control; n=9) living and training at 300 m above sea level. All subjects trained 5 d•wk-1 for 4-wks on a cycle ergometer. The intensity of exercise training was 50% of the peak power output of each condition. Before and after each training regimen subjects conducted an incremental load exercise to exhaustion on a cycle ergometer under normoxic and hypoxic (FIO2=12%) conditions to define the VE. In addition, the pulmonary function at rest, namely forced vital capacity (FVC), forced expiratory volume in 1 sec (FEV1), peak expiratory flow (PEF), slow vital capacity (SVC) and maximum voluntary ventilation (MVV) was assessed by a spirometer (Cardiovit AT-2plus, Schiller, Switzerland).

Results: There were no significant differences in the FVC, FEV1, PEF and SCV in all groups post training. However, MVV was significantly ($p<0.05$) increased in the SH-TL group (Control: Pre: 183.4±34.0, Post: 185.0±29.9; SH-TL: Pre: 195.8±29.4, Post: 224.2±37.3). Moreover, VE was increased in SH-TL by a mean of 16.6±5 and 15.6±2 l∙min-1 in normoxia and hypoxia respectively, while no improvements were observed in the other three groups.

Discussion: SH-TL regime results in significant improvements in VE during exercise under nomoxia and hypoxia. These improvements accompanied by a significant increased MVV compared to Control group. We conclude that SH-TL is the most appropriate regimen to improve selected pulmonary variables at rest and ventilation during normoxic and hypoxic exercise.

SINGLE VS MULTIPLE SETS RESISTANCE TRAINING: EFFECTS ON UPPER AND LOWER BODY MUSCLE STRENGTH GAINS

BOTTARO, M., VELOSO, J., RIERA, T., MARTORELLI, S., MARTORELLI, A., GONÇALVES, D., AZEVEDO JUNIOR, H.

UNIVERSITY OF BRASÍLIA

Most studies reported that performing resistance training with multiple sets per training session is more effective for increasing strength as training with a single set. However, only few studies compared the effects of single vs. multiple sets on strength between small vs. large muscle groups, and upper-body vs. lower-body muscle groups (Paulsen et al., 2003; Ronnestad et al., 2007). PURPOSE: The purpose of this study was to determine the effect of single sets vs. multiple sets on different muscle group strength in untrained subjects. METHODS: Twenty seven apparently healthy, untrained male participated in the study protocol. The volunteers were randomly assigned into one of two groups: 1) elbow flexion single set and knee extension three sets (E1-K3; n=13; 22.5 yrs; 174,9 cm; 70,9 kg), or 2) elbow flexion three sets and knee extension single set (E3-K1; n=14; 23.4 yrs; 173,3 cm; 79 kg). Subjects trained 2 days per week for 12 weeks and each workout consisted of 1 closed chain knee extension exercise and 1 elbow flexion exercise. Training intensity varied between 8 repetitions maximum (RM) and 12RM. Unilateral knee extension and elbow flexion strength were tested for both groups at 60°/s on a Biodex System 3 isokinetic dynamometer. Strength was expressed as peak torque (PT). Statistical evaluation of the data was measured using a 2 x 2 x 2 analysis of variance [group (E1-K3 and E3-K1) x time (pre and post) x muscle group (elbow flexors and knee extensors)]. The probability level of statistical significance was set at $p < 0.05$ in all comparisons. RESULTS: ANOVA revealed the increase in PT of the knee extensors muscles from week 0 to 12 was significantly higher in the E1-K3 group (12.1%) than in the E3-K1 (5.5%) group, while no difference existed in PT gains between E1-K3 (14.3%) and E3-K1 (13.1%) of the elbow flexors muscles. CONCLUSIONS: It was concluded that performing three sets of strength training is superior to one set for increasing strength of the knee extensors muscles. It was also concluded that single-set training protocols for the elbow flexors muscles might be sufficient for untrained individuals in the first 12 weeks of a strength-training program.

THE EFFECTS OF A SHORT–TERM TRAINING PROGRAM IN THE RATE OF FORCE DEVELOPMENT AND CONTRACTILE PROPERTIES OF UNTRAINED ADULTS

PATIKAS, D., PARASCHOS, I., BASSA, E., SKOUFAS, D., GALAZOULAS, C., KOTZAMANIDIS, C.

ARISTOTLE UNIVERSITY OF THESSALONIKI, GREECE

Introduction: Rate of Force Development (RFD) is a term that describes the muscle's ability to produce rapidly force. Conflicting results are reported regarding the relationship between RFD and training and little evidence exists concerning the effects of a short-term maximum isometric training program on RFD, which is a major performance contributor in many sports (Aagaard et al., 2002). Thus, the purpose of this study was to investigate the changes in the voluntary torque, as well as the electrically evoked twitch torque properties, after a two days long program.

Methods: Nine untrained male subjects (age: 19.2±1.6 years, height: 181.0±5.0 cm, body mass: 79.4±7.3 kg) participated in the study. Training included two sessions of 30 maximal isometric, ballistic type plantar flexions, with 48 h interval. Evaluation of the calf muscles was assessed 48 h before and after the training. Maximum voluntary contraction, RFD and electromyogram (EMG) parameters were measured as well as electrically evoked twitch torque and maximum M-wave responses.

Results: After training the RFD during MVC increased in the later phase of contraction (after 100 ms) with no increase in the maximal force. No change in soleus EMG amplitude was observed, nonetheless medial gastrocnemius showed an increase during the force development period both in amplitude and frequency component, as assessed by spike analysis. Concerning the electrical evoked contractile properties, only peak twitch RFD increased significantly ($p<0.05$). All other examined parameters did not show any significant difference.

Discussion: The increase in voluntary RFD without concomitant increase of MVC could be explained by the increase in amplitude and firing frequency of gastrocnemius, in the absence of soleus or antagonist tibialis anterior electromyogram changes. The observed changes in gastrocnemius EMG gives evidence that spinal and/or supraspinal centers may contribute to adaptations after such short-term, isometric ballistic training (Del Balso and Cafarelli, 2007). The absence of adaptations in the soleus muscle, suggests that only muscles with larger proportion in fast twitch fibres are prone to the observed adaptations and may contribute to the voluntary RFD improvement.

SOCCER VS FLATWATER AND SLALOM KAYAK, IN RELATION TO BONE DENSITY AND MUSCLE MASS IN MALE COMPETITORS

CHRYSIKOPOULOS, K., DIAFAS, V., KALOUPSIS, S., MARIDAKI, M., SOTIROPOULOS, A., KOUTEDAKIS, Y.

NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS, DEMOCRITUS UNIVERSITY OF THRACE, UNIVERSITY OF THESSALY

We investigated the effects of different weight-bearing and non weight-bearing physical activities on bone mineral density (BMD) and appendicular muscle mass (AMM) in male competitors. One hundred-six male (aged 18-26 yrs) volunteered. The sample included flatwater kayakers (Kflat; Ν = 22), slalom kayakers (Κslalom; Ν = 19), and soccer players (S; Ν = 33) who competed at national and international level. Thirty two age-matched non athletic individuals served as controls (C). All competitors exercised regularly at least 8 yrs for an average of 10 mo per year, 6 d•wk-1 for a minimum of 3 h•d-1. Segmental, total BMD and AMM were assessed with a dual-energy x-ray absorptiometry (DEXA). DEXA analysis also includes bone mineral content (BMC) and fat and lean masses. Total BMD was significantly higher ($p < 0.01$) in flatwater kayakers (mean ± SD: 1.31 ± 0.16 g•cm-2), slalom kayakers (1.36 ± 0.14 g•cm-2) and soccer players (1.47 ± 0.17 g•cm-2) than the C group (1.18 ± 0.13 g•cm-2) while soccer players revealed the highest. Soccer players had significantly higher regional BMD of the legs (1.59 ± 0.18 g•cm-2) compared with the three groups ($p < 0.05$). AMM was significantly higher ($p < 0.01$) in all three athletic groups (Kflat: 32.9 ± 3.2 kg; Κslalom: 31.2 ± 3.9 kg; S: 35.3 ± 4.4 kg) compared with C (26.4 ± 3.9 kg). Body fat percentage (% weight) was significantly lower ($p < 0.05$) in all competitors (Κslalom: 13.2 ± 5.1; Kflat: 11.0 ± 3.5 and S: 8.4 ± 3.1 kg) than the C group (17.5 ± 7.1 kg). Individuals engaged in competitive weight-bearing activities (soccer players) and also non weight-bearing activities (flatwater and slalom kayakers), have significantly higher total BMD and AMM than controls. These results suggest that competing either in weight or non weight-bearing activities may be an important factor in achieving a high peak bone mass and reducing osteoporosis risk in elite male competitors.

MAXIMUM DYNAMIC STRENGTH AND ENDURANCE RELATIONSHIPS IN TWO LOWER-BODY RESISTANCE EXERCISES

BOULLOSA, D.A., IGLESIAS, E., CARBALLEIRA, E.

FACULTY OF PHYSICAL EDUCATION AND SPORT SCIENCES

Introduction: The purpose of this study was to examine the influence of maximum strength and exercise mode on the number of repetitions performed at the same intensity (%). The two lower-body resistance exercises selected were 90º Squat (Sq) and knee concentric extension (KE).

Methods: Seven male subjects (mass = 77.2 kg; height = 177.7 cm) experienced in resistance training were evaluated in repetition maximum (1RM) for Sq (1RMSq) and KE (1RMKE). The following days, with a minimum of 48 h between evaluations, they performed in randomized order the maximum number of repetitions (MNR) at 70% of 1RM. Continuous set configuration was used with interrepetition rests of 2 s. During the execution of the test, participants were suggested to perform all repetitions with maximum volitional velocity.

Results: MNR was of 33 ± 7.17 and 12 ± 3.45 for Sq and KE, respectively. Wilcoxon test showed significant differences among exercises in MNR ($p<0.05$). We did not find any significant correlation between 1RM and MNR. Spearman´s rank order significant correlation was detected between MNR in Sq and MNR in KE ($r = -0.767$; $p=0.044$).

Discussion: From these results, it was suggested that MNR at 70% of 1RM could be influenced by exercise mode but not by 1RM. Likewise, the negative correlation between MNR performances could be interpreted as an existence of different limiting factors from exercise mode differences. These factors could be related to the muscular type contraction and the muscle mass involved.

SPECIFICS OF TRIATHLON COMPETITIONS

LEITE, G., ANGELOCCI, L., BORIN, J.P.

NOVE DE JULHO UNIVERSITY, STATE UNIVERSITY OF CAMPINAS

The performance in Triathlon, sport that combines swimming, cycling and running has been much studied in recent years. Among them the studies of physiological responses of the triathlete and biomechanical analysis of methods that make up the Triathlon. However, there are few studies that address the specifics in these competitions. This study aimed is determine whether there are differences in the

contribution of swimming, cycling and running performance in the overall results of Triathlon with different distances. It examined the performance of elite male athletes, top ten in race, in competitions of Triathlon held in Brazil in the last three years. For the characterization of evidence with different distances, the performance in swimming, cycling and running was correlated with the overall time of the different races analyzed, considering the significant correlations with $p < 0.05$. In step of Ironman held in Brazil, the modalities cycling and running were determinants ($r = 0.88$ and 0.77, $p < 0.05$, respectively), with swimming having no significance for the outcome ($r = 0.35$, $p > 0.05$). Brazilian Championship of Long Distance (3 km of swimming, 80 km cycling and 20 km running) running and cycling were the decisive manner ($r = 0.93$ and 0.85, $p < 0.05$, respectively), with swimming having no significance for the outcome ($r = 0.50$, $p > 0.05$). In the Brazilian Championship Olympic Triathlon (vacuum permitted), running and swimming were determinants ($r = 0.99$ and 0.74, $p < 0.05$, respectively) and cycling had negative influence on the performance of the race ($r = - 0.79$, $p < 0.05$). In Short Triathlon (vacuum permitted and allowed distances of 0.75 km of swimming, 20km cycling and 5km running), all procedures were important to the overall performance, especially the running ($r = 0.90$, $p < 0.05$), cycling ($r = 0.85$, $p < 0.05$) and finally the swimming ($r = 0.66$, $p < 0.05$). After the analysis and interpretation of data, we can conclude that: i) the tactics used in race with the vacuum permitted seems different the race without vacuum, ii) there are differences between the tactics employed for the Triathlon held at different distances, so it is necessary to analyze the distance from race to the athlete direct his tactics for the competition; iii) the running is the main modality in determining results of Triathlon, in the most distances analyzed. There is still a need for further studies on the performance of triathletes at different distances, including female athletes.

THE IMPACT OF MUSIC ON PHYSIOLOGICAL, PSYCHOLOGICAL, COORDINATIVE EFFECTS IN RECREATIONAL AND ELITE RUNNERS

FERRAUTI, A., KRANASTER, D., SANDTLER, H., TINNEFELD, P.

RUHR UNIVERSITY OF BOCHUM

The common consumption of electronic music by small and light mp3 players during running raises the question if there is a performance benefit on the one hand or a cardiovascular risk on the other hand, respectively, for recreational and elite runners.

In our study eight recreational runners (RR: age 24.8±3.3 yrs; size 182±4 cm; body mass 81.0±7.9 kg; BMI 22.5±2.2; anaerobic threshold [v4] 3.26±0.48 m/s) and eight elite runners (ER: age 28.6±3.5 yrs; size 182±3 cm; body mass 73.8±5.1 kg; BMI 20.5±1.5; v4 4.36±0.25 m/s) completed an incremental treadmill test (TT) and a continuous running session (RS) until exhaustion at a velocity of 90 % v4. Both experimental parts were repeated twice with at least three days of recovery in between. The runners listened to self selected and sorted music by an mp3 player with earphones (volume was not limited) during one of the two exercise repetitions in a matched cross-over design. In TT we determined sub maximum (4 mmol/l blood lactate, LA) and maximum values for running velocity (v), heart rate (HR), VO2 and rate of perceived exertion (RPE). In RS we measured total running time and total running distance as well as LA, HR, respiratory exchange ratio (RER), RPE, stride frequency (SF) and stride length (SL) for every 10 min interval of running time.

The following results (mean ± standard deviation) were calculated using a multi factor ANOVA (main factors were performance group, music intervention and measurement time). In TT the music intervention (M) had no main effect on sub maximum and maximum running velocity, HF and VO2. RPE at 2 mmol/l LA was significantly lower in M (10.8±3.5 vs. 12.5±1.2, $p<0.05$) but was not affected at higher intensities. In RS total running time and total running distances until exhaustion were significantly increased in M for both groups (RR: 14.0±2.5 km in 80±12 min vs. 12.6±1.8 km in 73±13 min; ER: 21.2±3.1 km in 90±13 min vs. 18.1±2.8 km in 79±14 min , $p<0.01$ for main factor music intervention). No main effect for music intervention was found for LA, HR and RER. Running time until reaching RPE 15 was significantly longer in M in both groups (67±18 min vs. 47±14 min, $p<0.01$). Running coordination (step frequency and length) were unaffected by the music.

We conclude that a music intervention has no considerable effect on physiological and coordinative aspects during running. On the other hand running performance can be increased especially during moderate running (2 mmol/l LA). Obviously, recreational and elite runners are tolerating moderate intensities for a longer time because of a decreased work load perception. We conclude that music intervention may be helpful to increase training volume. The cardiovascular risk of music intervention in healthy runners seems to be low, since the autonomous signalling of peak intensity seems to be not affected. In case of a cardiovascular disease, off course, even a prolonged moderate run (e.g. during a marathon) can be dangerous.

PP-TT13 Training and Testing 13

INCREASE OF SPECIFIC RAPIDITY OF JUDO THROUGH STIMULATION METHOD

VILLANI, R., CAMPIONI, C., DISTASO, M.

UNIVERSITY INSTITUTE OF CASSINO - MOTOR SCIENCES FACULTY

Introduction: Today Judo high level athletic competitions, such us Olympics and Internationals ones, are characterized by always more quick and offensive matches. The trainers pay attention to training methods able to increase the explosive strength in techniques projection of Judo. In this work we analyzed, Verchoshanskij stimulation method: an overload training done before technique exercises, to increase rapidity. We applied this method on judo training.

Methods: The experimentation was conducted on 10 Judo agonistic athletes (age: 16/29; weight: 57/93 kg; height: 153/185cm; age of practice: 8/21). To measure the improvement of rapidity obtained by the method of stimulation, we calculated the time of technique execution, with the TEP test (Projection Execution Time – Villani et all, 2001), an integrated system of photocells and a footboard with piezoelectric cells, that permits to calculate the split time and projection time of Judo techniques. Athletes performed the TEP test during 4 repetitions of preferred techniques (Tokui Waza or special technique) at the highest speed, making a 45 seconds pause between the techniques. After this Judokas performed a sequence of squat warm up and subsequently 3 series of 4 squat repetitions at 85% of 1RM, with a pause of 3 minutes between the series. At the end of 4 minutes recovery, the athletes repeated again the test as the first time. The

difference of the results obtained before and after the squat has been analysed statistically. The reliability of the protocol has been verified by test-retest correlation.

Results: The correlation between the results of the test and retest highlighted some values of r higher than 0,90 in all the parameters considered ($p<0.001$) so the protocol can be defined very reliable.

The analysis of the split time pointed out a very high correlation with r values of 0,99. The comparison of the results before and after the squat trial, revealed, in every studied case, a higher rapidity in the execution of techniques after the stimulus with percentage differences in all the parameters, varying from 10% to 17% ($p<0,05$).

Conclusions: The Anova results obtained permit us to confirm that the performed techniques after specific squat is really better than pre-squat values. So, the method of stimulation can be considered an important system of training useful to increase the rapidity/explosive strength .

Anyway, is important to point out that the results have been inferior to the results obtained by Verchoshanskij in previous tests, conducted over other athletics discipline. (improvement over 20%)

To obtain more interesting results it will be probably necessary to use the method of stimulus on athletes with more experience in the training with overloads.

EVALUATION OF SPECIFIC RAPIDITY IN SANDA

VILLANI, R., DI PASQUALE, G., DISTASO, M.

UNIVERSITY INSTITUTE OF CASSINO - MOTOR SCIENCES FACULTY

Introduction: From the analysis of Sanda matches we can understand that rapidity execution of punches and kicks, the frequency rapidity of techniques and the rapidity of reaction of the athlete are important factors to win this discipline. We organised a research to control the rapidity of reaction of specific action of Sanda techniques. In this research we studied two specific tests: the FSPK (Frequency Speed of Punch and Kick – Villani et all. 2006, mod.) and TEP test (Execution Time throwing techniques – Villani, 2001 mod.) mode PCP (Posterior Fall Point), which allow to take the time of reaction to luminous stimulus and the effective time of technique, with an integration system of photocells, of footboard with piezoelectric cells and of a luminous starter.

Methods: The athletes of this research were 20 all of these male between 18-24 years old and experts of Sanda from many years. Ten athletes are agonists while the other 10 athletes are amateurs. We have before administered the FSPK test in which we have analysed 3 combinations of jab and circular low kick for left and right position, in reaction to visual stimulus; later we have made the TEP test mode PCP with 3 projection, always in reaction to visual stimulus given from the luminous starter. The difference between the amateur and the agonist group, able to show discrimination capacity of tests, has been statistically analyzed with difference percentage and Anova. The group has repeated the whole battery of tests in two consecutive trainings for studying the reliability with test-retest correlation.

Results: The correlation between test and retest data concerning all the technique combinations analysed has resulted particularly high with value of r between 0,80 and 0,93. In FSPK test the agonist group has always significativity been faster of amateur group, with a difference between means of 14% ($p<0,05$) for reaction time of techniques, and 6% ($p<0,03$) for the action time.

This difference has been stronger in TEP test PCP, in which the agonists have reported an higher action rapidity (13%; $p<0.001$) and reaction times better of 16% ($p<0,05$) then amateurs.

Conclusions: The correlation test-retest has showed the great reliability of tests studied.

About the study of discrimination capacity of tests, the results don't have showed an absolute supremacy of agonist athletes in relation of amateurs (it's sure caused by the similar athletic and technique preparation level of the two groups), but the difference of the two groups appears however important and significative in all the tests analysed.

Then we can said that the FSPK test and the TEP test mod. PCP can be considered valid and reliable instruments for valuing the rapidity of reaction and action of Sanda athletes and for monitoring their performances during different phases of training.

EFFECTIVE PRACTICE SCHEDULE FOR IMPROVEMENT OF BALANCE

ZEMKOVA, E., DZURENKOVA, D.

FACULTY OF PHYSICAL EDUCATION AND SPORT, COMENIUS UNIVERSITY BRATISLAVA

Variety of exercises and methods are incorporated into balance training. However, there are no scientific guidelines concerning effective practice schedule for improvement of balance. Therefore, using retention tests we investigated a) optimal practice-rest ratios, and b) efficient exercise mode for balance training. A group of 14 PE students (age 21.0±2.3, height 181.2±8.9 cm, weight 74.2±8.0 kg) underwent different combinations of practice and rest on two balance tasks, making the percentage of time actually spent in practice (20%, 40%, 60% and 80%, respectively) of the total 30-min period. Thus, the protocol was as follows: a) 6 min practicing (12 x 30 sec) / 24 min rest (12 x 2 min), b) 12 min practicing (12 x 1 min) / 18 min rest (12 x 1.5 min), c) 18 min practicing (12 x 1.5 min) / 12 min rest (12 x 1 min), d) 24 min practicing (12 x 2 min) / 6 min rest (12 x 30 sec). This schedule was examined under different conditions: a) balancing or performing squats on wobble board, b) performing squats with different velocities while standing on wobble board, c) performing squats with different additional loads (AL) on wobble board. The learning was tested by administering a transfer test, which was given on the second day. The COP velocity was registered at 100 Hz by means of posturography system FiTRO Sway check based on dynamometric platform. While exercising and standing on stabilographic platform, cardiorespiratory parameters were monitored using breath-by-breath system Spiro-ergometry CS 200. Velocity of movement during squats was measured using the FiTRO Dyne. Results showed that for balancing on wobble board, the optimal condition for learning occurred when 80% of the time was spent practicing. However, by adding squats, such a combination of 2 min practice and 30 sec rest induced a gradual increase in ventilation and heart rate (peak values about 13.4%). Subjects also reported fatigue in lower limbs, which influenced their ability to perform exercise properly. The transfer test showed that for squats performing on wobble board, the optimal condition for learning occurred when 40% of the time was spent practicing. In addition, retention tests of various exercise mode showed that for improvement of balance are more efficient a) squats performing on wobble

board than balancing on unstable surface, b) explosive squats (~180 cm/s) than those performing with slower velocity (~90 cm/s), c) squats on wobble board with lower AL (e.g., 25% of body weight) than those performing with higher AL (50% and 75% of body weight). These findings indicate that explosive squats performing on wobble board with AL of 25% body weight for 1 min with 1.5 min rest in-between (i.e., 12 min practicing / 18 min rest in 30 min session) is effective schedule for improvement of balance. Previous experience also showed that adaptive changes in balance performance of elite athletes may be induced if such a schedule is provided 4-5 days per week for >25 training days.

THE EFFECT OF 8-WEEK INSTABILITY AGILITY TRAINING ON SENSORIMOTOR PERFORMANCE IN UNTRAINED SUBJECTS

ZEMKOVA, E., CEPKOVA, A., POTOCAROVA, L., HAMAR, D.

FACULTY OF PHYSICAL EDUCATION AND SPORT, COMENIUS UNIVERSITY BRATISLAVA

The study evaluates the effect of 8-week instability agility training on balance, reaction time and sensorimotor parameters. Untrained subjects divided into experimental (n = 16, age 21.1±1.0 y, height 179.6±8.1 cm, weight 72.3±8.5 kg) and control group (n = 16, age 21.0±0.8 y, height 181.8±5.7 cm, weight 75.9±6.6 kg) underwent reaction tasks similar to game-like situations in floorball on wobble boards (one 30 min session a week for a period of 8 weeks). Prior to and after the training sensorimotor parameters, balance and reaction time were evaluated. Sensorimotor parameters including distance, time and velocity of sway trajectory were measured by means of FiTRO Proprio check consisting of an unstable spring-supported platform equipped with PC system for feedback monitoring of COP movement. The task of the subject was to hit, as fast as possible, the target appearing randomly in one of the corners of the screen by horizontal shifting of COM (60 stimuli). Postural stability was assessed under both static and dynamic conditions (wobble board) with eyes open and eyes closed, respectively. The COP velocity was registered at 100 Hz by means of posturography system FiTRO Sway check based on dynamometric platform. Visual multi-choice reaction time was measured using FiTRO Reaction check. Two sets of 20 stimuli were performed in random order, one under normal conditions and another one while balancing on wobble board. During the task execution both sway velocity and reaction time were measured. Results showed that COP velocity registered under unstable conditions as a parameter of dynamic balance improved significantly (p≤0.05) from 121.7±18.7 mm/s to 97.0±16.1 mm/s. Even more profound decrease (p≤0.01) in sway velocity was found while responding on visual stimuli concurrently with balancing on wobble board (from 141.0±24.7 mm/s to 106.9±18.0 mm/s). Also multi-choice reaction time measured under unstable conditions significantly (p≤0.05) decreased (from 986.8±120.3 ms to 852.5±125.2 ms). However, this effect was not observed while standing on stable surface (from 833.2±118.4 ms to 812.6±114.0 ms). Similarly, there were no changes in COP velocity registered in static conditions with eyes open (from 13.6±2.7 mm/s to 13.1±2.4 mm/s) as well as with eyes closed (from 15.6±3.8 mm/s to 16.1±2.4 mm/s). Unfortunately, no information on changes in dynamic balance without visual control could be obtained because during pre-testing most of the subjects were not able to stand on wobble board with eyes closed. Training program applied has also proved to be unsufficient to improve sensorimotor performance. After the same training control group failed to show any significant improvement in all examined abilities. It may be concluded that balance exercises performed simultaneously with reaction tasks represent an effective means for improvement of balance on unstable surface, namely when responding to visual stimuli, and for decrease in multi-choice reaction time.

ENERGY EXPENDITURE AND COMFORT DURING NORDIC WALKING WITH DIFFERENT POLE LENGTHS

HANSEN, E.A., SMITH, G.

NORWEGIAN SCHOOL OF SPORT SCIENCES

Nordic Walking is a fitness activity that has been practiced for about 10 years and which has spread internationally to for example Germany, UK, and USA from the Nordic countries. For many practitioners of Nordic Walking, an attractive characteristic of the activity is that energy expenditure is greater than during ordinary walking. Notably, the excess energy expenditure is attained without negatively affecting the perceived exertion or comfort. The lengths of the Nordic Walking poles are self-selected by practitioners on the basis of experience rather than research.

The purpose of the study was to investigate whether the aerobic demand of Nordic Walking could be enhanced further by adjusting pole length and through that achieve still higher energy expenditure, without compromising the comfort of the activity.

Twelve experienced participants [2.8±0.5 (mean±SEM) years of Nordic Walking on a regular basis of around 2 times per week] performed 6-min bouts of uphill (12˚), downhill (12˚), and horizontal Nordic Walking on a treadmill with their preferred pole length of 67.6±0.6% of body height and with 7.5 cm shorter poles. Participants were not unusual in stature or aerobic fitness [171.5±1.5 cm, 67.0±2.7 kg, 50.6±2.4 years, maximal oxygen uptake (VO2max) of 43.4±2.8 ml kg-1 min-1]. Treadmill velocity was self-selected by each participant for each slope and was maintained for both pole lengths. Energy expenditure was calculated from measured oxygen uptake while comfort was self-rated on a 1- to 10-point scale where 1 and 10 corresponded to "very, very uncomfortable" and "very, very comfortable", respectively.

The self-selected velocities during uphill, horizontal, and downhill were 1.13±0.04, 1.65±0.06, and 1.50±0.04 m s-1, respectively. During uphill Nordic Walking, the oxygen uptake and energy expenditure were 3.0±1.1% and 3.2±1.0% higher (P<0.05) with the short poles compared to the poles of self-selected length. For comparison, no differences of oxygen uptake or energy expenditure were found between the pole lengths during horizontal and downhill Nordic Walking. None of the comfort scores were different between the pole lengths during Nordic Walking at any of the slopes (P>0.05). The relative exercise intensity during Nordic Walking with self-selected pole length ranged from 43.7±2.4% (during downhill) to 86.8±2.2% (during uphill) of VO2max across the slopes. Underlining the peculiarity of Nordic Walking, participants rated comfort to above 7 at the same time as they exercised at above 85% of their VO2max during uphill Nordic Walking.

In conclusion, aerobic demand increased by about 3% for experienced practitioners of Nordic Walking using 7.5 cm shorter poles compared with self-selected poles for uphill walking at the same velocity. Notably, the excess energy expenditure with shorter poles was obtained without changes in the self-rated comfort. For horizontal and downhill conditions, energy expenditure and comfort were similar between pole lengths.

POSTURE ANALYSIS: VARIATIONS AND RELIABILITY OF BIOMECHANICAL PARAMETERS IN BIPEDAL STANDING BY MEANS OF FORMETRIC SYSTEM

SCHROEDER, J., MATTES, K.

UNIVERSITY OF HAMBURG

Introduction: Testing human motor behavior has to take care of motion variability (Hatze, 1986). It is the purpose of this investigation to verify test reliability in three repeated trials of bipedal standing for posture analysis by means of Formetric® system parameters with regard to natural inherent motion variations.

Methods: N=69 back pain patients (36 females, 33 males; age 43 y ±12 y) participated in this investigation, where they went through three repeated posture measurements separated by a two minute brake minimum and with comletely new positioning. Back shape was analyzed by means of Formetric® system (resolution 7.500 pts/cm²; reconstruction error <0.2 mm) (Drerup & Hierholzer, 1994) and expressed in several parameters describing spine and pelvis character in the frontal plane (trunc imbalance, pelvic tilt, vertebral side deviation), the sagittal plane (trunc inclination, pelvis inclination, lordosis and kyphosis angles) and the transversal plane (vertebral surface rotation, pelvis torsion). Reliability for the three trials was calculated using the Intra Class Correlation (ICC) coefficiant (SPSS 12.0). Variations of posture parameters were expressed using the standard error of the mean (SEM) based on the three repeated trials.

Results: SEM for pelvic inclination and torsion, all kyphosis and lordosis angles, as well as for all surface rotation parameters indicated a variability of ± 1-2°. For pelvic tilt it was ± 1-2 mm and for trunc inclination and imbalance it was ± 2-3 mm. ICC coefficiants of the posture parameters were higher than 0.9 for trunc and pelvic inclination, kyphosis and lordosis angles and were higher than 0.8 for trunc imbalance, pelvic tilt and all surface rotation parameters. ICC coefficiants were less than 0.8 for pelvic torsion and most of vertebral side deviation parameters.

Discussion: This study is embedded in a larger investigation, where spine shape deformities should be detected automatically and lead to a specific exercise therapie; following posture alterations should be observed in a pre-post design (Schröder & Färber, 2009). Technical accuracy of the Formetric® system is proved (Drerup & Hierholzer, 1994) and the system is known to be helpful in the diagnosis of back shape disorders (Asamoah et al., 2000). The results of this study make sure that test reproducability is given (ICC). The knowledge of the value of motion variability (SEM) in bipedal standing enables an investigator to judge both, an actual value of a spine shape parameter being normal or irregular, and modifications of posture parameters being accidental variations, or possibly being systematic, following the specific exercise therapy.

DIFFERENCES BETWEEN BLOOD AND SALIVA LACTATE

REER, R., SEMERAK, P., SCHMIDT, T., LOPPOW, D., BRAUMANN, K.M.

UNIVERSITY OF HAMBURG

The determination of saliva lactate concentrations in saliva samples represents a non-invasive and an innovative method for determination of endurance capacity and endurance diagnostics. Therefore, the purpose of this study was to assess the concentration of saliva lactate (SL) in contrast to blood lactate concentration (BL).

18 healthy subjects (13 male, 5 female; age: 27.3±6.2 yrs; physical activity: 6.9±2.7 h*wk-1) performed four cycle ergometer tests (one lactate minimum test [LMT] and 3 constant load tests at 95%, 100% and 105% of the workload at the maximum lactate steady state [MLSS] determined from the LMT). Blood and saliva samples were collected simultaneously and analyzed for lactate.

All tests exhibit a clear delay in SL measurements when compared to BL. SL values were lower than BL values (range: 2-5 times). SL curve leveled off later than BL during the constant load tests. Workload of MLSS from the constant load test [BMLSSCL] (209.7±44.8 W) was significantly lower in comparison to workload measured for maximum lactate steady state during LMT generated from blood [BMLSS] (219.7±45.5 W; n=18; $p<0.05$) and saliva [SMLSS] (235.9±58.4 W; n=16; $p<0.05$).

The results demonstrated that more inertial appearance of SL may be explained by an additional diffusion of lactate in the salivary glands. An approximation of BMLSSCL by SMLSS is not possible when using the established protocol with an increment duration of 3 min. due to the delayed appearance of lactate in saliva.

MASTERING OF THE MAIN GYMNASTIC EXERCISES ON THE BASE OF THEIR BIOMECHANICAL ANALYSIS

SHLYAHTOV, V., SEMENOV, D., MEDVEDEVA, E.

ACADEMY OF PHYSICAL EDUCATION AND SPORTS

Introduction: The core of technique performance training at initial stages in artistic gymnastics is the basic skill training and mastering of specific main exercises of gymnastic all-around. The main exercise technique performance training becomes more and more important for gymnasts at the stage of initial specialization.

Methods: Biomechanical analysis of several main exercises was conducted for defining the kinematic parameters of their performing and for optimization of the main exercise mastering process. Those exercises were acrobatic forward handspring and back handspring, forward handspring vault, swing back to handstand on parallel bars and a giant circle on high bar. 6 experienced gymnasts performed these exercises and the performance was video recorded and processed in "Star Trace" computer programme. This way we've got the data of angular kinematics of the given exercises.

Results: 10 gymnasts of the initial specialization stage mastering the main exercise technique performance took part in our research. Their performing of the main exercises under research was also recorded and processed. The comparing of results showed the evident differences between the two groups, mostly in kinematics of joint angles.

The kinematic parameters of high qualification gymnasts' performance of the main exercises became the model for training of gymnasts at the stage of initial specialization. The achieved results were a target for the young gymnasts in their training process.

The technological approach of conditioning gymnasts is based on the following principles: algorithm of the methods aimed at effective achievement of the goal; minimization and optimization of the aids and means of training; selection and usage of training means adequate to individual gymnasts' conditions and those of sport facilities.

Discussion: The final comparison of the young gymnasts test group results with the high qualification gymnasts' data showed less significant differences between them. It certifies that the young gymnasts' main exercise technique performance changed to be closer to the model one. In addition, the test group results' dynamics was considerable and there were some significant differences between the initial and final results of the main exercise technique performance.

This research certifies that usage of the additional instrumental methods of gymnastic exercise performance evaluation allows to reveal performance errors more precisely. It will promote the efficiency of the training process.

A COMPARISON OF GROUND AND TREADMILL ENERGY COST OF RACE WALKING

BOSQUET, L., GAYDA, M., PAP, F., LÉGER, L.

UNIVERSITY OF POITIERS

Purpose: A prerequisite in the development of a multistage field test is the knowledge of the energy cost of the specific mode of locomotion. There are only few data available about race walking, and most of them have been measured on a treadmill. Therefore, the aim of this study was to compare ground and treadmill energy cost of race walking with the purpose of determining the incrementation rate of a specific multistage field test.

Methods: Six highly trained race walkers of national to international calibre gave their written informed consent to participate in the study. They completed two randomly ordered sessions separated by at least 24 h, one on a 200 m indoor synthetic track, one a laboratory motorized treadmill. The protocol consisted in walking with proper technique at 8, 10, 12 and 14 km.h-1 for 4 minutes without rest in between. Thereafter, speed was incremented by 0.5 km.h-1 every minute until exhaustion to determine peak oxygen consumption. Oxygen uptake and related gas exchange measures were determined continuously on a 30 s basis using an automated cardiopulmonary exercise system (K4b2, Cosmed, Italy).

Results: Mean was 64.5 ± 10.3 ml.min-1.kg-1 and was reached at 14.7 ± 0.8 km.h-1. Combining data of all participants resulted in almost identical -speed relationships between track (y = 4.90x – 7.10, R2 = 0.53) and treadmill race walking (y = 4.85x – 6.74, R2 = 0.72). There was a high interindividual variability, as evidenced by a large standard error of estimate (SEE; 9.3 and 7.6 ml.min-1.kg-1 for track and treadmill race walking, respectively), and by the ~ 30 ml.min-1.kg-1 difference between less and more economical race walkers at 14 km.h-1. Interestingly, we observed a significant relationship between economy of walking at 14 km.h-1 and (r = 0.68, $p<0.05$). In this small sample of athletes, less economical race walkers compensated their lack of efficiency by higher . The visual inspection of individual curves confirmed the validity of using a linear model. The average energy cost of race walking estimated from such a model increased by 5 ml.min-1.kg-1 per km.h-1, either on the track or the treadmill. In comparison, the average energy cost of running is 3.5 ml.min-1.kg-1per km h-1. (X1 in ml kg-1 min-1) and walking economy (X2, at 14 km h-1 during the track test in ml kg-1 min-1) explained 92% of the variability of the maximal speed attained during the treadmill test (Y = 15.089 + 0.073 X1 - 0.07862 X2, R2 = 0.84 SEE = 0.39 km h-1).

Conclusion: Despite a high interindividual variability, our results underscore the usefulness of developing a specific multistage field test for race walking. Considering that optimal incrementation should allow an increase in of ~ 3.5 ml.min-1.kg-1 every two minutes, a speed incrementation of 0.5 to 0.75 km.h-1 every two minutes appears to be more specific to race walking than the 1 km.h-1 every two minutes incrementation that is usually used in running.

OPTIMAL ELECTRODES SETTING FOR TRANSCUTANEOUS ELECTRICAL STIMULATION OF THE QUADRICEPS

VANDERTHOMMEN, M., TROKA, S., DEMOULIN, C.

UNIVERSITY OF LIEGE

Introduction: Treatment or training sessions with neuromuscular electrical stimulations (NMES) are generally performed in a transcutaneous manner with the aid of surface electrodes. Several investigators have highlighted the benefits of quadriceps stimulation during rehabilitation following traumatic injury or surgery of the knee and during physical preparation of athletes (Kramer and Mendryyk, 1982). However, the practical modalities of quadriceps stimulation (number, size and localization of electrodes) remain controversial (Vanderthommen and Duchateau, 2007). The present work aimed to determine the optimal electrodes setting for NMES applied to the quadriceps.

Methods: Twenty physically active men (23 ± 2 years, 180 ± 8 cm, 75 ± 12 Kg) underwent first an evaluation of left quadriceps maximal isometric voluntary torque (QMIVT). The exact localization of the motor points of vastus medialis (MPVM) and vastus lateralis (MPVL) was also determined. Then, we tested unilaterally, isometrically and consecutively five electrodes settings (ES) including rectangular (10 x 5 cm) (RE) or square (5 x 5 cm) (SE) electrodes, with identical stimulation parameters (biphasic symmetric rectangular pulses, 80 Hz, pulse duration 0.35 ms, constant current intensity (42 ± 11 mA)): ES1= 1 channel, 2 RE transversally on the thigh (with the distal electrode placed on MPVM and MPVL); ES2= 1 channel, 2 RE longitudinally on MPVM and MPVL; ES3= 1 channel, 2 SE on MPVM and MPVL; ES4= 2 channels, 4 SE (with 2 SE placed on MPVM and MPVL); ES5= 2 channels, channel 1= 1 SE on MPVM and 1 RE transversally on the proximal part of the thigh, channel 2= 1 SE on MPVL and 1 RE transversally on the proximal part of the thigh. For each ES we measured the electrostimulated torque.

Results: The mean QMIVT reached 200 ± 51 Nm. The MPVM and MPVL were situated 10 ± 2 cm and 14 ± 3 from the patellar base, respectively. The stimulated contractions reached 9.2 ± 7.4 Nm (4.6% of QMIVT) for ES1, 8 ± 4.8 Nm (4% of QMIVT) for ES2, 15 ± 8.3 Nm (7.5% of QMIVT) for ES3, 16.3 ± 7.7 Nm (8.2% of QMIVT) for ES4 and 40.4 ± 11.3 Nm (20.2% of QMIVT) for ES5 ($p<0.05$).

Discussion: During NMES programs it appears crucial to use a proper electrode setting ensuring efficient muscle recruitment and therefore optimized training effects. However, physiotherapists and trainers often place electrodes empirically especially for NMES applied to the quadriceps. This study demonstrated the relevance of using two channels for quadriceps NMES and of setting, for each channel, one small "excitative" electrode exactly on the motor point of vastus medialis or lateralis and one bigger "dispersive" electrode transversally on the proximal part of the thigh (in order to close the circuit).

UTILITY AND VALIDITY OF THE STEP TEST IN WATER BASED ACTIVITIES

RAFFAELLI, C., LANZA, M., ROSATI, F., GALVANI, C.

FACULTY OF EXERCISE AND SPORT SCIENCES - UNIVERSITY OF VERONA

Applied Exercise Physiology Laboratory, Catholic University of Milan, Italy

Introduction: The Actiheart –AH- (Cambridge Neurotechnology, UK) is a relatively new waterproof device that combines heart rate (HR) and activity data for objectively measuring physical activity (PA) and inferring energy expenditure (EE). It has been already demonstrated (Brage, 2005) that the ramped step test, designed to establish the individual heart rate (HR) physical activity intensity (PAI) relationships and to derive a prediction equation for fitness, allows a greater accuracy in the estimation of physical activity energy expenditure (PAEE) activities on land.

The purpose of the present study was to examine the utility and validity of the step test in water based activities (WA).

Methods: 12 physically active women (age 26±2,9 yr; BMI 19,7±1,6 kg/m2; resting V'O2 3,4±0,6 ml/kg/min) volunteered to participate in the study and performed in two separate weeks the following tests: a laboratory test (incremental test to exhaustion on treadmill) in order to identify the actual maximal oxygen consumption (V'O2max, K4b2, Cosmed, Italy) and two ramped step tests (one on land and the other in water). Oxygen consumption was measured continuously throughout the step tests by indirect calorimetry (IC) and participants wore the AH on the chest for simultaneous estimation of HR-PAI relationships. V'O2max was predicted at the end of the step tests from AH data.

Results: HR-PAI relationships obtained with IC, even if significantly correlated (r=,905, p<,0001), significantly differ on land and in water (p<,0001). HR-PAI relationships estimated by the AH were highly correlated with IC both on land and in water (r=,906 and ,737, p<,0001 on land and in water respectively) even if they resulted significantly different in both conditions (p<,0001). The positively correlated errors with measured values in the plots of both land and water models indicate a proportional difference in these equations (mean difference between methods= land 15,4±9,7, water -18,2±18,5; 95% limits of agreement= land -4 to 34,7, water -18,8 to 55,3). The variances of the two methods significantly differ (p<,0001). In fact, the shared variance between predicted HR-PAI relationships from the IC was R2 = 0,71 (SEE = 5,22 ml/kg/min) on land and R2 = 0,54 (SEE = 12,62 ml/kg/min) in water. V'O2max predicted at the end of the step tests from AH data significantly differ from the actual values (p<,001), even if it is highly correlated (r=,791, p<,001).

Discussion: The significant differences detected between HR-PAI relationships on land and in water with IC underline the necessity to perform the step test both on land and in water to increase the accuracy for estimating EE if WA are concerned. The AH significantly underestimates HR-PAI relationships and V'O2max, so it can be suggested to use HR-PAI relationships derived from IC when possible.

EFFECTS OF TRAINING CESSATION ON MUSCLE STRENGTH, BODY COMPOSITION AND RESTING HORMONES IN ELITE KAYAKERS

SANCHEZ-MEDINA, L., CARRASCO, L., GARCIA-PALLARES, J.

UNIVERSITY PABLO DE OLAVIDE, SEVILLE

Introduction: In top-level athletes, there is a need to incorporate some regeneration period after the conclusion of the main event of the season in order to allow for physical and mental relief before the start of a new training cycle (Bompa, 1999). Usually, this layoff is associated with performance declines that are dependent on the chosen recovery strategy (reduced training or inactivity), initial fitness level, and total time under reduced or absence of training stimuli (Mujika and Padilla, 2000). However, the consequences of these post-season breaks on performance are not fully understood. The aim of this study was to analyze changes in muscle strength, body composition and resting hormones during 5-wk of training cessation (TC) in ten elite kayakers.

Methods: Maximal strength and power testing, body composition assessment and blood sampling were conducted 7-d before the start of the Flatwater Racing World Championships (T1), and after 5-wk of TC (T2). One-repetition maximum (1RM) and mean velocity with 45% 1RM load (V45%) were assessed in the bench press (BP) and prone bench pull (PBP) exercises. Body fat (BF) and muscle mass (MM) were estimated from anthropometric measurements. Blood samples were assayed for testosterone (T) and cortisol (C) by radioimmunoassay.

Results: From T1 to T2, significant declines in 1RM values were found for BP (-9%) and PBP (-8%). Similarly, V45% significantly decreased by 13% and 9% for BP and PBP, respectively. No significant changes were observed in body mass. However, BF significantly increased (21%) and MM decreased (6%) from T1 to T2. Cortisol decreased (-30%) and T increased (12%); consequently, T/C drastically increased (70%).

Discussion: The main findings of the present study were that 5-wk of TC resulted in significant reductions in maximal strength and muscle power, decreases in muscle mass and increments in body fat, elevation in T and T/C and reduction in C. Thus, short-term TC resulted in a true detraining effect, with large declines experienced in physiological markers of highly conditioned athletes. Positive changes were those related to an apparently increased androgenic-anabolic activity, possibly due to the body's reaction to combat the catabolic processes induced by the high levels of physical and mental stress experienced during the precedent season. Our findings support previous research (Häkkinen et al., 1981; Izquierdo et al., 2007), and demonstrate the need of a maintenance program of reduced training to avoid excessive declines in neuromuscular function in cases where a prolonged break from formal training is required.

RELIABILITY OF LUMBAR POSITION SENSE TEST USING ELECTROGONIOMETER IN SEATED POSITION ON A SWISS BALL.

SOLANA, M.

UNIVERSITY RAMON LLULL

Introduction: Joint position sense has been used to measure proprioception with isokinetic dynamometer (Lephart & Fu, 2000) or 3space track (Newcomer et al, 2000; Shum et al, 2007). It hasn't been measured with electronic goniometer on lumbar spine.Therefore, the aim of this study was to determine the reliability of lumbar position sense test over a swiss ball using electrogoniometer (Transducer TSD130A from Biopac Systems, USA).

Methods: Twelve healthy volunteers, 8 men and 4 women (22.3+/-2.6 vs. 23+/-1.8 respectively) performed maximal flexion and extension lumbar movement 3 consecutive trials, sitting over a Swiss ball with hips and knees between 80º and 90º of flexion maintaining the back straight keeping the sight to the front and both hands over the knees on a relaxed position. This was repeated in two different days. The Electrogoniometer was attached on the skin, its cranial arm following lumbar line up to L3 level and lower arm following lumbar line under L3 level. Repositioning error data were collected. It was required to maintain during 3 seconds each perceived maximal flexion and extension position during each of the three trials. There was neither feedback nor order along the test. Intertest repeatability was obtained calculating the variability coefficient between trials in the same day of test. Intratest repeatability obtained using Wilcoxon non parametric statistic analysis between tests in two different days. Intertest repeatability was considered when variability coefficient was lower than 100% and Intratest repeatability was considered with Wilcoxon significance p≥ 0.05.

Results: Variability coefficient means were from 5.8% to 10% for both repositioning errors. Bilateral signification from Wilcoxon test was p=0.285 reaching maximal flexion and p=0.508 reaching maximal extension.

Conclusions: The results suggest that the electrogoniometer is a reliable instrument to measure the lumbar position sense over a Swiss ball. It could be an easy and less sophisticate way to improve lumbar proprioception researches.

ANALYSIS OF HEART RATE IN THE ELITE KITEBOARDING: NATIONAL CUP 2008

PEREZ-TURPIN, J., CORTELL-TORMO, J.M., CHINCHILLA-MIRA, J.J., CEJUELA-ANTA, R.

UNIVERSITY OF ALICANTE

Introduction: The principal aim of this study is to identify the intensity that supposes competition to participant in 2008 Spain National Cup. Physiological demands and intensity of the effort have been analyzed in new Olympic windsurf board (Castagna et al, 2007) and Laser and mistral sail (Vogiatzis et al, 2002). This data was recorded in Elite International level although it was not under racing conditions. Kiteboarding is a new water sport. The athlete (Nickel et al, 2004) uses a small board and transfers the energy of the wind into speed by a large maneuverable kite.

Methods: Ten male professionals windsurfers (n=9, 27.6±22 years, 174.1±5.1 cm Height, 74.4±8.6 Kg weight, 9.91±3.4 kg body fat). Were chosen the ten first qualified of elite Kiteboarding: Spain National Cup 2008 (organised by Royal Spanish Sailing Federation,and the Spanish Association of Kiteboarding (AEK), Santa Pola (Spain) 2008) and were monitorizaded during the firts race, (racing form,R1) valid to the final classification in the championship. It was used a GPS recording unit (outdoor sports computer series W 600). The software was used in order to analyze data to FRWD outdoor sports computers series for the GPS data. After assessment, data was analysed statistically using the SPSS 13.0 software package to compare kiteboarding parameters. Wind´s speed varied from 10 to 14 $m \bullet s^{-1}$. Anemometer was (AVM-40, Kestrel 4000).

Results: Heart rate (HR) and average temperature (30.6±1.2ºC) was recorded, making a difference in the total time of the course (16.5±1.4 min). On one hand with up-wind leg (8±0.1 min, 19.02±7.2 $km \bullet h^{-1}$, 127.37±4.1 $beats \bullet min^{-1}$) and also on the other hand with down-wind leg (8.5±0.7 min, 14.43±8.1 $km \bullet h^{-1}$, 140±8.5 $beats \bullet min^{-1}$).

Discussion: Values of heart rate are significantly higher than those obtained in other studies windsurf (Castagna et al, 2007; Vogiatzis et al, 2002). This may be due to the way in which data were recorded (higher wind speed, the kite higher and the structure of competition). Actually there are significant differences (p <0001) between heart rate and speed record with a maximum wind and wind leg to leg. Find similar differences in other studies (Castagna et al, 2007; Vogiatzis et al, 2002). In summary, heart rate is a parameter warning intensive effort in kiteboarding, but is influenced by external parameters (the competition, the wind speed and size of the kite) and internal (age and educational level).

RELIABILITY AND VALIDITY OF A KAYAK ERGOMETRY TESTING.

CARRASCO, L., GARCIA-PALLARES, J., SANCHEZ-MEDINA, L.

1. UNIVERSITY OF SEVILLE, 2. UNIVERSITY OF MURCIA, 3. PABLO DE OLAVIDE UNIVERSITY.

Introduction: Flat-water kayaking is an olympic sport that combines different types of boats (canoe and kayak) and distances (500 m for female and 500 m and 1000 m for male competition). The contribution of aerobic metabolism at individual races has been established between 60 and 80% for 500 m and 1000 m, respectively. In this sense, an accurate assessment of optimal training intensities for to

develop aerobic and anaerobic metabolisms is needed. This assessment can be achieved through field tests (open water environment) or under simulated conditions in laboratory environment using specific kayak ergometers. Several investigations have attempted to test the validity of these ergometers, comparing open water kayaking and kayak ergometry (Larsson et al., 1988; Witkowski et al., 1989; Van Someren & Dunbar, 1996). The results of some of these studies showed a lack of correspondence of physiological responses to open water and ergometric tests. Probably, drag resistance generated by ergometer (laboratory test) and open water (field test) can to produce these differences modifying, indeed, the kayaking technique. However, there have been advancements in the development of air-braked kayak ergometers that can to offer new possibilities in the application of laboratory test for prescription and evaluation of kayak paddlers. So, the aims of this study are to determine the validity of a specific kayak ergometer and to evaluate its application in training prescription and evaluation of top-level kayak paddlers and to design an ergometric test protocol for the assessment of certain physiological and technical parameters that can to define kayaking performance.

Methods: Fourteen male top-level kayak paddlers (all members of Spanish Kayaking National Team) participated in this investigation. All subjects carried out two ergometric tests (Ergo1 and Ergo2) and one open water test (OWT) in random order.

Results: At anaerobic threshold (AnT) intensity, the results showed acceptable levels of reliability (comparison between data of Ergo1 and Ergo2 tests) in the assessment of velocity ($r=0.784$; $p=0.004$), stroke frequency ($r=0.976$; $p<0.001$), heart rate ($r=0.964$; $p<0.001$), and blood lactic acid concentration ($r=0.899$; $p<0.001$). Validity coefficients showed a strong relationships between Ergo2 and OWT tests in all physiological and technical parameters with the exception of velocity ($r=0.498$; $p=0.121$).

Conclusions: It can be concluded that specific ergometry can be used to evaluate and to prescribe training AnT intensities of top-level kayakers attending to parameters such us heart rate, whole blood lactic acid concentration, and stroke frequency. Nevertheless, the training prescription through specific ergometry must be taken cautiously when velocity is the parameter of reference.

THE EFFECT OF THREE DIFFERENT COMPRESSION GARMENTS ON TIME TO EXHAUSTION, OXYGEN UPTAKE AND LACTATE CONCENTRATION DURING HIGH INTENSITY EXERCISE

HAEGELE, M., SPERLICH, B., ZINNER, C., WAHL, P., MESTER, J.

GERMAN SPORT UNIVERSITY COLOGNE

Introduction: Compression stockings have become common among endurance athletes not only in long lasting events (e.g. marathon) but also in short and middle distance running. Although their use is widespread during these intense exercises, few scientific research were executed observing their influence during these kinds of exercise. Furthermore the majority of these studies focus on wearing stockings, whereas no study has investigated the effect on performance and related physiological variables when increasing the amount of compressive area onto the body. The aim of the study was therefore to investigate the influence of three different compression garments (stockings, stockings + tight, whole body compression) on maximal endurance performance and performance influencing parameters.

Methods: 14 male well-trained endurance athletes (age: 27,1 ± 4,8 yrs, height: 183,1 ± 7,6 cm, weight: 76,3 ± 7,6 kg, VO2peak: 63,7 ± 4,9 ml*kg*min-1) performed an incremental step test on a treadmill, to assess the velocity for the following four high intensity exercise bouts (HIB), which started four days after the initial testing. During HIB, all subjects randomly wore textile with different compressive surface: 1. regular non compressive running gear, 2. compression socks, 3. compression tights and 4. whole body compression (tight & top). During each of the high intensity exercise bouts time to exhaustion (TLim), lactate concentration (LAC) and oxygen uptake (VO2peak) was measured.

Results: TLim was 310 ± 130, 280 ± 76, 296 ± 90 and 281 ± 91 seconds for the non compressive, sock, tight and whole body condition, which constitutes no statistically significant difference ($p<0,05$). Either not significant was LA, where values of 7,6 ± 2,88, 7,31 ± 2,29, 7,64 ± 2,46 and 7,12 ± 2,11 mmol*l-1 were measured. This is supported by VO2peak, which was 59,8 ± 13,6, 62,9 ± 7,3, 60,3 ± 8,9 and 61,1 ± 8,6 ml*kg-1*min-1 and not significant as well.

Conclusion: For the first time the effects of increasing the amount of compressive surface vs non compression on maximal endurance capacity was evaluated. The results of this study revealed no beneficial effects neither on time to exhaustion (TLim) nor on performance affecting variables like VO2 or LAC when wearing compressive textile. Although, one has to consider that the data was detected during a high intense exercise bout. Scientific data concerning long distance events like Marathon or Ironman are yet to be undertaken, what disallows suggestions about the physiological and psychological effects of compression clothing during long lasting endurance events.

INCREASING PASSIVE RECOVERY DURATION LEADS TO GREATER PERFORMANCE DESPITE HIGHER BLOOD LACTATE ACCUMULATION AND PHYSIOLOGICAL STRAIN DURING REPEATED SHUTTLE 30-S SPRINTS

BUCHHEIT, M., DUTHIE, G., AHMAIDI, S.

FACULTY OF SPORT SCIENCES, UNIVERSITY OF PICARDIE, JULES VERNES

Introduction: Increasing recovery duration during very short (i.e., <6 s) repeated sprints has been shown to improve performance and to decrease physiological strain (Balsom et al., 1992; Glaister et al., 2005), inferred from lower heart rate (HR), post-exercise blood lactate accumulation ([La]) and rating of percieved exertion (RPE)). Whether this effect is preserved when considering sprints (i.e., 30 s) and recovery (i.e., >60 s) of longer durations is not known. The aim of the present study was to examine the effect of increasing recovery duration on repeated 30 s sprint performance and HR, [La], and RPE.

Methods: Thirteen male team-sports players (21±1 y; 76.8±6.3 kg; 1.79±0.10 m) performed 6 maximal 30 s shuttle sprints, each interspersed with either 35 (RS35) or 80 s (RS80) of passive recovery. The two assessments were performed one week apart and in a random order. HR was measured continuously (Polar S810, Polar Electro, Kempele, Finland), and [La] (Lactate Pro, Arkray Inc, Japan) and RPE (0-10 Borg scale) were collected 3 minutes post trial. Maximal and mean distance covered, as well as speed decrement index (%Dec) (Glaister et al. 2005) were computed for each recovery condition.

Results: Maximal distance was similar for both trials (135±10 vs. 137±9 m, $P=0.30$), whereas mean distance was lower (117±7 vs. 127±9 m, $P<0.001$) and %Dec higher (13±7 vs. 8±3 %, $P=0.03$, ES=-0.91) for RS35 compared with RS80. Maximal HR was similar for both conditions (94±4 vs. 94±4% HRmax, $P=0.75$), whereas mean HR was higher for RS35 (88±4 vs. 84±1% HRmax, $P<0.001$ for RS35 vs. RS80,

respectively). [La] and RPE were greater for RS80 compared with RS35 (15.1±1.7 vs. 13.3±2.2 mmol.l-1, P=0.03, ES=0.84 and 8.7±0.9 vs. 7.9±1.0, P=0.07, ES=0.74).

Conclusion: Increasing passive recovery from 35 to 80 s during repeated 30 s maximal shuttle running sprints in team-sport players leads to greater total distance covered and lower speed decrement, despite an increase in physiological strain (RPE) and [La] accumulation. This beneficial effect on running performance is not surprising; the longer passive recovery duration may enabled greater PCr resynthesis between sprints. However, the increase in [La] accumulation contrasts previous studies (Balsom et al. 1992; Glaister et al. 2005). This could be related to a decrease in aerobic participation with increased recovery duration, possibly leading too an increased anaerobic deficit at the initiation of each sprint. Increasing passive recovery duration can be used by coaches to trigger anaerobic system participation during 30-s repeated sprints.

POWER AND SPEED AMONG YOUTH ATHLETES FROM DIFFERENT TEAM SPORTS

STANGANELLI, L.

STATE UNIVERSITY OF LONDRINA

Introduction: Team-sport training is generally characterized and by a diverse range of training types. Power and speed are variables that influence the performance of the athletes and are frequently tested to provide a profile as well as training-induced adaptations. Considering that the performance is specific to training and to the type of sport, the aim of this study was to evaluate the jump capacity (countermovement-jumps (CMJ), squat jumps (SJ) and CMJ with arms swing (CMJW)) and speed 20 meters sprint (20S)) of young athletes from different team-sports Basketball, Futsal, Handball and Volleyball during the preparation phase for the 2008 Youth Games of Parana State-Brazil.

Methods: The sample was composed of 45 male (Age: 16.3±0.6 years; Height: 1.81±0.4 m; Weight: 73.6±9.9 kg) and 41 female (Age: 15.5±1.1 years; Height: 1.66±0.4 m; Weight: 60.4±6.7 kg). The study was approved by the university human ethics committee and all subjects signed an informed consent document. The vertical jumps were collected according to Bosco protocol. The subjects stood on a contact mat and the jump height was calculated by an Ergojump apparatus (Bosco system). Three attempts were allowed and the highest one was recorded for each test. The speed was measured with a wireless time system composed of 3 pairs of infrared emitters at the 0-m, 10-m and the 20-m marks. Each subject completed two attempts and the fastest trial was recorded. The One way ANOVA was utilized to test the differences among the group of means and the Scheffee Pos Hoc was used as the follow-up test. The significance level was set at p ≤ 0.05.

Results: For the male athletes the results were: VERTICAL JUMP: Basketball (N 12)-SJ: 33.6±4.5 cm; CMJ: 37.5±4.0; CMJW: 45.0±5.1.Futsal (N 10)-SJ: 33.6±4.5 cm; CMJ: 37.4±3.1; CMJW: 43.7±3.9.Handball (N 13)-SJ: 35.3±5.8 cm; CMJ: 38.5±6.5; CMJW: 43.7±3.9.Volleyball (N 10)-SJ: 36.4±5.9 cm; CMJ: 40.1±6.7; CMJW 46.3±6.7), SPEED: Basketball-3.11±0.11s; Futsal-2.98±0.03s; Handball-3.11±0.17s; Volleyball-3.00±0.18s.

For the female athletes the results were (VERTICAL JUMP: Basketball (N 12)-SJ: 26.6±3.1 cm; CMJ: 28.4±3.1; CMJW: 32.1±3.3. Futsal (N 10) -SJ 20.0±4.1 cm; CMJ: 23.9±4.5; CMJW: 28.2±3.1. Handball (N 12)-SJ 24.3±3.7 cm; CMJ: 26.6±4.1; CMJW: 31.0±5.1. Volleyball (N 7)-SJ 27.3±3.6 cm; CMJ: 30.9±3.7; CMJW 35.5±5.3. SPEED: Basketball-3.38±0.16s; Futsal-3.37±0.11s; Handball-3.43±0.13s; Volleyball-3.36±0.18s. The statistical analysis revealed that there were no significant differences among the group means of the four types of team-sports considering either male or female subjects.

Discussion: Based on these results the used tests did not show differences when evaluating athletes from different types of team-sports. Despite the specificity of training and the characteristics of each sport, it was not possible to verify the differences caused by these aspects on such a young group of athletes.

MINIMUM OF HRV DURING EXERCISE COMPARED WITH LACTATE MINIMUM AND CONCONI TEST

KNOEPFLI-LENZIN, C., RUSCA, F., BOUTELLIER, U.

EXERCISE PHYSIOLOGY, INSTITUTE FOR HUMAN MOVEMENT SCIENCES AND SPORT, INSTITUTE OF PHYSIOLOGY AND ZURICH CENTER FOR INTEGRATIVE HUMAN PHYSIOLOGY (ZIHP)

BACKGROUND: Heart rate variability (HRV) decreases to a minimum with increasing exercise intensity (Tulppo et al., 1996).

PURPOSE: We compared HR and power output at HRVmin with HR and power output at lactate minimum (LM) as well as the point of HR deflection of a Conconi test (CT).

METHOD: 41 subjects (19 men and 22 women; age: 29 ± 5 years, weight 69 ± 12 kg and height 175 ± 9 cm) performed 3 tests on a treadmill and 57 subjects (30 men and 27 women; age: 31 ± 6 years, weight 69 ± 12 kg and height 175 ± 9 cm) performed 3 tests on a cycle ergometer to determine HR and speed (power output) at HRVmin, LM and CT. HRV during exercise was analysed plotting each RR-interval as a function of the previous RR-interval (Pointcaré plot). Standard deviations of instantaneous beat-to-beat variability were calculated in windows of 100 RR-intervals. HRVmin matches with the lowest standard deviation of the consecutive RR-window.

RESULTS: In running, speed at HRVmin was lower than at LM and CT (11.0 ± 2.2 km/h vs. 12.2 ± 1.6 km/h, $p < 0.05$, and 12.7 ± 1.7 km/h, $p < 0.001$). In cycling, power output at HRV min corresponded to power output at LM but was lower than at CT (190 ± 44 W and 194 ± 47 W vs. 228 ± 61 W, $p < 0.01$). HR at HRVmin was lower than at LM and CT in running (155 ± 12 min-1 vs. 167 ± 12 min-1 and 170 ± 9 min-1, $p < 0.001$) as well as in cycling (145 ± 16 min-1 vs. 160 ± 13 min-1 and 154 ± 11 min-1, $p < 0.001$). HR at HRVmin corresponded to 82 ± 6 % of HRmax during running and 79 ± 7 % during cycling.

CONCLUSION: Speed, power output and HR are lower at HRVmin than at LM and CT except for power output at LM. Therefore, HRVmin is not suited as a tool to determine anaerobic threshold but rather to determine a useful endurance training intensity for moderately trained subjects.

EFFECTS OF DIFFERENT WARM UP INTENSITIES ON POWER OUTPUT AND METABOLISM DURING AND AFTER SHORT TERM MAXIMAL SPRINT EXERCISE

WAHL, P., ZINNER, C., HAEGELE, M., BLOCH, W., MESTER, J.

GERMAN SPORT UNIVERSITY

Introduction: Despite limited scientific evidence supporting their effectiveness, warm-up (WU) routines prior to exercise are a well-accepted practice. As a result, warm-up procedures are usually based on the trial and error experience of the athlete or coach, rather than on scientific study. Several previous studies have demonstrated that a number of physiological changes occur with active warm-up, some of which are potentially capable of improving performance. The majority of the effects of warm up have been attributed to temperature-related mechanisms. The purpose of the present study was to determine the effect of three different WU regimes on metabolism and performance during and after short term maximal exercise.

Methods: At three subsequent visits to the laboratory, subjects (n=11) performed 30 s lasting maximal sprint tests on a cycle ergometer (SRM) with different prior warm up (WU) intensities: 1. without prior warming up (W), 2. extensive warm up (E): 12 min cycling at 60% of VO2 peak, 3. intensive warm up (I): 12 min cycling at 60% of VO2 peak including three 10 s lasting peaks at 200% of VO2 peak. After the warming up, subjects stayed in a sedentary position for 5 min, followed by the sprint test. Blood samples were taken under resting conditions, after warming up, before sprint exercise (pre M), and in minute intervals during recovery (0 min-15 min) to determine lactate concentrations [La]. Spirometric data were collected during the whole session.

Results: The peak power (PP) output as well as the mean power (MP) output for the sprint test was significantly lower for W (PP: 951 ± 91 W & MP: 680 ± 181 W) compared to E & I (PP: 1007 ± 110 W & MP: 738 ± 192 W; E) (PP: 1022 ± 90 W & MP: 740 ± 191 W; I).

[La] after WU were all significantly different from each other. After the 5 min rest only (I) was still significantly elevated. During the recovery period neither differences in [La] nor in La kinetics were found (only the increment directly after sprint test (pre M-0') was significantly lower between (W) vs. (I)). Peak oxygen consumption after sprint tended to be higher after E & I conditions compared to W without reaching statistical significance.

Discussion: Several possible effects of WU (systemic/local) are discussed in literature which might have an effect on performance. Our results show that performance during 30 s sprint is enhanced by WU irrespective of WU intensity. Contrary to previous studies (Gray et al. 2002) we found no differences in blood La accumulation. Improved performance was not related to differences in measured aerobic or anaerobic metabolism, although VO2 tended to increase higher after exercise (although muscle metabolism might be different). Although pre exercise [La] were different between the 3 conditions, high [La] had no negative effects on performance in this test, supporting the new view for La as a metabolite and signaling molecule and not as a factor of fatigue.

DEVELOPING BODY COMPOSITION REGRESSION EQUATIONS FOR MALE ADOLESCENT ATHLETES.

KUCUKKUBAS, N., HAZIR, T., ALPAR, R., ACIKADA, C.

UNIVERSITY OF MUSTAFA KEMAL

The objective of the study is to develop regression equations for the male adolescent athletes at the ages of 15-17 years old by using hydrostatic weighting as a criterion method. 155 male adolescent athletes (basketball, volleyball, football, handball, swimming, track and field athletes) participated voluntarily in this study. The athletes were training for at least 1 year, 2 hours/3 days/week. Body density (BD), body fat percentage (%BF), and lean body mass (LBM) were determined by using Hydrostatic Weighting (HW). Oxygen dilution method was used to determine residual volume. Anthropometric variables; body weight (BW) in kg, height (H) in cm, skinfold thicknesses (mm), circumferences (cm), width (cm) were measured. Resistance (R)(ohm) and reactance (ohm) measurements were taken by using Bioelectric Impedance (BIA). Resistance Index (RI) (cm2/ohm) was calculated by dividing H-squared to R. To develop regression equations, dependent and independent variables were treated to Multiple Stepwise Analysis after Pearson Product Moment correlation coefficient determined between variables. Highest R-squared (0.77) and lowest SEE (0.00519) BD regression equations for anthropometric measurement is BD= 1.064 - 0.0001162(H) + 0.002204(age in years) + 0.0001633(BW) - 0.0007809(abdomen skinfold thickness) - 0.0005526(thigh skinfold thickness); highest R-squared (0.77) and lowest SEE (2.0795) BF% regression equations for anthropometric measurement is BF% =21.317 - 0.906(age in years) -0.02027(BW) + 0.305(abdomen skinfold thickness) + 0.202(thigh skinfold thickness); highest R-squared (0.97) and lowest SEE (1.487) LBM regression equations is LBM= -6.918 + 0.886(BW)+ 0.01794(RI) +0.635(age in years) -0.226 (abdomen skinfold thickness) -0.159(thigh skinfold thickness). All equations were then tested by using cross validation (R-squared for 1st and 2nd group are 0.79, 0.73; 0.80, 0.70 ;0.97, 0.96 respectively), by dividing the data randomly into two groups. Therefore, these high R-squared and low SEE regression equations were recommended for use in estimating BD, BF% and FFM of adolescent athletes.

CORRELATION BETWEEN ANXIETY AND CARDIAC LOAD IN TEAMGYM PERFORMANCE

DE PERO, R., MINGANTI, C., CAPRANICA, L., AMICI, S., PIACENTINI, M.F.

UNIVERSITY OF ROME

Introduction: Teamgym is a fairly new and popular form of Gymnastics including only trampoline, tumbling and floor exercises. Compared with other categories of gymnasts, teamgym athletes reported a significantly higher occurrence of injuries (Harringe et al., 2007). Therefore, anxiety is the psychological factor most commonly linked to motor performance during gymnastics, often related to heart rate frequencies (Cottyn et al., 2006; Gramer, Saria, 2007). The aim of the present study was to investigate the correlation between anxiety, heart rate frequency and teamgym performance during National and European Championships.

Methods: Ten Italian elite gymnasts, 5 males and 5 females, (mean age 21 ± 2) performed the same exercise program during National (NC) and European Teamgym Championships (EC). Gymnasts' cardiac load (HR) was measured recording heart rate (Polar team System)

and was classified based on the percentage of time spent in three zones (Low-intensity: <85% HRmax; High-intensity: 86-95% HRmax; Maximal effort >95% HRmax). The State-Trait Anxiety Inventory form Y (STAY-Y) (Spielberger, 1983) was administered to test the anxiety levels before competition. Friedman's test Anova was calculated to verify the heart rate, anxiety levels and penalty scores differences in the two different competitions. Furthermore, correlations between heart rate, anxiety and penalties points were calculated.

Results: Significant differences (p<.05) emerged between anxiety levels during NC (46pts ± 8pts) and EC (54pts ± 8pts). National tumbling competition showed significantly lower values (p<.05) both in heart rate frequencies (<85% HRmax= 91%;) and in assigned penalty points (0.30pts ± 0.10pts) compared to EC (<85% HRmax= 71%; 0.50pts ± 0.20pts)

Significant correlations emerged only during the tumbling performance between heart rate and penalty points (Spearman Rho= 0.80; p<0.01) during NC and between anxiety levels and penalties (Sperman Rho= 0.73; p<0.01) during EC.

Discussion/Conclusion: Despite the exercise program did not differ between National and European Championship, the higher HR, anxiety levels and penalty points observed during the latter competition might be attributed to a higher arousal determinated by the high level and importance of the event.

Furthermore, correlations between high heart rate frequencies, anxiety levels and penalty points assigned to the team during the tumbling performance, probably depends to the gymnasts' concern in performing the more difficult and risky acrobatic elements at this apparatus.

RECOVERY STRESS PERCEPTION AND SALIVARY CORTISOL BEHAVIOUR OF SWIMMERS IN DIFFERENT TRAINING PERIODS

SIMOLA, R., PRADO, L.S., SAMULSKI, D.M.

UNIVERSIDADE FEDERAL DE MINAS GERAIS

Introduction: Many investigations have studied the psychological, physiological and biochemical responses of athletes to different load training periods with the aim to monitor more precisely the load training effects. However, those studies have been showing different results (Coutts et al. 2007). Therefore, we investigated the effects of different training loads on stress and recovery perception (SRP) and salivary cortisol (SC) in different training periods.

Methods: Subjects were highly trained, male swimmers (17.7 + 1.3 y.o.). SRP and SC were evaluated after three distinct training phases (T1, T2 and T3). In T1, subjects swam approximately 50.000 meters in a week. After one month (T2), swimmers covered an average of 45.000 meters in a week with a higher intensity. In T3, after a month, swimmers covered an average of only 25.000 meters. SC were measured through enzymatic immunoassay. SRP was evaluated using the questionnaire RESTQ-Sport for the Portuguese language (Costa & Samulski, 2005). The Anova one-way with repeated measures and Pearson's product moment correlation were used for statistical analysis. P<0.05.

Results: From T1 to T3, it were observed a significant reduction in RESTQ-Sport scales, Fatigue (2,28 + 1,11; 1,12 + 0,71), Lack of Energy (2,33 + 0,93; 1,5 + 0,61), and an increase in SC (0,23 µg/dL + 0,15; 0,47 µg/dL + 0,19). Between T2 and T3, it were observed a reduction in Fatigue (2,29 + 1,08; 1,12 + 0,71), Lack of Energy (2,02 + 0,84; 1,5 + 0,61), Disturbed Breaks (2,0 + 0,7; 1,23 + 0,75), and an increase in SC (0,38 µg/dL + 0,15; 0,47 µg/dL + 0,19). From T1 to T2, there were significant augments in SC (0,23 µg/dL + 0,15; 0,38 µg/dL + 0,19). It were observed significant correlations between SC and SRP only in T1, in scales Social Recovery (p=0,002), General Well Being (p=0,031) and Disturbed Breaks (p=0,034). Conclusion: Different load training may cause changes on SRP and SC. However, psychological stress (SRP) may not necessarily be correlated with the physiological stress (SC). Moreover, the results highlight that it is necessary different variables to monitor the load training more precisely and that the SC can show the same behaviour direction when the load training is increased or decreased.

THE EFFECTS OF 12 WEEKS PILATES ON BALANCE, FLEXIBILITY, MUSCLE STRENGTH IN ELDERLY WOMEN

BABAYIGIT IREZ, G.

MIDDLE EAST TECHNICAL UNIVERSITY

THE EFFECTS OF 12 WEEKS PILATES ON BALANCE, FLEXIBILITY, MUSCLE STRENGTH IN ELDERLY WOMEN

Babayigit Irez, G., Evin, R., Ozdemir, R.A.,Irez, S.G.,Korkusuz, F.

Middle East Technical University,Ankara Turkey

Introduction: The popularity of Pilates has recently increased over the past decades in health care and sports medicine field as well as fitness field which has influenced research studies to examine the effects of Pilates. The purpose of this study was to determine if Pilates exercise could improve dynamic balance, flexibility, reaction time and muscle strength in older women.

Methods: Subjects were recruited from 60 female volunteers aged over 65 years old on a Nursing Home in Ankara. Participants were invited to join a 12-week series of one hour Pilates exercise meeting three times per week. Dynamic balance, flexibility, reaction time, number of falls and muscle strength were measured before exercise and after 3 months of exercise.

Results: There were significant differences between pre-and post-tests in exercise group. Flexibility (p<0.05);balance (p<0.01);get up go (p<0.05);hand grip strength,right (p<0.01),left (p<0.01);reaction time (p<0.05);muscle strength (p<0.01) and number of falls (p<0.05).There was no significant differences between pre and post tests in control group.

Discussion: Some researchers studied the effects of Pilates based training on balance in an elderly population and found positive effects. In our study, we found positive effects on balance and we searched also,muscle strength, flexibility, number of falls and reaction time.

MEASUREMENT OF LOWER LIMBS INVERSE DYNAMIC WITHIN GOLF SWING

GRYC, T., ZAHÁLKA, F., MALÝ, T.

CHARLES UNIVERSITY IN PRAGUE, FACULTY OF PHYSICAL EDUCATION AND SPORT

Introduction: Weight transfer within golf swing has a great effect on its success. Weight transfer patterns within golf swing are described in Richards et. al. (1985) and Ball & Best (2007). Lower limbs are differently effected by unevenly weight transfer in separate phases of the golf swing. Publications about golf practice engage in weight transfer especially in conjunction with equilibrium abilities (Wiren, 1990).

Methods: Three male golfers aged 19-24 years with handicap between 0-5 were measured. Pressure effects against ground-sheet were measured in three directions (vertical, antero-posterior, lateral) with unit KISTLER. To evaluate measured signals software BioWare was used. Kinematic analyzer unit CODA Motion System was synchronously connected with force plates. Data were evaluated in separate phases of the golf swing.

Results: Take-away, Mid Backswing, Late Backswing, Top of Backswing, Early Downswing, Mid Downswing, Ball Contact and Follow Through were used phases of the golf swing. The obtained data show different pressure forces of lower limbs with ground-sheet during separate phases of the golf swing. The maximum pressure action of left lower limb with force plates were measured in Ball Contact Phase in vertical direction (370N) and lateral direction (23N – in swing way). The maximum pressure force in antero-posterior direction was measured in Early Downswing Phase (27N – posterior).

There were not measured such high values of pressure force of right lower limb into pressure plate in any direction. The maximum pressure forces were measured as follows - in vertical direction in Mid Backswing phase (150N), in lateral direction in Ball Contact Phase (13N – in swing way), and in antero-posterior direction in Early Downswing Phase (26N – anterior).

Conclussion: Left lower limb pressure force is higher in any direction compared with right lower limb, especially in vertical direction. The measured pressure forces were in accordance with weight transfer within golf swing described in Wiren (1990). Repeated measures showed equalities between strokes of all five tested subjects. It proves high interindividual stability of the performance of the movement task of all probands.

THE INFLUENCE OF SWEAT AND ALCOHOL ON CAPILLARY BLOOD LACTATE MEASUREMENT

ACHTZEHN, S., SPERLICH, B., NITSCH, S., MESTER, J.

GERMAN SPORT UNIVERSITY COLOGNE

Introduction: In order to receive proper blood lactate values during exercise it is important to know that human sweat also contains lactic acid. In daily routine, e.g. in exercise testing, it is possible that arterial blood samples might be contaminated by sweat leading to higher blood lactate values. From this point, to ensure high quality standards, the blood obtained from the earlobe needs to be free of sweat in order to measure capillary blood lactate concentration. Further, alcohol is often used to clean the earlobe which might also influence the accuracy of arterial blood lactate measurement.

To our knowledge it is generally unknown that sweat influences arterial blood lactate values. In this study we want to detect the influence of low and high concentration of sweat within a blood sample on the accuracy of arterial lactate measurement.

Methods: The subjects participating in the study exercised for 60 minutes at 160 watt on a cycle ergometer. Capillary blood samples were taken from earlobe every 10 minutes. At the same time sweat was collected from skin with capillary tubes. The system for lactate measurement (EBIOplus, Eppendorf, Germany,) requires 20 µl blood. After exercise the blood samples were diluted with sweat and alcohol at different rates.

Results: The lactate concentrations from undiluted blood samples during exercise ranged from 0.88 to 1.76 mmol/L. The diluted samples with sweat showed higher concentrations: The lowest dilution with sweat (1:1.05) revealed a concentration of 2.78 mmol/L compared to 0.88 mmol/L of the undiluted blood sample. Lactate values of the highest dilution (1:2) with sweat showed a concentration of 18.85 mmol/L. The dilutions with alcohol show, in contrast to sweat, lower value of lactate to undiluted blood.

Discussion: The results of this study show, as expected, higher levels of lactate concentration compared to undiluted samples. Alcohol, within the blood sample, on the other hand results in lower lactate values. Regarding the results it is a justified claim that all scientific personnel handle the collection of arterial blood with care, especially when the subjects produce a high amount of sweat.

ESTIMATING ANAEROBIC POWER BY NEW ZIGZAG TEST: TARBIAT MODARES ANAEROBIC TEST <TMAT>

AGHA ALINEJAD, H., GHARAKHANLOU, R., YOUSEFVAND, S., DELFAN, M.

1,2,3. TARBIAT MODARES UNIVERSITY, 4. SHAHID BEHESHTI UNIVERSITY

Introduction: The ability to produce high rates of power output is essential for performance in many sports (Macintosh et al., 2003). The use of jump tests for anaerobic power assessment has more application as a sport-specific test than cycle or treadmill tests. The purpose of this study was to design new zigzag test titled of Tarbiat Modares Anaerobic Test (TMAT) that validated by the gold standard test, 30s Wingate test, (Benke et al., 2002).

Methods

Thirty female athletes (age: 22.46±1.8 yrs; body mass: 53.53±5.50 kg; height: 162.18±5.31 cm; body fat percent: 25.54±5.60) participated in this study. TMAT consists of 6 bouts of 8 peer zigzag jump with 10 second rest between them. The height of hurdle was 20 cm and the distance of jumping line to hurdle was 10 cm. The changes of blood lactate and heart rate was measured in the 30s Wingate test and TMAT. Peak, average and minimum power values and fatigue indices was determined in two tests. Also, subjects were tested on 2 separate occasions to assess reliability of TMAT,

Results: The equation for calculation of power in TMAT was P(w)=8mg×0.43906/t (t=time). The results showed that there is a significant correlation in peak, average and minimum values of anaerobic power indices between TMAT and the 30s Wingate test ($p<0.01$, $r=0.73$; $p<0.01$, $r=0.69$; $p<0.01$, $r=0.55$ respectively). But this correlation was no significant in fatigue index between two test ($p>0.01$, $r=0.31$).There was no a significant difference in changes of blood lactate amounts between two tests from rest to 5 min after test. Also there was no significant difference in heart rate changes between two tests from rest to immediately after tests but the moderate correlation was shown of fatigue index.

Discussion: The finding of the present study showed that the TMAT is a valid and reliable field test to assess anaerobic power of athletic performance because there was significant correlation between the peak, average and minimum power indices of the TMAT and the 30s Wingate anaerobic test (validity) and the significant correlation between TMAT test and retest its (reliability).

DYNAMICAL AND KINEMATIC VARIABLES OF DIFFERENT VERTICAL JUMPS: A PRELIMINARY STUDY

CARVALHO, C., CARDOSO, J., RODRIGUES, C., BARBOSA, T.,3, SILVA, A.,4, MARINHO, D., GABRIEL, R., CAMPANIÇO, J.,4, VIEIRA, L., CARVALHO, A.,2

1. CENTRO DE INVESTIGAÇÃO DE DESPORTO, SAÚDE E DESENVOLVIMENTO HUMANO, 2. INSTITUTO SUPERIOR DA MAIA, 3. INSTITUTO POLITÉCNICO DE BRAGANÇA, 4. UNIVERSIDADE DOS TRÁS-OS-MONTES E ALTO DOURO - PORTUGAL

Introduction: The main aims of this preliminary study were: (i) to assess a group of relevant dynamical and kinematical variables to study the vertical jump; (ii) to analyse the differences between vertical jumps with and without counter-movement, based on the abovementioned variables (Stretch Shortening Cycle - SSC versus no SSC) and between different SSCs (longSSC versus shortSSC); (iii) to establish the relations between neuromuscular factors gained during the vertical jumps analysed.

Methods: Nine students of the 4th year of the Physical Education and Sport Course, without relevant sports history, performed five times each type of jump [squat jump (SJ), counter-movement jump (CMJ) and drop jump (DP)]. The best jump of each subject in SJ, CMJ and DP was selected, according to the maximal height accomplished. Dynamical and kinematical data were acquired with a force plate AMTI BP2416 with a 1000 Hz of frequency and 2 video cameras JVC9800 with a 100 Hz, being the data analysed with the Software SimiMotion 6.1, using the adapted gravity centre model of Dempster.

Results: The results pointed out differences in the performance between different jumps. The maximal height was 48, 44 and 42 cm in the CMJ, DJ and SJ, respectively. Thus, the SSC jumps presented best results in relation to the no SSC jumps. Concerning the displacement, a difference between the longSSC and shortSSC was noticed. The DJ presented a lower decrease of the centre of mass and a difference of 22.8 cm to the CMJ was found. Significant differences between the no SSC jump (SJ) and the SSC jumps in the beginning of the propelling phase were observed. For example, at null velocity, SJ showed only 944 N (corresponding almost to the weight of the subject) and in CMJ and DJ the force was 2.5 and 3.5 times higher. The duration of the lift phase, as expected, was lower in the shortSSC. Concerning the force and muscular power, an increase in the SJ, CMJ and DJ was verified: peak force of 2188, 2131 and 3577 N and mean power of 1977, 2200 and 2884 W, respectively.

Discussion: With this study we attempted to associate dynamical and kinematic data to vertical jump performance, analysing the relations between the variables of cause-effect and the jump performance. The relations described in previous studies (Bobbert et al., 1996; Aragón-Vargas & Gross, 1997) were verified considering jumps with and without SSC and between longSSC and shortSSC.

IMPORTANCE OF SOME DIMENSIONS OF MOTOR AND MORPHOLOGICAL SPACE IN POLICE OFFICERS

ZOREC, B.

FACULTY OF CRIMINAL JUSTICE AND SECURITY, LJUBLJANA

Introduction: The research of the interrelations among the various subsystems of the psychosomatic status is often in the focus of interest of many researchers. Among them, motor abilities and morphological characteristics – on which performance as regards motor efficiency depends – certainly have a special place since successful job performance of police officers or criminal investigators in field work significantly depends on the dimensions of the motor and morphological space.

Methods: In the present research, we focused on establishing the correlations between certain dimensions of the motor and morphological space between police officers and criminal investigators. The morphological status was defined by 14 morphological dimensions and the motor status comprised 6 motor variables. The significance of the differences between the results of the morphological dimensions and motor variables was assessed by the application of the t-test for small dependent samples.

Results: When examining basic statistical parameters, we have found that criminal investigators are, on average, three years older than police officers and that they also have 15 % more fat tissue. The larger quantity in fat tissue could be explained by the theory on the increased accumulation of subcutaneous fat tissue on the upper body associated with age (McArdle at al., 1996). The reason also lies most probably in the motorics of the work performed. The work of a police officer requires a well developed energy component of movement which reflects in the motor abilities associated with endurance, be it speed or strength. In addition, the demands of professional work of

police officers in mastering complex motor programmes (self-defence, overcoming the hurdles, etc.), which are characterised by variability and involvement of several different factors, are much greater in comparison with criminal investigators. I assume that police officers are aware of the importance of strength in their operational work (use of force) and increase, by means of training, their muscle mass which replaces fat tissue as found in the research carried out on the sports population.

Discussion: In the research, negative correlations were established between the voluminosity and motor abilities associated with strength. In the morphological status, test subjects differ in the thickness of the subcutaneous fat. In the motor status, however, they differ in aerobic ability, repetitive and explosive power. The results of the research point to a large influence of morphological characteristics (subcutaneous fat) on motor abilities and require that they should be monitored in relation to the motor space.

THE EFFECT OF BACK EXERCISES ON DRAWING ARMS IN ARCHERS

EROGLU KOLAYIS, I., ERTAN, H., KOLAYIS, H.

SAKARYA UNIVERSITY

According to some studies elite archers develop a specific forearm and pull finger muscle activation strategy by active contraction of the forearm extansors with the fall of the clicker. On the other hand the back muscles play the major role drawing and releasing phases of the bow and good working back muscles help to maintain forearm muscle activation strategy. This strategy requires relatively long training period. PURPOSE ; The purpose of this study was to investigate the effect of eight weeks of back strength development training on EMG activities at release and performance in beginner archers. METHODS ; Six man and two women beginner archers (age: 16,38±038 ; years of training 1,94±1,04; FITA scores 1083±71,2) were involved in the study. Each subject participated in double test session. Eight weeks of back strength development training (Lateral Pull Down, Rowing, Dumbell Lateral Rise, Dumbell Front Rise, Dumbell Behind Rise, Dumbell Shrug, Upright Rowing, Back Extansion, Sit up) were applied in %40-60 of max. between two test session. Forearm extansors and flexors, deltoid posterior, deltoid middle, trapezius middle and trapezius lower muscles EMG activities that belongs to the drawing arm and bow arm were measured in each test session, and performance was recorded. Subjects totally twentyfour successive shots at the each experimental part of the study.

Analysis/Results; EMG recordings 2 s prior and 1 s after the fall of clicker has been rectified, integrated and normalized in Microsoft Excel programmes. Differences between two test session was analysed in Wilcoxon statistical tests. According to the results of the study, there were significant differences in forearm flexors and extansors, deltoid posterior, deltoid middle, trapez middle and lower in drawing arm, and forearm extansors, deltoid middle and lower in bow arm and the performance between two test session ($p<0,05$).

CONCLUSIONS; As a result, positive development was observed with the effect of back strength development training in beginner archers, so that the archery trainers can give a place to the strength trainings in their training programmes besides technical training to gain more performance and time.

OPTIMAL LOAD FOR POWER PRODUCTION IN VERTICAL JUMPING

VUK, S., MARKOVIC, G.

UNIVERSITY OF ZAGREB

Introduction: Muscle power is considered one of the main determinants of athletic performance that requires explosive force production such as jumping (Kawamori and Haff, 2004). There has been an increasing volume of research focused on the load that elicits maximum power output. The mechanical output in isolated and complex movements depends on applied external load. The most of the studies in this area have investigated maximal power output in vertical jumping (VJ). In this work, we reviewed the results of all published studies that examined the effects of loading on mechanical output in VJ, with particular reference to training level of the tested subjects.

Methods: A computerized search of articles that studied the effects of the loading on mechanical power output during VJ was performed using MEDLINE and SCOPUS databases.

Results: From a total of 19 studies that examined the load-power relationship in VJ, the vast majority of authors reported that either an exceptionally small or zero external load (13 out of 19 studies) represents the optimal load for power production in VJ. Conversely, only six studies reported the optimal loads that were considerably higher than subjects' body weight. It should be also noted that most of the reviewed studies revealed a loading associated decrease in power output (Jaric and Markovic, 2009).

Discussion: This review of literature showed that about 70% of all included studies reported either body weight or the smallest external load applied as optimal for power production in VJ. It should be noted that these studies mainly used untrained individuals as subjects. In contrast, in about 30% of studies that revealed considerably higher external loads as optimal for power production in VJ, the authors used strength/power athletes as subjects. Besides the training level of subjects (Cronin and Sleivert, 2005), several other factors could be responsible for the observed discrepancy in optimal loading for power production in VJ. These include: 1) differences in data collection and analyses protocols (Dugan et al., 2004), 2) inclusion or exclusion of body weight in calculations of power, 3) determination of the loading and data collecting equipment (Crewther et al., 2005), and 4) use of free weights vs. machines (Dugan et al., 2004). In conclusion, this review showed that optimal load for power production in VJ appears to be the subject's body weight. In contrast, strength/power trained athletes produce maximal power in VJ when using external loads ranging from 20% to 70% of their 1 RM in back squat.

COMPLEX DIAGNOSTICS IN GREAT SAMPLES OF ELITE ATHLETES – BETWEEN DESCRIPTION AND PATTERN DETECTION

ENGELMEYER, E., SEIFRIZ, F., DE MARÉES, M., ACHTZEHN, S., SPERLICH, B., MESTER, J.
GERMAN SPORT UNIVERSITY COLOGNE

Introduction: To improve knowledge of specific training-load in elite sport, performance and health diagnostics are indispensable. The number of published articles on diagnostics of this kind therefore has expanded very rapidly. The presented study examined the individual characteristics of 322 elite athletes (Olympic sports) of different competition-levels in the following areas: biomechanics, dentistry, nutrition, orthopaedics, psychology, sports medicine and training science. These standardized tests have been carried out by the German Research Centre of Elite Sport (momentum). Data comprised of more than 2100 parameters per person. For the scientific analysis of a matrix of 322x2100 cells, different kinds of statistical methods have been used.

Methods: 322 athletes (156 male: 18±3,4 years, 181±10,2 cm, 74±14,6 kg; 166 female: 17±3,6± 3,5 years, 167,39±10,5 cm, 57,38±11,7 kg) participated in this study. Three groups of statistical methods with the following goals were selected: (A) univariate traditional descriptive data analysis for comparing e.g. clinical standard values collected from non-athlete samples with athletes. (B) Hypothesis based inferential bi- and multivariate data analysis for detecting correlations and mean value differences for certain subgroups (e.g. sport disciplines, gender, age). (C) A posteriori, explorative data analysis with pattern detection methods for discovering unknown characteristics.

Results: A: In general clinical reference values often differ significantly from our data. This refers to blood parameters such as LDL (52% of athletes), hematocrit (58%) und CK-NAC (69%). Performance parameters such as VO2max, the anaerobic threshold (V2,V4), maximum strength, jumping height and others are currently used for the development of new reference values in certain sport disciplines. These results shall also serve for grouping criteria for competition squads. On the other hand the descriptive data highlighted in parts remarkable deficits in various categories of physical fitness and led to new concepts of training especially in youth sports.

B: New insights with respect to explained variance between hematological, performance and anthropometric data could be shown. The same is true e.g. for differences between the above mentioned subgroups (sport disciplines, gender, age). Especially the multiple data-interaction in disjunct scientific disciplines, such as nutrition components, blood parameters and performance were found to be interesting.

C: In the frame of pattern detection decision tree prediction showed – in contradiction to traditional group based statistics - remarkable new characteristics of subgroups, if intelligent classification algorithms are used. Other techniques such as single case studies and time series analysis showed the importance of individual characteristics. Finally data-mining tools promise to be useful also for prediction of performance indicators.

NEUROMUSCULAR, ENDOCRINE AND PERCEPTUAL RESPONSES DURING DIFFERENT LENGTH BETWEEN-MATCH MICROCYCLES IN PROFESSIONAL RUGBY LEAGUE PLAYERS

COUTTS, A.J., MCLEAN, B.D., KELLY, V., CORMACK, S.J., MCGUIGAN, M.R.
UNIVERSITY OF TECHNOLOGY, SYDNEY

INTRODUCTION: Appropriate recovery between matches is critically important in team sports which have regular competition. Reduced neuromuscular performance, alterations in hormone levels and increased perception of fatigue have been reported in rugby league players enduring a mismatch between training stress and recovery [1, 2]. However, the recovery patterns in these variables following professional rugby league matches is unknown. Therefore, the purpose of this study was to examine the time course of change in neuromuscular, perceptual and hormonal measures following a professional rugby league match during different length between-match microcycles.

METHODS: Following familiarisation, 12 professional rugby league players from the same team were assessed for changes in countermovement jump (CMJ) (force, power, flight time)[3], perceptual responses (fatigue, well being and muscle soreness) and salivary hormone (testosterone (T) and cortisol(C)) levels during 5, 7 and 9 day between-match training microcycles. Measures were taken 4 h prior to the first match, and then 1, 2, 4, 6*, 7*, 8* and 9* days following (*depending on group). All training was prescribed by the club coaches and was monitored using the session-RPE method.

RESULTS: Significantly lower mean daily training load was completed on the 5-day compared with the 7 and 9-day conditions. Some CMJ variables (flight time and contraction time), perception of fatigue, well-being and muscle soreness were significantly reduced in the 2 days following the match in each condition ($P<0.05$). All CMJ variables returned to near baseline values following 4 days in each condition. Both CMJ maximum and relative power was lower in the 7 day condition when compared with the 9 day condition ($P<0.05$). Fatigue levels were reduced at 48 h in the 7 and 9-day groups ($P<0.05$) but had returned to baseline in the 5-day group. All perceptual measures returned to baseline levels prior to the following match in each condition and followed changes in training load. Salivary T and C did not change in response to the match.

DISCUSSION: Neuromuscular performance and perception of fatigue are reduced for at least 48 h following a rugby league match but these can be fully recovered within 4 days. CMJ variables involving flight time appear to be best for assessing acute fatigue caused by a match, and variables involving power may be useful in assessing accumulated fatigue. The perceptual measures were sensitive to both acute fatigue and accumulated fatigue. The salivary hormone analyses have limited practical value for assessing recovery. These findings show that with correct training, it is possible to recover neuromuscular, perceptual and endocrine measures within 4 days after a professional rugby league match.

RESPIRATORY MUSCLES TRAINING WITH ISOCAPNIC HYPERPNOEA <HY> METHOD IMPROVES VENTILATORY PARAMETERS AND EXERCISE CAPACITY

CHIARANDA, G., POMIDORI, L., ULIARI, S., COLETTO, C., GRAZZI, G., MANFREDINI, F., MAZZONI, G., COGO, A.
BIOMEDICAL SPORT STUDIES CENTER - FERRARA UNIVERSITY

Introduction: Recent evidences suggest that respiratory muscles training improves the exercise capacity.
Aim: To evaluate the efficacy of respiratory muscles training with HY (Spirotiger®) on respiratory parameters and exercise capacity.
Materials and Methods: 12 Females. Group A: 6 (age 24 ±0,8) with HY training (20 min/day x 5 weeks) for 1 month; Group B, control: 6 (age 23 ±2,6).
Respiratory function tests [vital capacity (VC, L), forced expiratory volume in 1st second (FEV1, L/sec), maximum voluntary ventilation (MVV, L/min), maximum inspiratory pressure (MIP, KPa)]; Incremental maximal cycle ergometer test: [Power output (PO, W), oxygen consumption (VO2, ml/min), tidal volume (VT), heart rate (HR, bpm), dyspnea scale (Borg)] before (T0) and after training (T1).
Ventilatory anaerobic threshold (VAT) was determined by V-Slope method. The daily physical activity was monitored by Armband at T0 and T1: unchanged. Statistical analysis by T-Test and Test ANOVA. The significance level was considered for values of P ≤ 0.05.
Results: Group A: a significant increase was observed for VC, MVV, MIP, PO at VO2max, PO at VAT: mean ± SD at T0 and T1 were respectively 3.87±0.32 and 4.15±0.35, 128±23 and 139±13, 7.16±1.03 and 8.74±1.75, 191±17.5 and 200±18,4, 111±8,9 and 116±10,8. Moreover, during the test, at T1 with respect to T0, HR and Borg scale were always significantly lower and VT was always significantly higher, whereas no significant difference was found for FEV1, VO2max and VO2 at VAT.
Group B: no significant change.
Conclusions: Respiratory muscles training with HY improved respiratory function parameters and power output expressed at VAT and at peak.

AEROBIC DANCE IS NOT CAPABLE OF USING THE WHOLE CARDIORESPIRATORY SYSTEM

EDVARDSEN, E., BØ, K., INGJER, F.
NORWEGIAN SCHOOL OF SPORT SCIENCES

Introduction: Aerobic dance must be able to utilise the whole cardio respiratory system, similar to running in order to be considered an adequate training activity of aerobic endurance. This demand must further be valid for untrained as well as for those who already have a high aerobic capacity. The aim of the present study was to compare maximal oxygen uptake (VO2max) between aerobic dance and treadmill running in fit women.
Methods: Thirteen well trained female aerobic dance instructors, mean age 31 years (range 20 - 47), mean BMI 20,9 (range 17,9 – 23,3) exercised to exhaustion by running on a treadmill for measurement of VO2max and maximal heart rate (HRmax). Additionally, all subjects performed aerobic dancing until exhaustion after a choreographed videotaped routine for measurement of oxygen uptake (VO2) and heart rate (HR) response. Mean differences in VO2max and HRmax between aerobic dance and treadmill running were analysed by Student's paired T-test. Correlation between exercise forms was assessed by Pearson's correlation coefficient (r) with 95 % confidence intervals.
Results: VO2max in aerobic dance was significantly lower (52,2 ml•kg-1•min-1, 49,7 – 54,6) (mean, 95% CI) compared to treadmill running (55,9 ml•kg-1•min-1, 52,9 – 58,9) (p>0,0003). Further, HRmax in aerobic dance was 182 beats•min-1 (95 % CI: 176 - 187) and running 193 beats•min-1 (95 % CI: 187 - 199), giving no difference in oxygen pulse between the two exercise forms (p=0,09).
Discussion: Aerobic dance seems not able to use the whole cardiorespiratory system as achieved during running. This may result in a total lower work load during maximal interval training in endurance trained women in aerobic dance compared to running.

THE EFFECT OF ONE-NIGHT SLEEP DEPRIVATION ON PACING STRATEGIES AND INTERMITTENT-SPRINT PERFORMANCE

SKEIN, M., DUFFIELD, R., MUNDEL, T., EDGE, J., SHORT, M.
CHARLES STURT UNIVERSITY

Introduction: Sleep deprivation prior to team sport exercise may result from a variety of reasons, including travel commitments and anxiety; however the ensuing effects on performance and recovery remain equivocal. Therefore, the aim of this study was to examine the effect of overnight sleep loss (~30hrs) on pacing strategies and performance for intermittent-sprint exercise.
Methods: Seven male, team sport athletes completed a familiarisation session, including a graded exercise test to determine VO2peak, and two conditions consisting of 2 consecutive days each including a 30min graded exercise run at 60-80% VO2peak followed by a 50min free-paced intermittent-sprint protocol (ISP). Each day was separated by either a normal night sleep (CONT) or an absence of sleep (SDEP). The ISP consisted of a 15-m sprint each minute followed by self-paced exercise in a shuttle run format at varying intensities (hard running, jogging, walking and bounds) for the remainder of each minute. Each day, pre and immediately post exercise, 15 maximal voluntary contractions (MVC) with a resting (Pf) and superimposed (SIF) twitch on the first and final 5 MVC of the right knee extensors were assessed. Pre and post exercise muscle biopsies were obtained from the vastus lateralis and assessed for muscle glycogen. Heart rate (HR), core temperature (Tcore), blood lactate (La) and glucose (Glu), and Rating of Perceived Exertion (RPE) were recorded throughout, while Profile of Mood States (POMS) was completed pre and post exercise.
Results: Sprint times were reduced on Day2 compared to Day1 within both conditions (P<0.05) however a greater reduction was evident within SDEP. Distance covered during self-paced exercise was negatively affected in SDEP Day2 compared to Day1, with a lower total distance during hard running bouts (P<0.05); however no significant differences were evident within the CONT condition. Mean distance covered during bounds was also lower in SDEP (P<0.05). Muscle glycogen was significantly lower pre exercise on Day2 following SDEP compared to CONT. Blood La and Glu were lower on Day2 in both conditions compared to Day1 (P<0.05). RPE and POMS were also adversely affected by sleep loss compared to Day1 (P<0.05). Finally, MVC, SIF & VA pre exercise on Day2 were significantly lower during SDEP compared to CONT (P<0.05).
Discussion: Results indicate that the ISP was negatively affected by ~30h sleep deprivation, through the reduction in self-selected exercise intensities (pacing strategies). Further, sleep loss retards the repletion of muscle glycogen and may be responsible for the greater decline in performance on the second day. Accordingly, the reduction in muscle glycogen and increased psychological strain prior to exercise may result in the reduction of voluntary muscle recruitment noted in MVC and thus be responsible for the slower pacing strategies and reduced performance noted following sleep loss.

ENERGY EXPENDITURE AND CARDIO-RESPIRATORY COSTS PLAYING INTERACTIVE COMPUTER GAMES: COMPARISON WITH SUB-MAXIMAL EXERCISE PARTICIPATION.

DONNE, B., MARNANE, M.

TRINITY COLLEGE DUBLIN

In the developed world people typically spend less time engaged in physical activity and more time in front of the TV, computer and games console. Interactive computer consoles have recently entered the marketplace (Nintendo Wii) with the aim of increasing energy expenditure during computer gaming. A key question is whether these new systems increase activity sufficiently to result in increased energy expenditure (EE) and cardio-respiratory (CR) costs while permitting common screen-based activities. This study assessed EE and CR associated with playing the Nintendo Wii by comparison with other sub-maximal exercise modalities; and investigated if EE could be further increased by imposing additional lower limb movements in a 2m diameter circular grid while playing the Nintendo Wii.

Twenty male volunteers (mean age 23 yr, mass 85 kg, resting HR 82 beats.min-1 and resting VO2 4.9 mL.kg-1.min-1) completed 6 by 12-min randomized test elements; walking at 5.6km.hr-1, jogging at 9.6km.hr-1, cycling at 120W, seated PC game, playing Nintendo Wii and Nintendo Wii+ with imposed lower limb actions (Wii+). During exercise elements, VO2 and HR were continuously recorded on-line. Data were analysed using repeated measures ANOVA, post-hoc Tukey tests quantified significant differences, for all tests $P<0.05$ inferred statistical significance.

Mean±SD HR and VO2 during Wii were similar to walking (114±27 vs. 110±15 beats.min-1 and 11.4±5.5 vs.14.5±1.0 mL.kg-1.min-1, respectively). Mean HR during Wii+ (131±26 beats.min-1) was significantly greater ($P<0.001$) than walking or standard Wii play but not significantly different ($P>0.05$) from cycling (139±19 beats.min-1). Mean VO2 during Wii+ was significantly ($P<0.001$) greater than walking (19.8±5.2 vs. 14.5±1.0 mL.kg-1.min-1) and standard Wii play (11.4±5.5 mL.kg-1.min-1). Mean VO2 and HR data for all sub-maximal exercises and Wii game-play were significantly greater ($P<0.001$) than rest or playing a seated PC game. However, cardio-respiratory costs were significantly higher during running compared with all other assessed modalities. Mean EE was greater ($P>0.05$) during walking than standard Wii (17.5±1.3 vs. 13.8±6.7 kJ.hr-1.kg-1), however Wii+ (24.1±6.5 kJ.hr-1.kg-1) increased EE to a rate significantly higher ($P<0.001$) than standard Wii play or walking, and equivalent to cycling (28.4±4.7 kJ.hr-1.kg-1).

In conclusion playing the Nintendo Wii resulted in increased cardio-respiratory costs equivalent to walking at 5.6km.hr-1. When additional lower limb activities were incorporated into playing the Wii (Wii+), the cardio-respiratory costs and EE rates were significantly increased and were equivalent to cycling at 120W. As such, there is potential to further increase energy expenditure and cardio-respiratory costs associated with these new generation video games by incorporating supplementary lower limb activity.

ACUTE EFFECT OF VIBRATION AND PNF STRETCHING TECHNIQUE ON FLEXIBILITY

DOUSKAS, T., THEOS, A., TSIGGANOS, G., MARIDAKI, M.

UNIVERSITY OF ATHENS

INTRODUCTION: Flexibility has been defined as the range of motion about a joint or a related series of joints (4). Local vibration and the hold-relax Proprioceptive Neuromascular Facilitation (PNF) maneuver have been used as methods for increasing joint range of motion (3, 2). The purpose of the present study was to examine the acute effect of local vibration and PNF on flexibility and to compare the two Methods: METHODS: Ten male recreational athletes participated in this study (age: 23.8 ± 1.0 yrs). After a standardized warm-up participants performed the sit-and-reach test, which was used as an indicator of flexibility (1). The best of four trials was used as the test value. Then the subjects executed either the vibration (V) or the PNF maneuver (P) in a randomized and counterbalanced order. In condition V participants performed hamstrings stretching, one leg at a time, on a vibration platform. The vibration frequency was 30 Hz, with amplitude of 2 mm and 30 sec duration. In condition P participants lay supine and an experienced physiotherapist passively stretched the hamstrings until the subjects reported mild pain. Next, they were asked to execute isometric contraction of the hamstrings against the instructor ˋs manual resistance for 10 seconds. A 10 second relaxation period followed the contraction and the whole procedure was repeated three times for each leg. Sit-and-reach test was performed immediately after condition V or P. Differences between the two conditions and before - after the intervention were examined using t-test. Results are presented as mean ± SE.

RESULTS: The sit-and-reach scores before the intervention did not differ between the two conditions (V = 23.1 ± 1.9 vs P = 24.0 ± 2.1 cm). After either vibration or PNF the sit-and-reach scores were significantly higher compared to the pre measures (V = 27.3 ± 1.9 and P = 28.0 ± 2.1 cm, $p<0.001$).

DISCUSSION: According to the results either local vibration or PNF can be used as methods for increasing flexibility. The above mentioned increase could be attributed to: a) increase in pain threshold, b) increase in blood flow and temperature and c) induced relaxation of the stretched muscle (3).

THE SOME ANTROPOMETRIC EVALUATIONS AND GRIP AND LEG STRENGTH OF TURKISH SPORTIVE CLIMBERS

EROGLU KOLAYIS, I., MIMAROGLU, E., KOLAYIS, H., SEN, M.

SAKARYA UNIVERSITY

PURPOSE ; The purpose of this study was to investigate the some skinfold evaluations and Grip and Leg Strength of Turkish Sportive Climbers

METHODS ; Eight man (age: 25,00±4,28; years of training 5,68±4,80) and five women (age: 28,00±1,87; years of training 4,30±3,10) Sportive Climbers were involved in the study. Right left hand grip strength ang leg strenght has been measured with dynamometer. The

skinfold measurements has been recorded from ten skinfold areas which are triceps, biceps, subscapula, chest, suprailiac 1, suprailiac 2, midaxillar, abdomen, thigh and calf by skinfold caliper (Holtain, 0,2 mm)

ANALYSIS/RESULTS; The right hand strength has been found 48,46±6,35, left hand grip strenght 46,51±4,58 ang leg strenght151,63 ±22,70 in men sports climbers. The right hand strength has been found 30,30±4,74, left hand grip strenght 28,86±2,82 ang leg strenght 69,93 ±39,95 in women sports climbers The skinfold measurements has been found triceps 8,84±4,57, biceps 3,78±1,18, subscapula 11,09±3,14, chest 6,8±,2,5 suprailiac 15,16±9,57, suprailiac 2 7,23±3,35, midaxillar 9,93±4,78, abdomen 14,75±5,73, thigh 11,59±5,72 and calf 8,06±4,59 in men sport climbers. The skinfold measurements has been found triceps 15,42±7,10, biceps 5,4±1,90, subscapula 10,54±3,04, chest 11,9±8,35 suprailiac 15,93±9,53, suprailiac 2 10,31±4,58, midaxillar 9,26±2,19, abdomen 18,54±8,27, thigh 25,93±9,65 and calf 17,26±9,66 in women sport climbers.

CONCLUSIONS; With these results, sportive climbers can be define with the aspect of the skinfolds and grip strength. Sportive climber trainers can give a place to the strength trainings in their training programmes besides technical training to gain more performance and time.

A COMPARATIVE STUDY OF AGGRESSION IN MARTIAL ARTS

SALESI, M.

SHIRAZ UNIVERSITY

Introduction: Aggression in sport is define as any behavior , not recognized as legal within the official rules of conducts , directed toward an opponent , official , team-mate or spectator who is motivated to avoid such behavior. A number of sport psychologists have noted that aggression and violence are serious problems in sport, particularly contact sport. The purpose of present study was to investigate the aggression in martial arts and comparison with non-athletes.

Methods: 209 elite martial arts athelets (53 tackwondo, 52 judo, 54 Kong fu and 50 karate) with 48 non-athlete (aged 20.3+ 0.7) participated in this study. They completed Buss and Perrys (1992) aggression questionnaire. It consists of 29 items, distributed unequally among physical aggression, verbal aggression, anger and hostility.

Results: our results showed significant difference in aggression items between groups (P<0.001).Tukey test also showed that, the most difference was in kong fu group in relation with non-athletes and judo group. Other athletes groups do not any difference with non-athletes.

Conclusions: Findings showed that the type of martial arts have own effects on aggressive characterized of athletes.

REINTERPRETING COMPETITIVE STRESSORS WITH A REVERSAL THEORY FRAMED EXPRESSIVE WRITING INTERVENTION

THATCHER, J., DAY, M.C.

ABERYSTWYTH UNIVERSITY AND UNIVERSITY OF CHICHESTER

Introduction: Expressive writing can improve physical (e.g. reported physical symptoms) and psychological (e.g. depression) health indices (Chung and Pennebaker, 2008; Goldman et al., 2007). However, no studies have examined its use in helping athletes to cope with competitive stressors. This preliminary qualitative study explored the use of expressive writing combined with a Reversal Theory (RT; Apter, 2001) framed imagery intervention. This involves participants interpreting an experience from different perspectives defined by the motivational states in RT: serious-playful; rebellious-conforming; self-other; mastery-sympathy.

Method: Sixteen athletes completed the Motivational Style Profile (MSP: Apter et al., 1998; motivational dominance measure) and 20 min of expressive writing about a recent competitive stressor. They were taught the key principles of RT and how to use imagery to engender RT states which they then used to recreate different motivational states. They wrote about their experience from these different state perspectives in four 20 min sessions in counterbalanced order. They completed a final 20 min writing session without the intervention. Sessions ran on consecutive days and participants completed affect measures pre and post writing. Participants discussed their experiences of the intervention in a follow-up interview and completed the MSP again.

Results: Key results suggest individual differences in affect changes following writing with increases in positive affect, negative affect, or both. Participant and researcher noted changes in writing content and the participant's interpretation of the stressful event from the first to the final session included increased: emotional awareness; focus on others; self-confidence, and, self-awareness and analysis. Participants identified changes in their approaches to training or competition including: adopting a more playful approach to competition, optimising the social aspects of competition to increase enjoyment, and, valuing co-operation with others to make training more meaningful.

Discussion: A RT framed writing intervention may help athletes to reinterpret competitive stressors, resulting in positively perceived changes in training and competition approaches and increased self-awareness. Individual differences in affective responses to RT writing need consideration when applying this intervention in practice and in future research. Further developments to this preliminary study could include drawing comparisons between the use of RT framed writing and 'standard' expressive writing to help athletes to cope with competitive stressors.

IT'S NATURAL! HOW BRAZILIAN OLYMPIC WOMEN PERCEIVE PAIN

RUBIO, K., GODOY MOREIRA, F.
UNIVERSITY OF SÃO PAULO

The effort performed by high-level athletes in training and competition situations lead them to experiencing a new uncomfortable daily event characterized as pain. This feeling may reach extreme levels, depending on the moment lived in the training periodization, whose effects are a lowering in the motivation and the loss of competitive objectives. Aiming at improving their technical gesture, these athletes develop mechanisms to face up with limit situations that lead them to support different types of pain, which in many cases causes serious lesions. Although pain perception, besides being subjective, is a cultural construction related to the individual's history of life, the actual extent of its limiting force on performance has been little studied, perhaps due to the ethical difficulty caused by the need of experimenting with human beings; therefore, its importance should not be underestimated. Methods: The study included 62 Brazilian Olympics women that participated in Olympic Games from 1952 until 2008. The athletes were interviewed in a life-history format so that elements could be gathered.

Discussion/Conclusion The pain was comparable to obstacles that could have interrupted or hampered the women athlete's career. The team participation, which includes the trainer, the physician and the athlete's family, represents a fundamental part of the process of injury overcome. Of note, by tapping into and mobilizing the athlete's psychological reserves, the professional team and the social environment contribute greatly to a rapid and steady recovery. The ability an athlete has to resist to, and the capability to recover from, pain when it does occur is as decisive in the course and duration of a competitive sports career as it is for the achievement of the athlete's full potential. The effort accomplished in a training and competition situation is understood as natural and necessary in order to achieve high performance levels. In face of this, training days when physical exhaustion is not achieved are seen as "lost days" or inefficient ones. On the other hand, the search for the resistance threshold leads to a vulgarization of pain which may conduce athletes to bone and/or muscle lesions. This vulgarization of pain leads to extreme situations, such as the acknowledgment of non-pain as the end of the career when a new routine is lived and experienced and the absence of painful feeling makes the athlete to recognize new emotional states never lived before.

THE REPRESENTATION OF PAIN IN HIGH LEVEL SPORTS

SILVA, E., RUBIO, K.
UNIVERSITY OF SAO PAULO

One of the events widely pointed as limiting the performance (and, therefore, acting as a barrier to the achieve of success) is pain. Pain is defined as a 'sensitive and emotional displeasing experience, associated with real or potential tissue damage, or described within terms of such lesion'. This way we perceive that the dialectic established by the common sense between injury - painful sensation is not always valid. Pain is always subjective. Each being learn how to utilize this term by means of his/her own previous experiences (IASP). The indications of literature about the subjective component of pain, added to the cultural implications and diverse representations constructed throughout the individual's history of life, demonstrate the necessity to redouble attention on the painful complaint since its manifestation can disguise latent contents as dissatisfaction, doubt and fear linked to present situations or future perspectives related to the individual´s personal and professional life.

This experimental research try to evaluate the representation of pain among athletes. The subjects evaluated will be brazilian athletes competing in different modalities and in all spheres of sports (municipal, national or international). The instrument used to collect objective data will be the Sports Inventory for Pain (SIP- Meyers, Bourgeous, Stewart & LeUnes, 1992) and to collect the qualitative data the athletes will be interviewed and asked to narrate theirs "stories of pain". We intend to investigate in which ways the athletes cope, face and control pain episodes, the athlete´s capacity to discriminate different types of pain (training x injury) as well as their sensibility to respond to sign and limits, essencial conditions in the pursuit of the best result for the team and for the athlete as human being and as social hero.

HIGH EMOTIONAL INTELLIGENCE SCORE IS RELATED TO THE USE OF TASK-ORIENTED COPING IN ECUADORIAN SPORT SCIENCE STUDENTS

LABORDE, S., CHÁVEZ, E.
UFR STAPS, UNIVERSITY OF CAEN; ESPE, QUITO

Objective: To establish a relationship between Emotional Intelligence (EI) score and coping strategies used during stressful sport events.

Method: Ecuadorian Sport Science students (N=155) answered to both, the TEIQue (Trait Emotional Intelligence Questionnaire; Petrides & Furnham, 2003) and the CICS (Coping Inventory for Competitive Sport; Gaudreau et Blondin, 2002) with respect to a personal stressful sport event.

Results:

Higher trait EI score is positively correlated with the use of task-oriented coping (r=.43; p<.0001) and negatively correlated with the use of disengagement-oriented coping (r=-.22; p<.05).

Conclusion: Ecuadorian Sport Science students with higher EI score present more efficient coping strategies when they face up to a stressful event. Future research should confirm the consistence of these results across different cultures.

SELF, COPING STRATEGIES AND PHYSICAL ACTIVITIES IN PREADOLESCENTS: AN ACTION RESEARCH WITH PREADOLESCENTS

NICOLOSI, S., FREDA, J.A., LO PICCOLO, A., SCHEMBRI, R., CARLOMAGNO, N., LIPOMA, M.

1. UNIVERSITY KORE OF ENNA, 2. UNIVERSITY S.ORSOLA BENINCASA OF NAPLES

Introduction: Few studies explored a connection between self (physical and social), variables connected with building an identity and physical activities (Lidor R., 2004; Theodosius & Papaioannou, 2006; Annesi, J. J., 2007). Nonetheless, the research conducted to date has not considered these variables as aspects related to educational orienteering, even though they are part of a global process related to growth and identity construction. The main objective of educational orienteering is to put the adolescent in a position where he can make pondered and realistic decisions, helping him to discover himself. Working in orienteering in junior high school means early intervention on the psychological components implicated in the process of choice and decision making, involved in learning. Research-intervention achievement wants to estimate the incidence of physical activity in Self and in the prerequisites of educational orienteering (self-esteem, self-efficacy, interpersonal adaptation, coping and meta-cognition). The general purpose is to build an 'expanded' educational orienteering itinerary that also includes physical and sport activities.

Methods: Research-intervention is composed of three phases. In the I phase (actually in progress and will conclude on May 2009) pretests will be administered for the assessment of the variables analysed. In the II phase, (that will be realize in the 2010) participants (200 pre-adolescents from 12 to 14 years of age) involves physical activities, educational itineraries including obstacles courses aimed at empowering coping and meta-cognitive abilities. In the III phase the participant's final levels will be tested. The instruments that will be used are Semantic Differential for analyzing the physical and social self; the Physical Self-Description Questionnaire (PSDQ) in short form; the self-esteem Multidimensional Test; the interpersonal adaptation questionnaire and the AMOS 8-15 test for research on the meta-cognition aspects of the learning process.

Expected results: Results of the first phase will be presented. In accordance with the previous research, specific physical activities cause significant changes of the variables measured, essential elements of the Self building and educational orienteering prerequisites.

DOES IT MATTER WHERE CHILDREN LEARN? ORIENTEERING AS AN ENSAMPLE

BJERVA, T., SOLBAKKEN, T., SIGURJÓNSSON, T.

HEDMARK UNIVERSITY COLLEGE

Introduction: Teaching within the topic map understanding has long been characterized by the rationalistic tradition (Johansen, 1999). An alternative to the traditional method is situated learning (Griffin, 1995). The starting point of this investigation is that indoor and outdoor space creates different sense impressions. Moreover map reading can be considered as a cognitive exercise. The requirement for this type of tasks is linked to three different knowledge areas; declarativ, prosedural and strategic knowledge (Thomas& Thomas, 1994). In this study we wanted to test these three forms of knowledge, through various orienteering tasks.

Methods: Action Research has been selected as the research design in this study. The results are based on an intervention study of 54 kids in 4. grade in primary school (9- and 10-year-olds). The two groups of pupils where going through a five-week-long intervention where they worked with the same learning activities, but in different spaces (indoor and outdoor). 12 pupils (6 boys and 6 girls) were pretested, post-tested and retested (one year after) in the three mentioned areas of knowledge.

Results: Declarative knowledge - the pupils had an average of 1.4 correct links between mapsymbols and its referrer rendered in color photo in the pre-test. In the post-test the average increased to 11.8, and in the retest it had decreased to 5.8.

Procedural knowledge - 6 of the pupils managed to orient the map in the pre-test, 7 pupils in the post-test, and 8 pupils in the retest.

Strategic knowledge - the wayfinding exercise shows that 5 pupils mastered the task satisfactorily in the pre-test. This increases to 10 pupils in the post-test, and 7 pupils in the retest.

In all three tests, we see relatively small differences between those who were outside and those who were inside during the intervention period. The most consistent findings are related to gender.

Discussion: Use of situated learning in different contexts (indoor vs.outdoor) has shown that both approaches lead to the development of knowledge and skills, but these have largely been temporary. The result of the study indicate that the development of declarative knowledge is not space dependent and that pupils from the outdoor group, in the long run, build up procedural knowledge with more resistance. The investigation also concludes that there are differences between boys and girls. The boys score higher on all tests. This is consistent with other studies examining the spatial task solutions (Malinowski & Gillespie, 2001).

GENDER DIFFERENCES IN SWIMMING COMPETENCE AND PERCEIVED COMPETENCE

STALMAN, R., DAHL, D., MORAN, K., KJENDLIE, P.L.

NORWEGIAN SCHOOL OF SPORT SCIENCES

Introduction: An increased risk for drowning is seen in males, particularly since they may overestimate their abilities, compared to women. Moran (2008) has found gender differences in New Zealand, particularly that men overestimate their ability and women underestimate their ability. The purpose of this study was to investigate the gender differences of practical swimming skills and self reported perception of swimming competence.

Methods: Eighty one (81) university students were asked to fill out a questionnaire and also to perform practical tests of their swimming competence. The questions addressed their perceived competence (in a pool), their perception of whether they could perform as well outdoors in open water, and their perception of risk in five risk scenarios. The practical tests covered seven essential skills. The Mann – Whitney U test was employed to examine statistical differences. A 0.05 level of confidence was accepted as significant.

Results and Discussion: Of the seven practical tests, four showed a significant gender difference: floating ability, entry dive from pool deck, surface dive to 2m depth, and rescue towing. In every case, the women performed better than the men. Self reported perception of competence showed significant gender differences for only three of 21 items. The women reported greater competence than the men for "the ability to stay afloat in deep water without support", while the men reported greater competence for "surface dive to the bottom of the deep end of the pool (4m). Eighty percent of the men reported that surface diving would be easy/very easy, while only 62% of the women reported the same. Interestingly, the women both reported greater competence and actually demonstrated greater competence than the men on the floating test. On the other hand, while the women actually performed better on surface diving, the men reported the perception that they were more competent in this skill. Lastly, there were no significant gender differences in perceived risk for the five risk scenarios.

Conclusions

It can be concluded that there are few gender differences both in practical and perceived ability in Norway. It does not support the hypothesis that a possible gender difference makes males more susceptible for drowning.

THE BODY AS AN INSTRUMENT OF EXPRESSION OF EMOTIONS IN SPORT

LARA SÁNCHEZ, A.J., ZAGALAZ SÁNCHEZ, M.L., HERRADOR COLMENERO, M., HUERTAS HERRADOR, J.A.

UNIVERSITY OF JAEN

Introduction: We can communicate without words and we can convey emotions and attitudes towards situations, physical status and identity, with the body movement performed. Motos (1983) described the gesture as an intentional movement and y it is fraught with meaning that reflects the personality of the person. It is an expression of emotion. May be it is voluntary or involuntary.

The aim is to observe the communication and expression of emotions and feelings in sport, through the use of the body of athletes, depending on the time of the party and the marker.

Methods: 12 volleyball players have participated They had a mean age of 20.9 ± 3.3 years. They were playing in a mid-level team. At the time of measurement they were in first position with aspirations to upgrade. To gather the data has been compiled a schedule of observation.

Results: There are certain behaviors that are characteristic of the times that a game is won and therefore the players are happy and full of satisfaction. On the other hand, there are other behaviors that are characteristic of those moments where they lose the point and sentiments of the players are radically opposed.

Discussion: The players express their feelings and emotions through the body and movement without being aware. Score a point implies a feeling of joy that is manifested by the body open; symmetrical form; quick, enthusiastic and intense movements, longer duration and with a sense of lightness. Conversely, losing a point implies a feeling of anger and rage. It is manifested in a feeling of heaviness and sinking, in which the subject prefers the solitude and isolation and it shows through the body closed, asymmetrical shapes, and slow, short and heavy movements. At the time of addressing a new point, when players score a point, they are much more active, happy, dynamic... Conversely, when they have missed the point it seems that they try to forget this game quickly and focus on the following. By the way to express and interact themselves each player with their peers, it seems that the level of cohesion of this team is high.

CHANGES IN MOTOR EFFICIENCY OF SLOVENIAN YOUTH AFTER THE ELIMINATION OF THE EFFECTS OF MORPHOLOGICAL CHARACTERISTICS

JURAK, G., BERANIČ, L., STREL, J.

UNIVERSITY OF LJUBLJANA, FACULTY OF SPORT

Motor efficiency depends on morphological characteristics (Momirovič, Hošek, Džamonija, & Gredelj, 1989). In Slovenian children, negative trends in the manifestation of motor efficiency and morphological characteristics have been noticed (Strel, Kovač, & Jurak, 2007), therefore the purpose of the study was to find out what effects did the morphological characteristics have on the motor efficiency of both genders over the ten-year period (1994-2004).

The sample of measured subjects included 1396 pupils in 2004 and 1352 pupils in 1994, aged between 15 and 19 years. Fourteen anthropometrical measurements were used to evaluate morphological dimension and thirteen measuring procedures were used to evaluate motor efficiency of measured subjects. The effects of morphological characteristics were eliminated with the use of multiple analysis of covariance by considering anthropometrical measurements as covariates.

Partialization revealed that in pupils morphological characteristics accelerate motor efficiency of boys and decelerate motor efficiency of girls. Different effects of morphological characteristics on motor efficiency can be explained with biological differences between the genders and different physical maturation of boys and girls in this age period. These differences can be most clearly explained when observing the changes in morphological characteristics at the age of 15 and 16.

Namely, at this age an increase of body height and decrease of skin fold can be noticed in boys, whereas in girls an increase is seen in both weight and skin fold.

In general, accelerating effects of morphological characteristics on motor efficiency of boys was higher in 1994, whereas the largest decelerating effects in girls have been noticed in 2004. The tendency of the direction of the effects leads to conclusion that the changes in morphological characteristics of boys and girls at this age and for the studied period (1994 - 2004) had negative effects on partial motor efficiency. However, as a result of earlier biological maturation (and consequently larger muscle strength) and various compensatory mechanisms (e.g. improvement in technique) these negative effects have not been revealed on the manifest level of motor efficiency.

THE ORIENTATION OF ADOLESCENTS' PHYSICAL ACTIVITY WHEN APPLYING BRIEF COUNSELLING

RAKAUSKIENE, V., KARDELIENĖ, L.

LITHUANIAN ACADEMY OF PHYSICAL EDUCATION

Introduction: There is hardly any doubt that the physical and psychical welfare of humans is strongly related with physical activeness. Overview of explorations concerning the education of physical culture at school demonstrates that from the historical perspective, school physical culture programs did not use to be adequately related with the habits of healthy lifestyle, physical activeness and health (Kardelienė, Kardelis, 2006).

In the process of alteration of educational paradigms influencing physical culture at school when the achievement of individual health and good fitness throughout the life is desired, forms and methods promoting physical activity of adolescents have been sought for.

Methods

From three to six solution-focused interventional sessions with adolescents were conducted using the Educational Consulting Method, which is created on the basis of works of the creators of Solution focused brief therapy method, Steve de Shazer and Insoo Kim Berg (de Shazer, 1985).

115 students aged 13 to 19 took part in the analyses. 65 students (the experimental group) aged 13 to 19 were consulted by using the Educational Consulting method. The changes were evaluated by using a ten-point progress evaluation scale. The experimental group's results were compared to the comparative group. The comparative group was important to assess spontaneous alterations of issues related with physical activity because no educational intervention was used with these students.

Results: 79.3 per cent of consulted adolescents and 25.6 per cent of the comparison group adolescents showed improvement on the progress evaluation scale ($p<0.05$). No significant changes happened in students within the group of comparison. An inductive presupposition is developed stating that the physical activity of adolescents may be promoted by applying educational consulting.

Discussion: The data confirmed that adolescent counselling in the school setting based on the Educational Consulting method is an efficient method improving the adolescent capacity for solutions and orienting adolescents' physical activity. The method of Educational consulting possesses clearly and precisely specified educational technologies and is based on ideas of positive psychology as well as on the cognitive attitude to learning: active processes, cooperation, application of knowledge in a novel environment (transference of whatever has been learnt), emphasis on the social context, underlining the individuality of the trainee as an expert of his/ her individual situation.

THE RELATION BETWEEN THE SPECIFIC AND GENERAL COMPETENCES IN PHYSICAL EDUCATION TEACHERS' TRAINING

MIHAILESCU, L., MIHAILESCU, N.

UNIVERSITY OF PITESTI

Introduction. In this context the university education graduates will have to accomplish the four direction of education with the help of these competences and specific capacities that were obtained in concordance with the content of the "formation" term, as an activity of

integration of activity socio-professional training at the level of some specific education models in the course of one's life, Mihailescu L. (2004).

Hipotesis.We consider that the training of formatters is the most responsable instructive activity of the education system because the modern society is changing permanently and this requires the pedagogues some competences for a process of education for changing in the course of one's life. From this perspective we will analyse the context of formatores' training in „physical education and sport" area.

Content. The research objectives are: to analyze the structure of the education system; to analyze the way in which the curriculum was changed starting with the projection level to the purpose level; to evaluate the competences of the university education graduated in the fundamental domain of "physical culture and sport" in order to accomplish efficiently the four main trends of education:"learning to know".

Focusing the didactic process on competences supposes the identification of the general and specific competences (cognitive abilities) realized by the syllabus of the Physical Education and Sport domain and psyhopedagogy module. We identified the main competences on the three cycles of the syllabus Bologna and the relation between them: general competence, specific cognitive abilities, competences in psychology domain, competences in general pedagogy domain, competences in specialitiy methodology domain, psychological competences.

Conclusions: 1.On the capacities and competences' accomplishment route, in concordance with the final performance standards of the education in our domain, are teh followings: the priority of the educational process; objectives–contents concordance; a functional relation between objectives and contents; the evaluation integration in the curricular documents' structure as a strategy of adjustment and self adjustment ;the adoptability of the evaluation system to different alternatives;the individualization of the education

2.In the new syllabus the contents on disciplines and activities become, depending on the necessary and possible knowledge, formation means of the theoretical and practical - methodical competences, of the necessary behavior and attitudes, and also relational, of high level.

ANALYSIS OF A POSSIBLE RELATIONSHIP BETWEEN MOTOR AND SPORT ACTIVITIES AND TYPE OF PLANTAR PRESSURE DISTRIBUTION IN THE PRIMARY SCHOOL STUDENTS IN ITALY

GALDIERI, M., RAIOLA, G., CARLOMAGNO, N., D'ELIA, F., MANGO, P., SANGIORGIO, A., SIBILIO, M.

1. UNIVERSITY OF SALERNO, 2. UNIVERSITY OF CASSINO, 3. UNIVERSITY OF NAPLES

Introduction: The enhancement of motor activity in the school is a way to improve the educational process as stated by the National Guidelines of the Ministry of Education.

Indeed, the engagement in motor activities gives students the chance to live experiences that leads to correct and healthy lifestyles including the prevention of diseases related to hypokinesia as some forms of flat foot resulting from postural defeats or overweight.

Objectives

This research was aimed to study the possible relationship between plantar structure and motor and sport practice, lifestyle and eating habits in children aged 6 to 11 years.

Material and Methods

The research was carried out using a sample of 500 children aged between 6 and 11 years, attending 3 primary schools in Naples, Salerno and Caserta.

The experimental protocol was previously established through the joint action between the school teachers, parents and researchers, who shared the aims of the survey. Data about age, dietary habits, motor and sports practice played by students were previously and indirectly collected through the support of the families. Information on weight and height were directly collected. The research team analyzed the plantar pressure distribution through a practical and immediate system of analysis: the PDM - multifunctional strength platform. This tool allows to perform static and dynamic analysis of forces and pressures while the subject is in standing position or in motion , with or without shoes. It also evaluates the distribution of loads, allowing detailed analysis about the characteristics of the different moments of the pressure distribution of the foot (provided by the software that processes data in real-time).

Results: The results of the survey showed not only a relationship between height, weight, dietary habits, lifestyles and the type of plantar pressure distribution, but also revealed a possible relationship between motor-sport practice and the characteristics of the pressure distribution of the foot. The research opens up to further studies on the 'modelling' functions of motor-sport practice related to the type and the characteristics of foot pressure distribution.

ENERGY EXPENDITURE AND PSYCHOMOTOR AND TRADITIONAL TEACHING METHODOLOGIES: A POSSIBLE RELATIONSHIP?

GOMEZ PALOMA, F., BALDASSARRE, G., GALDIERI, M., PIGNATO, R., LO PICCOLO, A., SIBILIO, M.

1. UNIVERSITY OF SALERNO, 2. UNIVERSITY KORE OF ENNA

Introduction: Studies on the relationships between body and learning processes are embedded in a broad area of research that studies the relationship between education and neuroscience (Gallese, 2006), investigating the neurophysiological (Iacoboni, 2005) and neuropsychological (LeDoux, 2002) mechanisms that regulate the bodily dimension of the person (Sibilio, 2002). The aim of the work is to analyze a possible relationship between the energy / calories expenditure (EE) of students of primary school and low secondary school and learning through the traditional teaching actions and the psychomotor-methodological ones.

Methods: The study, carried out in 14 schools of the Province of Salerno, was conducted on a sample of 95 pupils (45F-50M) of an age ranging between 7 and 10 years and between 12 and 15 years.

The instrument used for the detection of the EE is the SenseWare Armband, put on the right arm of the students. It records data on the EE calculated thanks to an exclusive and patented algorithm in different conditions and environments.
Data have been collected firstly during teaching interventions based on the traditional methodology (frontal lesson) and, subsequently, during psychomotor activities inside the historical and spatial subject-areas.
Results: The data emerged during the teaching activities were assessed in relationship with many variables as the method used, the sex of the student and the class he/she belonged to.
Discussion: The expected results will allow to evaluate the possible relationship between the caloric expenditure and the teaching methods used. The meaning and aim of this research is to find a scientific justification to foster the active use of a psychomotor approach from which a learning process related to a healthy energy expenditure can take advantage. This can be the base on which to build up the wellness of the students of the Italian primary and low secondary school who currently spend most of his/her school life in a sedentary way.

EVALUATION OF GROSS MOTOR SKILLS IN CHILDREN IN THE CZECH REPUBLIC

CEPICKA, L., SPLITEK, M., KOTCHEROVA, I.
UNIVERSITY OF WEST BOHEMIA, FACULTY OF EDUCATION

Introduction: Gross motor skills are important for social interaction on the playground, for performance in physical education and they contribute meaningfully to a physically active childhood. Many physical educators consider these skills to be the most important motor skills in motor development because they are the cornerstones of many games (Butterfield, & Loovis, 1993; Williams, 1992). The aim of this study is to evaluate the developmental disorders in gross motor skills in Czech children through the Test of Gross Motor Development-2 (Ulrich, 2000).
Methods: Three hundred and fifteen children with a mean age of 7.9 years (SD = 1.09) participated; one hundred and fifty two were boys (M age = 7.85 years, SD = 1.05), and one hundred and sixty three were girls (M age = 7.96 years, SD = 1.13). Towards to compare results with US norm population, children have been divided into ten groups by age and gender; such as six years boys (from 5.5 to 6.49 years), seven years boys (from 6.5 to 7.49 years), other groups have been defined equally.Results: Czech children scored much lower in all categories. To evaluate a significance of differences between CZ and US norm population the effect size has been used. This shows that performance of Czech children is strongly behind American ones.
Discussion: Upwards denies conclusion of preliminary study which supposed that performance of Czech girls is similar to the performance of American girls. Now it appeared that when compared to American all Czech children scored lower. There would be different kind of explanation. These results are similar to the study on Dutch children by Houwen, Visscher, Hartman, and Lemmink (2007). These authors conclude that some skills are more typical of the American sport culture than for the Dutch children. This may have caused different performance of both Dutch and Czech children.
Acknowledgement: This study has been supported by a grant from the Grant Agency of the Czech Republic no. 406/07/0168.

HISTORY OF SPECIAL EDUCATION AND DISABILITY. RELATIONSHIP PHYSICAL EDUCATION AND SPORT.

HUERTAS, J.A., HERRADOR, M., LÓPEZ, S., RUIZ, I.
UNIVERSITY OF JAÉN

Introduction: Today you can design special education as a science that is included in the educational sciences and is part of the historical process of social integration of these people. Therefore it is necessary to undertake a journey through different historical stages in the concept of disability, their relationship with the sport and the development of education in special education. The main objective of this review will examine the historical evolution that has taken disability in relation to physical education and sport and its influence on the normalization of the individual.
Methods: It has a historical and legislative, to check both the legal reality of the disabled as the social and the involvement of sport for their normal development, through a discussion group, consisting of specialists in physical education.
Results: It has shown that the concept of disability and its relationship to sport has been narrowing due to the social reality they demanded, with a full phasing in society as the legal framework has been adapted to this need . At present it appears that the measures being taken are necessary to bring about a normalization of the individual and thus to encourage social inclusion. Also in education, physical education curriculum has undergone a transformation that has produced an adaptation of both the media and the teaching process - learning.
Discussions: The sport has been a key part to the success of disabled people through formal education (school) as well as informal education (through partnerships, programs, etc.).. Similarly through the current rules are guaranteed full rights to their normal develop-

ment. It is noted that through the same social, are adjusting resources and processes of learning and educational needs with these reforms, enhances the character of equality that prevails in education.

RELATIONSHIPE BETWEEN SALIVARY CHROMOGRANIN A AND FATIGUE COMPLAINT DURING JUDO AND LECTURE IN STUDENTS

SAKAMOTO, K.

HOGO COLLEGE OF MEDICINE

Relationship between salivary Chromogranin A and fatigue complaint during Judo and lecture in students

Kunihiro Sakamoto, Naomasa Sakamoto

Department of preventive medicine Hyogo College of Medicine

We have studied the relation between fatigue complaints and judo and lecture using questionnaire method of fatigue in student. Complaint items of fatigue were apparent sleepiness and yawning for the lessons. Salivary chromogranin A (CgA) was considered as an index of stress condition. But the change rate of CgA was close relation parasympathetic condition of the item of sleepiness and yawning in fatigue survey. In this study, the change rate of CgA was analyzed by the transition pattern of fatigue complaints of sleepiness and yawning after judo and lecture. The transition patterns of fatigue in which were the incidence case of complaint, the disappearance case of complaint, the continuous case of complaint and the no complaint case, expressed by using dummy number. Multiple regression analyses of the change rate of CgA to the transition pattern of complaint of sleepiness and yawning were down, The subjects were healthy six male students. They have Judo training one and half hour a week. Saliva was collected twice before and after judo or lecture lesson. The correlation coefficient(r) between the change rate of CgA and the transition pattern of complaint of yawning and sleepiness were examined. In judo, r=0.75 for the continuous complaint of sleepiness, and r=0.92 for the continuous complaint of yawning. In lecture, r=0.54 for both the continuous complaint of sleepiness and yawning. Thus the change rate of GgA seemed to be related positively to the complaints of sleepiness and yawning during the load. In multiple regression analyses, the standard partial regression coefficients of the change rate of CgA to transition pattern of complaint items were analyzed. In judo, the standard partial regression was positively 0.488 ($p<0.03$) for the continuous complaint of yawning, and was positively 0.75($p<0.01$) for the continuous complaint of sleepiness. In lecture, the standard partial regression was positively 0.84 for the continuous complaint of sleepiness and 0.52 for the continuous complaint of yawning. In order to confirm the results, all data that joined together the judo and lecture data were analyzed. The standard partial regression coefficient of the change rate of CgA to the transition pattern of fatigue was 2.413($p<0.039$) for the continuous complaint of yawning and 2.751($p<0.05$) for the continuous complaint of sleepiness. Thus, those results showed that the change rate of CgA level was positive correlation to the sleepiness and yawning as the parasympathetic sign. It seemed that it was important to check the correction of parasympathetic condition to the evaluation of salivary CgA level.

'YOU DON'T NEED ME TODAY...DO YOU?' AN ASSESSMENT OF THE SUPPORT PROVIDED BY LSAS IN MAINSTREAM PE LESSONS

SCATTERGOOD, A.

UNIVERSITY OF CHESTER

Introduction: In many countries over the last decade or so, physical education has been used increasingly by governments as vehicles of social policy targeted at promoting the inclusion of young disabled people and those with special educational needs (SEN) in mainstream schools. A feature of this increasing political commitment has been the growing expectation that teachers will work in collaboration with a range of other professionals, especially Learning (or Teaching) Support Assistants (LSAs), to help include these pupils in mainstream classes. Despite the emphasis that has come to be placed on the important contribution that LSAs are thought to provide to pupils experiences of PE, there is currently little research that has examined these issues.

Methods: The central objective of this paper is enhance our understanding of the ways in which LSAs are managing the constraints on them to help deliver teachers to deliver PE to pupils in PE lessons. In doing so, the paper reports on data generated by semi-structured interviews conducted with 22 LSAs currently working in secondary schools in North-East England.

Results: The findings of the study suggest that the kind, range and quality of support provided by LSAs within PE lessons varied – often quite substantially – from one school to another. This variation was related to the kinds of training that LSAs had received, their personal background and experiences, the value they attached to PE. The values and attitudes that LSAs expressed about their experiences of PE, and working with teachers, were significantly related to the ways in which they are able, in the course of their day-to-day lives, to manage the relational constraints they experience in schools.

Discussion: The findings of the study suggest that it is only possible to understand adequately the experiences and actions of LSAs, and how this impacts on the inclusion of disabled pupils and those with SEN in PE, by analyzing the particular networks of relationship of which LSAs are a part. An appreciation of these relational constraints, together with other broader changes in educational policy, are vital pre-requisites for developing a more realistic assessment of how LSAs help provide pupils what are regarded as worthwhile educational experiences. It is concluded that the use of PE and school sport as a means to pursue the government's non-sporting goals has had the effect of undermining the extent to which government are able to achieve its inclusion policy goals. It is also clear that whilst government has a greater capacity to make crucial decisions over the policy priorities to be pursued, the nature and complexity of the relationships in which they are involved means that the extent to which they are able to achieve their objectives is very dependent on the actions of other groups such as LSAs as they, too, attempt to protect, maintain and advance their own individual and/or collective interests.
