

Abstract

This study was aimed at describing the evolution of CD4 cell counts over time, for patients on antiretroviral therapy (ART) in Mildmay Uganda. It was also aimed at determining whether the evolution depends on selected patient characteristics.

Since repeated measures were taken from the patients, correlation has to be taken into account when analyzing these data. As such, this study illustrates the application of Linear Mixed Models to describe the changes in CD4 counts over time, for patients on ART. Separate models were fitted for patients with baseline age ≥ 15 years (presumed sexually active), for those with ($6 \leq \text{Age} \leq 14$) years, and for those with baseline age ≤ 5 years (whose absolute CD4 counts are not used in patient management).

Results show, that for patients who were aged ≥ 15 years at the start of ART, the evolution could be described by a cubic function of time. It was also noted that the effect of gender on the evolution depends on the patient's baseline CD4 category, also on the NNRTI drug that the patient uses. For the patients aged ≤ 5 years, also for those with ($6 \leq \text{Age} \leq 14$) years, linear functions of time were found appropriate to describe the evolutions, which depended on the baseline CD4 categories in either case.

In conclusion, the benefit of early treatment was shown in this study i.e. patients who started ART at higher baseline CD4 counts evolved higher than those who started at lower CD4 counts.

Acknowledgements

First and foremost I would like to thank my promoter, Prof. Dr. Ziv Shkedy. Thanks for the assistance and aid during this thesis. You always had new insights, interesting thoughts and helpful comments during our meetings. I never felt alone at any stage of this project. To my external promoter, Mr. Dan Kajungu, thank you too for all the assistance, insightful discussions and guidance throughout, you are a great man.

To Mildmay Uganda, for hosting me and giving me the best environment to write my thesis, I am greatly honored. Credit to the staff who manage the patients and the data management team in particular that handled all my data requests promptly; Daniel, Christine and Vastine, well done. A special note of thanks to Dr. Barbara Mukasa, Mary Odiit, Esther Kawuma and the placement team that I interacted with quite often, thank you all for smoothing my thesis writing period.

I acknowledge the financial assistance from the Belgian Flemish government through its Vlaamse Interuniversitaire Raad (VLIR), without which my dream of attaining a Masters degree in Biostatistics would have remained just that a dream! It was an honor to have received such a prestigious award, and my gratitude cannot be expressed. To all my professors at Hasselt University, for the knowledge imparted throughout the two years of this Master program, thanks for the dedication.

Profound gratitude to my friends, classmates, crazy neighbor and all my group members in our various projects; I could not have done it without you, hopefully we collaborate again on future projects. The members of CCG, the East African Community and all comrades who made my stay in Belgium memorable, thanks a lot.

For the unconditional love and unending support, from the Lubyayi family; dad, mum, brothers and sisters I dedicate my success to you. Heartfelt gratitude to our latest addition to the family, my dear wife Esther, thank you for being patient and encouraging me all the time.

Finally, I offer everything to God for without Him everything is nothing to me. I have had a miraculous journey to-date, all my achievements, opportunities, the precious gift of life, the list is endless. All I can say is, "Praise be unto Him."

Lawrence Lubyayi

1 Introduction

1.1 Background

Human Immunodeficiency Virus (HIV) is a lentivirus that causes Acquired Immunodeficiency Syndrome (AIDS) by reducing a person's ability to fight infection. HIV attacks an immune cell called the CD4 cell which is responsible for the body's immune response to infectious agents (Adams and Luguterah, 2013). As such, the number of CD4 cells per cubic millimeter of blood is widely used as an important biomarker for progression to AIDS when studying the efficacy of drugs to treat HIV-infected patients (Guo and Carlin, 2004). It is often measured repeatedly over follow-up periods in large-scale studies.

Since the beginning of the epidemic, almost 75 million people have been infected with the HIV virus, about 36 million people have died, 35.3 million [32.2-38.8 million] people were living with HIV at the end of 2012, an estimated 0.8% of adults aged 15-49 years worldwide are living with HIV, Sub-Saharan Africa remains most severely affected with 71% of the people living with HIV worldwide and nearly 1 in every 20 adults living with HIV (World Health Organization, 2014).

2012 HIV/AIDS statistics showed that 7.2 percent of Uganda's population was living with HIV. This amounted to an estimated 1.4 million people, which included 190,000 children. An estimated 62,000 people died from AIDS in 2011 and 1.1 million children had been orphaned by Uganda's devastating epidemic. HIV prevalence has been rising since its lowest rate of 6.4 percent in 2006. New infections are diagnosed in 150,000 people a year, of whom 20,600 are children (Avert, 2014).

Antiretroviral Therapy (ART) services have been available to HIV patients in Uganda for a while now. In May 2013, Uganda began the process of updating the ART guidelines to include recommendations from the 2013 WHO ART Guidelines which are aimed to dramatically increase access to ART and in turn provide new opportunities to save lives, improve clinical outcomes and reduce HIV incidence. The new guidelines recommend initiation of ART in all adults and adolescents with HIV at CD4 cut off of <500 cells/mm³ regardless of clinical stage. The guidelines also recommend immediate ART initiation for patients with: HIV and active TB disease, HIV and HBV co-infection with evidence of severe chronic liver disease, HIV positive partner in a sero-discordant sexual relationship, Most at risk Persons (MARPs) in hot-spots (fisher folks, Commercial sex workers, long distance truck operators), Pregnant and Lactating Mothers and for all HIV positive children below 15 years of age (Ario, 2014). It is worth noting that these guidelines have been changing over time, for instance, the 2010 recommendations had a threshold of 350 CD4 cells/mm³ (World Health Organization, 2014). Prior to 2010, there was a threshold of 250 CD4 cells/mm³.

Mildmay Uganda (MUg) opened in 1998 to provide palliative outpatient care for people living with HIV/AIDS, and to act as a teaching and training centre for HIV/AIDS health care personnel in Uganda. MUg is primarily a treatment centre for persons living with HIV/AIDS and their families. It currently offers family centered care and support to approximately 24,000 clients. MUg has one central clinic located in Lweza, 12km outside Kampala, the capital of Uganda. MUg is also involved in a district health systems

strengthening programme to build HIV/AIDS health care capacity in existing health centres in 18 local districts (Funk *et al.*, 2012). Against this background, this study was conducted using routine data for patients who started ART between 2009 and 2012 at MUg. CD4 counts are normally taken for patients on ART on routine basis every 6 months.

Few studies have been conducted about longitudinal analysis of CD4 cell count data for patients on ART especially in Sub-Saharan Africa. For instance, Adams and Luguterah (2013) report that the pattern of growth in CD4 cell counts was not linear. Picat *et al.* (2013), use nonlinear mixed-effects models, and conclude that higher long-term CD4 counts were predicted for children starting ART younger, and with higher CD4 counts. Reda *et al.* (2013) use mixed models regression and report a substantial increment in weight and CD4 lymphocyte count among the patients who were taking ART in eastern Ethiopia.

This study was aimed at providing a longitudinal analysis of CD4 cell count data for patients who initiated ART between January 2009 and December 2012 at Mildmay Uganda. By considering changes over time, the longitudinal approach has the added advantage of observing changes more accurately, by increasing the power and validity of measuring the change in CD4 cell counts.

1.2 Study Objectives

The objectives of this study were two-fold:

1. To describe the evolution of CD4 cell counts for patients on ART in Mildmay Uganda.
2. To determine whether the evolution depends on selected patient characteristics.

1.3 The Data

Cleaned records for patients who started ART at Mildmay Uganda between 1st January 2009 and 31st December 2012, and were on first line regimen drugs formed the dataset for this study.

This dataset was split into 3 parts. Patients with baseline $\text{Age} \geq 15$ years ($n=3241$) were analyzed separately because this population is presumed to be sexually active. Those with $6 \leq \text{Age} \leq 14$ years ($n=302$) were also analyzed separately from those with baseline $\text{Age} \leq 5$ years ($n=259$) because absolute CD4 counts are not used for clinical decisions for the patients with $\text{Age} \leq 5$ years. Further still, the young patients ($\text{Age} < 15$ years) were analyzed separately from the adults ($\text{Age} \geq 15$ years) because in most cases, drug administration and adherence for the children depends on their guardians/caretakers.

The response variable (CD4 count) was log transformed because it was heavily skewed. Therefore, throughout this report the log transformed version is used. Table 1 below explains the variables that were considered in this report.

Table 1: *Summary of variables in the datasets*

Variable name	Description
logcd4	Natural logarithm of the CD4 counts
agecat	Categorization of the baseline age (≤ 2 , 3-5, 6-9, 10-14, 15-24, 25-34, 35-49, ≥ 50)
cd4cat	Baseline CD4 category (≤ 200 , 201-350, 351-500, > 500)
gndr	Gender of patient (0=Female, 1=Male)
nrti	NRTI backbone used (d4t+3TC, TDF+3TC and AZT+3TC)
nnrti	NNRTI drug used (Nevirapine, Efavirenz)
change	Did the patient change drug combination (Yes/No)
yr	Year of starting ART (2009, 2010, 2011, 2012)
id	Unique identifier of patients

2 Methodology

2.1 Exploratory Data Analysis (EDA)

EDA was done in order to gain insight into the data prior to analysis. Descriptive statistics were generated and tabulated while histograms were constructed to show the distribution of number of measurements per patient, for each of the 3 datasets. χ^2 tests were used to compare baseline characteristics (in form of categorical variables) between patients treated with either efavirenz or nevirapine.

Individual profile plots were then constructed to gain some rough picture about how subjects evolve as well as to provide indications in terms of between and within subjects variability. Moreover, this exploration provided ideas about what random effects to start with.

Average profile plots were constructed to describe the mean evolution of CD4 counts, overall and according to different subgroups. From such exploration, indications were obtained, about the functional form of the evolution and also whether the evolution depends on given covariates. Smoothing using the Loess method was applied because the measurements were not equally spaced across the different subjects.

The variance structure was also explored for the 3 datasets. This was aimed at getting insight about how the variance evolves over time. This gave indications in terms of how the variance was to be modeled so that valid inferences could be made (Verbeke and Molenberghs, 2000). Smoothing techniques using the Loess method were again employed because of the unequal spacing of measurements.

2.2 The Linear Mixed Effects Model

Longitudinal designs which involve repeated measurements of a variable of interest in each of a series of individuals enable one to study changes within individual subjects over time or under varied conditions. However, the repeated measurements tend to be correlated, and this must be taken into account at the time of analysis or misleading conclusions may result. The Mixed Model is one of the statistical methods used to analyze repeated measurements in continuous longitudinal data in an easy, valid and flexible manner (Burton, Gurrin, and Sly 1998).

The Linear mixed model handles longitudinal data analysis in the continuous case. Moreover, since it assumes a linear regression for each cluster separately, it can be used for data with unequal number of measurements per cluster (Verbeke and Molenberghs, 2000). Against this background a linear mixed-effects model was fitted. According to Verbeke and Molenberghs (2000), the linear mixed-effects model is defined as,

$$\begin{cases} \mathbf{Y}_i = \mathbf{X}_i\boldsymbol{\beta} + \mathbf{Z}_i\mathbf{b}_i + \boldsymbol{\epsilon}_i \\ \mathbf{b}_i \sim N(\mathbf{0}, D), \\ \boldsymbol{\epsilon}_i \sim N(\mathbf{0}, \boldsymbol{\Sigma}_i), \\ \mathbf{b}_i, \boldsymbol{\epsilon}_i \quad \text{are independent.} \end{cases}$$

where \mathbf{Y}_i is the n_i dimensional response vector for the i^{th} subject, $1 \leq i \leq N$, N is the number of subjects, \mathbf{X}_i and \mathbf{Z}_i are $(n_i \times p)$ and $(n_i \times q)$ dimensional matrices of known covariates, $\boldsymbol{\beta}$ is a p -dimensional vector containing the fixed effects, \mathbf{b}_i is a q -dimensional vector containing the random effects, $\boldsymbol{\varepsilon}_i$ is an n_i -dimensional vector of residual components, and D is a covariance matrix of random effects.

Using the general guidelines for model building proposed by Verbeke and Molenberghs (2000), the preliminary mean structure was first stated using a model with plausible combinations of covariates considering the cubic evolution of CD4 counts of patients, with random intercepts and random slopes (for the Age \geq 15 dataset), for the other two datasets, linear functions of time were used to describe the evolutions. This was followed by the investigation of serial correlation, reduction of random effects, and reduction of mean structure consecutively.

Including serial correlation, if present, is far more important than correctly specifying it (Verbeke and Molenberghs, 2000). Hence to check for the appropriate serial correlation, likelihood based tests were used. Restricted Maximum Likelihood (REML) was preferred to Maximum Likelihood (ML) testing here, because it reduces the well-known finite sample bias in the estimation of the covariance (Fitzmaurice *et al.*, 2004).

The covariance estimates for the random effects were assessed using mixtures of chi-square distributions due to the boundary problem. This problem arises because these tests involve variances which cannot be negative. Thus a likelihood ratio test of the null hypothesis that a variance is zero is testing a null hypothesis that is on “the boundary of the parameter space” for a variance. One consequence is that the usual null distribution for the likelihood ratio test is no longer valid; instead, the null distribution is a mixture of chi-squared distributions (Fitzmaurice *et al.*, 2004).

Finally, to discover the most parsimonious mean structure, F-tests and Likelihood Ratio Tests were employed under ML estimation.

Since the random effects (b_i 's) of the linear mixed effects model are stochastic, Bayesian methods were used to estimate them. The estimates, known as Empirical Bayes (EB) estimates, were presented in scatter plots to help identify outlying profiles.

2.3 Statistical Software

Statistical Analysis System (SAS) version 9.3 was used for statistical analysis and graphics. Some graphics were produced in R version 2.15.3. For statistical tests, a significance level of 5% was used.

3 Results

3.1 Exploratory Data Analysis

3.1.1 Descriptive statistics for the patients with Age \geq 15 years.

Table 2 below shows the baseline characteristics of the population studied with Age \geq 15 years (n=3241), at the point of ART initiation. Overall, there were more females (68%) than males (32%). Patients starting nevirapine were predominantly female, more likely to use zidovudine (than tenofovir or stavudine) in their NRTI backbone and had lower median CD4 counts (195 versus 209 cells/mm³). The few patients who used stavudine in their NRTI backbone were not considered in the subsequent analysis, even so because that drug has been phased out of use.

Table 2: *Baseline characteristics for the patients Age \geq 15 years.*

Characteristic	Nevirapine, n=2058	Efavirenz, n=1183	P-value ^a

^a *Pearson's χ^2 test for independence of rows and columns*

Figure 1 below shows the distribution of the number of measurements per patient for the Age \geq 15 years dataset. The largest number of patients (575) had two measurements, followed by those with four measurements (492) and least of all was one patient with 12 measurements.

Figure 1: Frequency of number of measurements per patient for the Age ≥ 15 years dataset.

Tables 3 and 4 below show the changes that happened within the first line regimen drugs used. It can be seen that 89 patients changed from nevirapine to efavirenz based ART (see Table 3) while 76 patients changed from zidovudine to tenofovir use (see Table 4).

Table 3: Showing changes in NNRTI for patients with Age ≥ 15 years.

Original NNRTI	Current NNRTI			Total
	Nevirapine	Efavirenz	Others	
Nevirapine	1,921	89	48	2,058
Efavirenz	50	1,113	20	1,183

3.1.3 Descriptive statistics for the patients with Age \leq 5 years.

Table 8 below shows the baseline characteristics of the population studied with Age \leq 5 years (n=259), at the point of ART initiation. Overall, there were slightly more males (51%) than females (49%). Patients starting nevirapine were predominantly female, more likely to use stavudine (than tenofovir or zidovudine) in their NRTI backbone and had higher median CD4 counts (508 versus 451.5 cells/mm³). The 3 patients using tenofovir in their NRTI backbone were dropped from the subsequent analysis.

Table 8: *Baseline characteristics for the patients Age \leq 5 years.*

Characteristic	Nevirapine, n=227	Efavirenz, n=32	P-value ^a

3.1.4 Exploratory plots

Individual Profiles

Figure 4 depicts profiles for all patients split by our chosen 3 datasets. What can be noted from all the panels is that generally there is evidence of between subjects variability as well as within subject variability. The subjects have largely variable CD4 values at the start and also possibly different evolutions over time, this suggests that perhaps linear mixed models with random intercepts and slopes could be plausible starting points.

Figure 4: Individual profiles for patients with $Age \geq 15$ years (left panel), those with $(6 \leq Age \leq 14)$ years (middle panel) and for those with $Age \leq 5$ years (right panel)

Mean structure

Figure 5 shows the average evolution of CD4 counts over time for the 3 datasets. For the $Age \geq 15$ years dataset we observe a sharp linear increase in the mean CD4 counts up to month 4, then a little dip at month 6 and from month 9 up to about month 40 it appears to flatten out, followed by a more gentle increase for the later time points. In this regard, we might have to consider a higher order polynomial for modeling the mean structure. For the $6 \leq Age \leq 14$ years dataset, we observe a gentle increase in mean CD4 counts for the first 13 months and then it appears to flatten out for the remaining period. For the $Age \leq 5$ dataset, there appears to be a gentle increase in mean CD4 counts over time, a little bit more pronounced for the first 12 months.

Figure 5: *Smoothed average evolution for the $Age \geq 15$ years dataset (left panel), for the $(6 \leq Age \leq 14)$ years dataset (middle panel) and for the $Age \leq 5$ dataset (right panel)*

In terms of gender (see Figure 6), females seem to have higher average CD4 counts than males at all time points for the $Age \geq 15$ years, and $Age \leq 5$ years datasets. For the $6 \leq Age \leq 14$ years dataset, males have higher CD4 counts on average for the first 7 months from which point females rise above the males for the rest of the time.

Figure 6: *Smoothed average evolution by gender for the $Age \geq 15$ years dataset (left panel), for the $(6 \leq Age \leq 14)$ years dataset (middle panel) and for the $Age \leq 5$ dataset (right panel)*

In terms of age categorization (see Figure 7), for the $Age \geq 15$ years dataset, apart from the first 10 months in which the subjects with (35-49) years seemed to evolve differently from the others, at the other time points all age categories seemed to evolve in a similar manner. It is worth noting though, that the patients above 50 years had the lowest CD4 counts on average at most of the time points.

For the $6 \leq Age \leq 14$ dataset, the patients with (6-9) years had higher CD4 counts on average than those with (10-14) years, at all time points. For the $Age \leq 5$ dataset, the patients with (≤ 2) years had higher CD4 counts on average than those with (3-5) years, at all time points.

Figure 7: Smoothed average evolution by Age group for the Age ≥ 15 years dataset (left panel), for the ($6 \leq \text{Age} \leq 14$) years dataset (middle panel) and for the Age ≤ 5 dataset (right panel)

In terms of the NRTI backbone (see Figure 8), for the Age ≥ 15 years dataset, patients using AZT seemed to evolve in a similar way to those using TDF. The patients using d4T evolved in a different way, however, since these were few, they were not included in further analysis.

For the $6 \leq \text{Age} \leq 14$ years dataset, patients using d4T start with lower CD4 counts on average but beyond 35 months on ART, they have higher CD4 counts than those using AZT or TDF. For the Age ≤ 5 dataset, patients using AZT seemed to evolve in a similar way to those using d4T, but those using d4T had higher values on average at all times. There were very few patients using TDF, and these were excluded from further analysis.

Figure 8: Smoothed average evolution by treatment backbone for the Age ≥ 15 years dataset (left panel), for the ($6 \leq \text{Age} \leq 14$) years dataset (middle panel) and for the Age ≤ 5 dataset (right panel)

In terms of the NNRTI drug (see Figure 9), for the Age ≥ 15 years dataset, for the first 7 months, patients on nevirapine and those on efavirenz seemed to evolve in a similar way, between 7 to 20 months, those on efavirenz seemed to have higher CD4 counts while beyond 20 months those on nevirapine had higher counts.

For the $6 \leq \text{Age} \leq 14$ years dataset, patients on efavirenz seemed to have higher CD4 counts for the first 40 months, beyond which point those on nevirapine had higher counts. For the Age ≤ 5 dataset, patients on nevirapine had higher CD4 counts at all time points.

Figure 9: Smoothed average evolution by NNRTI for the $Age \geq 15$ years dataset (left panel), for the $(6 \leq Age \leq 14)$ years dataset (middle panel) and for the $Age \leq 5$ dataset (right panel)

In terms of Baseline CD4 categorization (see Figure 10), it is evident that the evolution differs depending on the baseline CD4 categorization for all the 3 datasets. It is also seen that, patients who start in higher CD4 categories remain with higher CD4 counts at almost all time points.

Figure 10: Smoothed average evolution by Baseline CD4 for the $Age \geq 15$ years dataset (left panel), for the $(6 \leq Age \leq 14)$ years dataset (middle panel) and for the $Age \leq 5$ dataset (right panel)

From Figure 11, we observe that there are minor variations in the average profiles between the patients who changed treatment and those who did not change. Whether these variations are significant will have to be tested using the fitted models.

Figure 11: Smoothed average evolution by change of treatment for the $Age \geq 15$ years dataset (left panel), for the $(6 \leq Age \leq 14)$ years dataset (middle panel) and for the $Age \leq 5$ dataset (right panel)

Variance Structure

Figure 12 shows the observed variance functions for the 3 datasets, which are changing over time, indicating the need for other random effects in addition to the random intercepts.

Figure 12: *Smoothed variance functions for the Age ≥ 15 years dataset(left panel), for the (6 \leq Age ≤ 14) years dataset (middle panel) and for the Age ≤ 5 dataset (right panel)*

3.2 Model Building

3.2.1 Selection of Preliminary Mean and Random effects Structures

Following from the observations in the exploratory analysis, good models that best describe the observed average trends and also reflect the observed variance structures, were sought for the 3 datasets. Verbeke and Molenberghs (2000) suggest that in case of highly unbalanced datasets with many covariates, it is necessary to use the most elaborate model one is prepared to consider for the mean structure, making it as extensive to answer the research question. In this case, all main effects and their two-way interactions were deemed sufficient to answer the research question. Several polynomials were then fitted on the same graphs with the observed average trends and the polynomials (functions of time) that seemed to best reflect the observed average trends were chosen. Figure 13 below shows the various fits. The decision on which polynomial to use was however taken after exploration of subject-specific regression models elucidated in the next subsection.

Figure 13: *Observed and fitted mean functions for the Age ≥ 15 years dataset(left panel), for the (6 \leq Age ≤ 14) years dataset (middle panel) and for the Age ≤ 5 dataset (right panel)*

The choice of random effects structures was based on the observed variance functions as highlighted in the exploratory data part.

3.2.2 Exploration of subject-specific regression models

To further explore subject-specific evolutions, subject-specific regression models were fitted. Polynomial models with increasing powers were fitted to capture the varied trends of the individual evolutions. For the $\text{Age} \geq 15$ dataset, Table 11 shows that R_{meta}^2 for the regression model with the linear effect of time was low at 0.4196, and it radically increased when the time covariate was raised to higher powers. Tests for model extension were conducted and p-values are also shown. Models with higher powers of time proved to be significant improvements from models with lower powers as shown by the significant p-values for the tests. However, with the aim of generating a model which is not only flexible but also parsimonious, the cubic polynomial model was chosen.

Table 11: R_{meta}^2 and tests for model extension for the $\text{Age} \geq 15$ dataset

Model	R_{meta}^2	F_{meta}	P-value
Linear	0.4196		
Quadratic	0.5809	0.6539	<0.0001
Cubic	0.6623	0.4122	<0.0001
Quartic	0.7444	0.4045	<0.0001
Quintic	0.7976	0.2847	<0.0001

For the $6 \leq \text{Age} \leq 14$ and the $\text{Age} \leq 5$ datasets, though the linear regression models had relatively low R_{meta}^2 values (see Tables 12 and 13 below), tests for model extension to higher order powers proved insignificant. Therefore, for these datasets, going forward, linear functions of time were chosen to describe the average evolutions.

Table 12: R_{meta}^2 and tests for model extension for the $6 \leq \text{Age} \leq 14$ dataset

Model	R_{meta}^2	F_{meta}	P-value
Linear	0.4388		
Quadratic	0.6883	1.0776	0.2348
Cubic	0.8288	0.9271	0.7288

Table 13: R_{meta}^2 and tests for model extension for the $\text{Age} \leq 5$ dataset

Model	R_{meta}^2	F_{meta}	P-value
Linear	0.3272		
Quadratic	0.4954	0.7479	0.9942
Cubic	0.7190	0.7460	0.9996

3.3 The Linear Mixed Effects Models

3.3.1 Results from the Mixed Effects Model fitted to the $\text{Age} \geq 15$ dataset

A linear mixed-effects model was fitted, using the repeated measurements of the CD4 counts of each person as a response. They were fitted against a cubic function of time, including all the 2-way interactions of all the covariates. On top of that, random effects for the intercept and linear slope were included to account for the variability between the different subjects. Extending the random effects structure to the quadratic and cubic slopes led to failure of convergence; because of this, robust inference was considered in the final model to circumvent problems of possible misspecification.

To assess the need for serial correlation, models with the same mean structures and random effects but different serial correlation, like Exponential, Power, Gaussian and Simple, were assessed. As shown in Table 14, there was no improvement in the log-likelihood for the models that considered serial correlation. Henceforth, for the proceeding models, the simple correlation structure was taken into account.

Table 14: *Models with several serial correlations and the associated values for the log-likelihood using REML (for the Age \geq 15 dataset)*

Residual covariance structure	REML log-likelihood
Measurement error	22466
Measurement error + Exponential	22466
Measurement error + Power	22466
Measurement error + Gaussian	22466

The need for reduction of the random effects structure was assessed using a mixture of chi-square distributions as mentioned in the methodology. Hence, the p-value under REML estimation for the comparison of Model 1 (with both random intercepts and slopes) versus Model 2 (with only random intercepts) (see Table 15) can then be calculated as:

$$\text{P-value} = P(\chi_{2:1}^2 > 554.24) = 0.5 P(\chi_2^2 > 554.24) + 0.5 P(\chi_1^2 > 554.24) < 0.0001$$

From the above result it was concluded that the variance structure should not be simplified by dropping the random linear slope effect from the model.

Table 15: *Random Effects Models with the associated values for the log-likelihood using REML estimation (for the Age \geq 15 dataset)*

Random effects	REML log-likelihood
Model 1: Intercept, time	22501.27
Model 2: Intercept	22778.39

Finally, the most parsimonious model in terms of the mean structure was assessed using the likelihood ratio test. The model was found to have a significant fit based on the null model likelihood ratio test, implying that it is indeed necessary to model the covariance structure of the data. Summary of test results are shown in Table 16.

Table 16: *Null model likelihood ratio test (for the Age \geq 15 dataset)*

DF	Chi-square	p-value
3	6587.74	<0.0001

The final model with only significant effects was thus formulated as:

$$\begin{aligned} \log(CD4count_{ij}) &= \beta_0 + b_{0i} + \beta_1 Gender_i + \beta_2 cd4cat_i + \beta_3 change_i + \beta_4 year_i \\ &+ \beta_5 nnrti_i + (\beta_6 + b_{1i})time_{ij} + \beta_7 time_{ij}^2 + \beta_8 time_{ij}^3 \\ &+ \beta_9 Gender_i * time_{ij} + \beta_{10} cd4cat_i * time_{ij} + \beta_{11} nnrti_i * time_{ij} \\ &+ \beta_{12} nnrti_i * time_{ij}^2 + \beta_{13} Gender_i * cd4cat_i + \beta_{14} Gender_i * nnrti_i \end{aligned} \quad (1)$$

Where: $\log(CD4count_{ij})$ is the natural log of the CD4 count of the i th patient at the j th time, $time_{ij}$ is the time (in months) at which the j th CD4 measurement is taken

for the i th patient and $\beta_0, \beta_1, \dots, \beta_{14}$ are regression coefficients while b_{0i} and b_{1i} denote subject specific deviations from the common intercept and linear slope. The latter are assumed to follow a multivariate normal distribution (see Molenberghs and Verbeke (2005)).

Table 17 below shows the covariance parameter estimates from the final model. It shows that the highest variability came from the random intercepts. It also shows that the variance of the random intercepts was higher than that of the random slopes, pointing to higher between patient variability than the within patient variability. The covariance of random effects is negative, implying that patients with high baseline CD4 counts tend to have smaller slopes than patients with low CD4 counts at baseline.

Table 17: *Covariance parameter estimates (for the Age \geq 15 dataset)*

Parameter	Estimate
Var(b_{0i})	0.3511
Cov(b_{0i}, b_{1i})	-0.00201
Var(b_{1i})	0.00013
Measurement error	
Var(ε_i)	0.1580

Results from the final model (see Table 18) show that there was a significant cubic evolution of the CD4 counts. The effect of gender on the evolution depends on the patient's baseline CD4 category (see Figure 14), also on the NNRTI drug that the patient uses (see Figure 15).

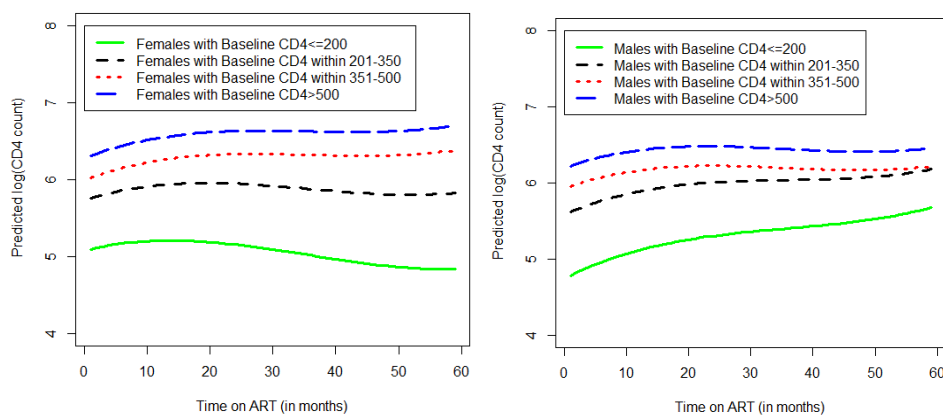

Figure 14: *Predicted CD4 count levels showing interaction of gender and baseline CD4 category, for the Age \geq 15 dataset*

Figure 15: Predicted CD4 count levels showing interaction of gender and NNRTI drug, for the Age ≥ 15 dataset

Table 18 also shows that patients who started ART between the years 2010 to 2012 had higher intercepts (CD4 starting values) than those who started ART in 2009. It also shows that patients who changed treatment drugs had lower intercepts (CD4 starting values) than those who didn't change.

Figure 21 in the Appendix shows the observed and predicted profiles plotted against each other for the Age ≥ 15 dataset. It shows that our model fits relatively well to the observed data.

Empirical Bayes estimates for random effects were also calculated in order to check whether there were outliers or not. The scatter plot of random intercepts and slopes for the Age \geq 15 dataset (see Figure 16), showed that there were some potential outliers which may need to be investigated further.

Figure 16: *Scatter plot of random intercepts and slopes for the Age \geq 15 years dataset.*

3.3.2 Results from the Mixed Effects Model fitted to the $6 \leq \text{Age} \leq 14$ dataset

A linear mixed-effects model was fitted, using the repeated measurements of the CD4 counts of each person as a response. They were fitted against a linear function of time, including all the 2-way interactions of all the covariates. On top of that, random effects for the intercept and linear slope were included to account for the variability between the different subjects.

To assess the need for serial correlation, models with the same mean structures and random effects but different serial correlation, like Exponential, Power, Gaussian and Simple, were assessed. There was no improvement in the log-likelihood for the models that considered serial correlation. Henceforth, the simple correlation structure was taken into account.

The need for reduction of the random effects structure was assessed using a mixture of chi-square distributions as mentioned in the methodology. Hence, the p-value under REML estimation for the comparison of Model 1 (with both random intercepts and slopes) versus Model 2 (with only random intercepts) (see Table 19) can then be calculated as:

$$\text{P-value} = P(\chi_{2:1}^2 > 187.2) = 0.5 P(\chi_2^2 > 187.2) + 0.5 P(\chi_1^2 > 187.2) < 0.0001$$

From the above result it was concluded that the variance structure should not be simplified by dropping the random linear slope effect from the model.

Table 19: *Random Effects Models with the associated values for the log-likelihood using REML estimation (for the $6 \leq \text{Age} \leq 14$ dataset)*

Random effects	REML log-likelihood
Model 1: Intercept, time	2717.1
Model 2: Intercept	2810.7

Finally, the most parsimonious model in terms of the mean structure was assessed using the likelihood ratio test. The model was found to have a significant fit based on the null model likelihood ratio test, implying that it is indeed necessary to model the covariance structure of the data. Summary of test results are shown in Table 20.

Table 20: *Null model likelihood ratio test (for the $6 \leq \text{Age} \leq 14$ dataset)*

DF	Chi-square	p-value
3	550.06	<0.0001

The final model with only significant effects was thus formulated as:

$$\begin{aligned} \log(\text{CD4count}_{ij}) &= \beta_0 + b_{0i} + \beta_1 \text{Gender}_i + \beta_2 \text{agecat}_i + \beta_3 \text{cd4cat}_i + \beta_4 \text{year}_i \\ &+ \beta_5 \text{nrti}_i + (\beta_6 + b_{1i}) \text{time}_{ij} + \beta_7 \text{cd4cat}_i * \text{time}_{ij} + \beta_8 \text{Gender}_i * \text{nrti}_i \end{aligned} \quad (2)$$

Where: $\log(\text{CD4count}_{ij})$ is the natural log of the CD4 count of the i th patient at the j th time, time_{ij} is the time on ART (in months) at which the j th CD4 measurement is taken for the i th patient; $\beta_0, \beta_1, \dots, \beta_8$ are regression coefficients while b_{0i} and b_{1i} denote subject specific deviations from the common intercept and linear slope respectively. The latter are assumed to follow a multivariate normal distribution.

Table 21 below shows the covariance parameter estimates from the final model. It shows that the highest variability came from the random intercepts. It also shows that the variance of the random intercepts was higher than that of the random slopes, pointing to higher between patient variability than the within patient variability. The covariance of random effects is negative, implying that patients with high baseline CD4 counts tend to have smaller slopes than patients with low CD4 counts at baseline.

Table 21: *Covariance parameter estimates (for the $6 \leq \text{Age} \leq 14$ dataset)*

Parameter	Estimate
Var(b_{0i})	0.3791
Cov(b_{0i}, b_{1i})	-0.00642
Var(b_{1i})	0.00036
Measurement error	
Var(ε_i)	0.2095

Results from the final model (see Table 22) show that there was a significant linear evolution of the CD4 counts. The baseline CD4 category had an effect on the evolution (see Figure 17). It is seen that the patients who had baseline CD4 counts ≤ 200 had steeper slopes than those who started in higher categories.

Figure 17: *Predicted CD4 count levels by baseline CD4 category, for the $6 \leq \text{Age} \leq 14$ dataset*

From Table 22, we observe that the effect of gender on the CD4 level depends on the current NRTI backbone that the patient uses. It also shows that patients who started ART between the years 2010 to 2012 had higher intercepts (starting CD4 counts) than those who started ART in 2009. Further still, it is seen that patients who were aged 6 to 9 years at baseline had higher intercepts (starting CD4 counts) than those who were aged 10 to 14 years.

Figure 22 in the Appendix shows the observed and predicted profiles plotted against each other for the ($6 \leq \text{Age} \leq 14$) years dataset. It shows that the chosen model fits relatively well to the observed data.

Table 22: *Parameter estimates and Robust Standard Errors (S.E.Robust) from the final model for the ($6 \leq \text{Age} \leq 14$) years dataset.*

Empirical Bayes estimates for random effects were also calculated in order to check whether there were some outlying profiles or not. The scatter plot of random intercepts and slopes for the $6 \leq \text{Age} \leq 14$ dataset (see Figure 18), showed that there were some potential outliers which may need to be investigated further.

Figure 18: *Scatter plot of random intercepts and slopes for the ($6 \leq \text{Age} \leq 14$) years dataset.*

3.3.3 Results from the Mixed Effects Model fitted to the $\text{Age} \leq 5$ dataset

A linear mixed-effects model was fitted, using the repeated measurements of the CD4 counts of each person as a response. They were fitted against a linear function of time, including all the 2-way interactions of all the covariates. Again, random effects for the intercept and linear slope were included to account for the variability between the different subjects.

To assess the need for serial correlation, models with the same mean structures and random effects but different serial correlation, like Exponential, Power, Gaussian and Simple, were assessed. There was no improvement in the log-likelihood for the models that considered serial correlation. Henceforth, the simple correlation structure was taken into account.

The need for reduction of the random effects structure was assessed using a mixture of chi-square distributions as mentioned in the methodology. Hence, the p-value under REML estimation for the comparison of Model 1 (with both random intercepts and slopes) versus Model 2 (with only random intercepts) (see Table 23) can then be calculated as:

$$\text{P-value} = P(\chi_{2:1}^2 > 27.2) = 0.5 P(\chi_2^2 > 27.2) + 0.5 P(\chi_1^2 > 27.2) < 0.0001$$

From the above result it was concluded that the variance structure should not be simplified by dropping the random linear slope effect from the model.

Table 23: *Random Effects Models with the associated values for the log-likelihood using REML estimation (for the $\text{Age} \leq 5$ dataset)*

Random effects	REML log-likelihood
Model 1: Intercept, time	2485.1
Model 2: Intercept	2498.7

Again, the most parsimonious model in terms of the mean structure was assessed using the likelihood ratio test. The model was found to have a significant fit based on the likelihood ratio test. Summary of test results are shown in Table 24.

Table 24: *Null model likelihood ratio test (for the Age ≤ 5 dataset)*

DF	Chi-square	p-value
3	353.37	<0.0001

The final model with only significant effects was thus formulated as:

$$\begin{aligned} \log(CD4count_{ij}) &= \beta_0 + b_{0i} + \beta_1 agecat_i + \beta_2 cd4cat_i + \beta_3 nrtime_{ij} \\ &+ (\beta_4 + b_{1i})time_{ij} + \beta_5 cd4cat_i * time_{ij} \end{aligned} \quad (3)$$

Where: $\log(CD4count_{ij})$ is the natural log of the CD4 count of the i th patient at the j th time, $time_{ij}$ is the time on ART (in months) at which the j th CD4 measurement is taken for the i th patient; $\beta_0, \beta_1, \dots, \beta_5$ are regression coefficients while b_{0i} and b_{1i} denote subject specific deviations from the common intercept and linear slope respectively. The latter are assumed to follow a multivariate normal distribution.

Table 25 below shows the covariance parameter estimates from the final model. It shows that the highest variability came from the random intercepts. It also shows that the variance of the random intercepts was higher than that of the random slopes, pointing to higher between patient variability than the within patient variability. The covariance of random effects is negative, implying that patients with high baseline CD4 counts tend to have smaller slopes than patients with low CD4 counts at baseline.

Table 25: *Covariance parameter estimates (for the Age ≤ 5 dataset)*

Parameter	Estimate
Var(b_{0i})	0.2818
Cov(b_{0i}, b_{1i})	-0.00297
Var(b_{1i})	0.00009
Measurement error	
Var(ε_i)	0.2471

Results from the final model (see Table 26) show that there was a significant linear evolution of the CD4 counts. The baseline CD4 category had an effect on the evolution (see Figure 19), evident in lower categories having steeper slopes than higher categories.

Figure 19: *Predicted CD4 count levels by baseline CD4 category, for the Age ≤ 5 dataset*

Table 26 shows that patients who were aged ≤ 2 years had higher intercepts (starting CD4 counts) than those aged 3 to 5 years. It is also evident that patients who had d4T

in their current NRTI backbone had higher intercepts (starting CD4 counts) than those who had AZT in their current NRTI backbone.

Figure 23 in the Appendix shows the observed and predicted profiles plotted against each other for the Age ≤ 5 years dataset. It shows that the chosen model fits relatively well to the observed data.

Table 26: *Parameter estimates and Robust Standard Errors (S.E.Robust) from the final model for the Age ≤ 5 years dataset.*

Effect	agecat	cd4cat	NRTI	Estimate (S.E.Robust)	P-value
Intercept				6.9673 (0.0565)	<0.0001
agecat	≤ 2			0.1704 (0.0667)	0.0108
agecat	3-5			0 (.)	.
cd4cat		≤ 200		-0.9124 (0.1353)	<0.0001
cd4cat		201-350		-0.4942 (0.1388)	0.0004

time*cd4cat		201-350		0.0119 (0.0047)	0.0101
time*cd4cat		351-500		0.0098 (0.0042)	0.0185
time*cd4cat		>500		0 (.)	.

AZT=Zidovudine, d4T=Stavudine, 3TC=Lamivudine.

Empirical Bayes estimates for random effects were also calculated in order to check whether there were some outlying profiles or not. The scatter plot of random intercepts and slopes for the Age ≤ 5 dataset (see Figure 20), showed that there were some potential outliers which may need further investigation.

Figure 20: *Scatter plot of random intercepts and slopes for the Age ≤ 5 years dataset.*

4 Discussion and Concluding Remarks

This project was aimed at describing the evolution of CD4 cell counts for patients on ART at Mildmay Uganda. It was also aimed at determining whether the evolution depends on selected patient characteristics. In view of this objective, exploratory data analysis was conducted to visualize the key hypotheses and to provide some initial basis for the subsequent statistical modeling.

For the $\text{Age} \geq 15$ years dataset, results from the final model showed that there was a significant cubic evolution of the CD4 counts. This result differs from that of Adams and Luguterah (2013) who described the evolution as a logarithmic function of time. It also differs from the result of Reda *et al.* (2013) who used a linear function of time to describe the evolution.

For both the $6 \leq \text{Age} \leq 14$ and the $\text{Age} \leq 5$ years datasets, linear functions of time were found to be appropriate descriptions of the evolution of CD4 cell counts. This result differs from that of Picat *et al.* (2013) who used non-linear models to describe the evolution of CD4 cell counts in children.

In contrast to the results of Adams and Luguterah (2013) that report male patients responding to treatment better than females, our results for the $\text{Age} \geq 15$ years dataset showed that the effect of gender on the evolution depends on the patient's baseline CD4 category, also on the NNRTI drug that the patient uses.

This study was in agreement with the studies of Reda *et al.* (2013) and that of Adams and Luguterah (2013), in showing the benefit of early treatment. A higher baseline CD4 cell count would result in a better rate of recovery of patients on ART. This is thus an additional voice to advocacy for early starting of treatment as opposed to waiting for dropping of CD4 counts to various thresholds.

For the $\text{Age} \geq 15$ years dataset, patients who started ART between the years 2010 to 2012 had higher CD4 counts over time than those who started ART in 2009. This could be because of the change in treatment guidelines over time that have seen a shift to higher thresholds for starting ART unlike in the earlier years. For instance, the latest WHO recommendations encourage initiation of ART in adults living with HIV when their CD4 cell count falls to 500 cells/mm³ or less, unlike the 2010 recommendations which had a threshold of 350 CD4 cells/mm³ (World Health Organization, 2014). Prior to 2010, there was a threshold of 250 CD4 cells/mm³.

Results for the $\text{Age} \geq 15$ years dataset also show that patients who changed treatment drugs had lower CD4 counts over time than those who didn't change. This phenomenon is as a result of treatment failure, since changes are made for patients who perform poorly on certain drugs.

This study showed (for the $\text{Age} \geq 15$ years dataset) that the age of patients did not have any significant effect on the evolution in contrast to the studies of Adams and Luguterah (2013) and that of Reda *et al.* (2013). This could be explained by the relatively young nature of the patients considered with median age (IQR) = 34 (28-40). Probably, the

behaviors of these people do not differ as much.

For both the $6 \leq \text{Age} \leq 14$ and the $\text{Age} \leq 5$ years datasets, the baseline CD4 category had an effect on the evolution. Results from these 2 datasets also showed the benefit of early treatment i.e. the patients who started ART at higher baseline CD4 counts evolved higher than those who started at lower CD4 counts. This result was similar to that of Picat *et al.* (2013).

For the $6 \leq \text{Age} \leq 14$ years dataset, the effect of gender on the CD4 level depended on the current NRTI backbone that the patient used. For instance, in as much as the females who were using d4T maintained higher values than females who used AZT or TDF, the males using d4T maintained lower values over time than their colleagues who used AZT or TDF.

For both the $6 \leq \text{Age} \leq 14$ and the $\text{Age} \leq 5$ years datasets, the patients who started ART at younger ages maintained higher CD4 counts over time than those who started older. This result was similar to that of Picat *et al.* (2013) and further highlights the need for starting ART as early as possible even for children.

For the $\text{Age} \leq 5$ years dataset, it was observed that the patients who had d4T in their NRTI backbone maintained higher CD4 counts over time than those who used AZT. Despite the fact that use of d4T has been stopped in Uganda (see e.g. Ario, 2014), patients (with $\text{Age} \leq 5$ years) using this drug had higher CD4 counts over time than those using AZT in this study.

This study also explored Empirical Bayes estimates which are vital in identifying subjects with outlying profiles. For each of the 3 datasets, scatter plots of the random intercepts and slopes were constructed from which potential outliers can be identified and investigated further.

In conclusion, this study shows that evolution of CD4 cell counts over time could be sufficiently described by a cubic polynomial for the patients with $\text{Age} \geq 15$, whilst linear functions of time could be used to describe the evolutions for the patients with $6 \leq \text{Age} \leq 14$ and those with $\text{Age} \leq 5$. The effects of several factors on the evolution were discussed and the influence of the baseline CD4 stood out in all three analyses.

It is recommended that further studies of this nature include other important covariates that were not included in this study. Such covariates include: viral load results, treatment failure, opportunistic infections and many others.

Another way in which the objectives of this research could be answered (especially for the $\text{Age} \geq 15$ dataset) is by use of linear spline models. Linear spline models provide a very useful and flexible way to accommodate many of the non-linear trends that can not be approximated by simple polynomials in time (Fitzmaurice *et al.*, 2004). Such a method has been used by Wools-Kaloustian *et al.* (2006) to determine the clinical and immunological outcomes of a cohort of HIV infected patients receiving ART.
